

2011

ANNUAL PROGRESS REPORT

DOE Hydrogen and Fuel Cells Program

U.S. DEPARTMENT OF
ENERGY

DOE/GO-102011-3422
November 2011

U.S. Department of Energy
1000 Independence Avenue, S.W.
Washington, D.C. 20585-0121

FY 2011
PROGRESS REPORT FOR THE DOE
HYDROGEN AND FUEL CELLS PROGRAM

November 2011
DOE/GO-102011-3422

Approved by Sunita Satyapal, Hydrogen and Fuel Cells Program Manager

NOTICE

This report was prepared as an account of work sponsored by an agency of the United States government. Neither the United States government nor any agency thereof, nor any of their employees, makes any warranty, express or implied, or assumes any legal liability or responsibility for the accuracy, completeness, or usefulness of any information, apparatus, product, or process disclosed, or represents that its use would not infringe privately owned rights. Reference herein to any specific commercial product, process, or service by trade name, trademark, manufacturer, or otherwise does not necessarily constitute or imply its endorsement, recommendation, or favoring by the United States government or any agency thereof. The views and opinions of authors expressed herein do not necessarily state or reflect those of the United States government or any agency thereof.

Available electronically at <http://www.osti.gov/bridge>

Available for a processing fee to U.S. Department of Energy and its contractors, in paper, from:

U.S. Department of Energy
Office of Scientific and Technical Information
P.O. Box 62
Oak Ridge, TN 37831-0062
Phone: (865) 576-8401
Fax: (865) 576-5728
E-mail: <mailto:reports@adonis.osti.gov>

Available for sale to the public, in paper, from:

U.S. Department of Commerce
National Technical Information Service
5285 Port Royal Road
Springfield, VA 22161
Phone: (800) 553-6847
Fax: (703) 605-6900
E-mail: orders@ntis.fedworld.gov
Online ordering: <http://www.ntis.gov/ordering.htm>

Printed on paper containing at least 50% wastepaper, including 20% postconsumer waste

Table of Contents

I.	Introduction	1
II.	Hydrogen Production.....	15
II.0	Hydrogen Production Sub-Program Overview.....	17
II.A	Distributed BDL Production.....	25
II.A.1	Pacific Northwest National Laboratory: Biomass-Derived Liquids Distributed (Aqueous Phase) Reforming	25
II.A.2	National Renewable Energy Laboratory: Distributed Bio-Oil Reforming.....	29
II.A.3	Argonne National Laboratory: Distributed Reforming of Renewable Liquids Using Oxygen Transport Membranes (OTMs)	33
II.B	Biomass Gasification	37
II.B.1	United Technologies Research Center: A Novel Slurry-Based Biomass Reforming Process	37
II.B.2	Gas Technology Institute: One Step Biomass Gas Reforming-Shift Separation Membrane Reactor	42
II.C	Separations	46
II.C.1	Arizona State University: Zeolite Membrane Reactor for Water-Gas Shift Reaction for Hydrogen Production	46
II.C.2	Media and Process Technology Inc.: Development of Hydrogen Selective Membranes/Modules as Reactors/Separators for Distributed Hydrogen Production.....	53
II.C.3	Pall Corporation: High Performance Palladium-Based Membrane for Hydrogen Separation and Purification	58
II.D	Hydrogen From Coal	62
II.D.1	Praxair, Inc.: Advanced Hydrogen Transport Membranes for Coal Gasification	62
II.D.2	Eltron Research & Development Inc.: Scale Up of Hydrogen Transport Membranes for IGCC and FutureGen Plants	66
II.D.3	United Technologies Research Center: Advanced Palladium Membrane Scale Up for Hydrogen Separation.....	69
II.D.4	Worcester Polytechnic Institute: Composite Pd and Alloy Porous Stainless Steel Membranes for Hydrogen Production and Process Intensification	73
II.E	Electrolysis.....	79
II.E.1	Giner Electrochemical Systems, LLC: PEM Electrolyzer Incorporating an Advanced Low-Cost Membrane.....	79
II.E.2	Proton Energy Systems: High Performance, Low Cost Hydrogen Generation from Renewable Energy	83
II.E.3	Avalence, LLC: High-Capacity, High Pressure Electrolysis System with Renewable Power Sources	87
II.E.4	National Renewable Energy Laboratory: Renewable Electrolysis Integrated System Development and Testing	92
II.E.5	H2Pump, LLC: Process Intensification of Hydrogen Unit Operations Using an Electrochemical Device.....	95
II.E.6	National Renewable Energy Laboratory: Hour-by-Hour Cost Modeling of Optimized Central Wind-Based Water Electrolysis Production	98
II.F	Hi-Temp Thermochemical	102
II.F.1	Science Applications International Corporation: Solar High-Temperature Water Splitting Cycle with Quantum Boost.....	102
II.F.2	Argonne National Laboratory: Membrane/Electrolyzer Development in the Cu-Cl Thermochemical Cycle	108
II.F.3	Sandia National Laboratories: Solar Hydrogen Production with a Metal Oxide-Based Thermochemical Cycle	112

II.	Hydrogen Production (Continued)	
II.F	Hi-Temp Thermochemical (Continued)	
II.F.4	University of Colorado: Solar-Thermal ALD Ferrite-Based Water Splitting Cycle	118
II.G	Photoelectrochemical	123
II.G.1	Stanford University: Nano-Architectures for 3 rd Generation PEC Devices: A Study of MoS ₂ , Fundamental Investigations and Applied Research	123
II.G.2	National Renewable Energy Laboratory: Semiconductor Materials for Photoelectrolysis	129
II.G.3	Lawrence Livermore National Laboratory: Characterization and Optimization of Photoelectrode Surfaces for Solar-to-Chemical Fuel Conversion	134
II.G.4	University of Nevada, Las Vegas: Characterization of Materials for Photoelectrochemical (PEC) Hydrogen Production	140
II.G.5	MVSystems, Incorporated: Photoelectrochemical Hydrogen Production	146
II.G.6	Midwest Optoelectronics, LLC: Critical Research for Cost-Effective Photoelectrochemical Production of Hydrogen	150
II.G.7	University of Arkansas, Little Rock: PEC-Based Hydrogen Production with Self-Cleaning Solar Concentrator	154
II.G.8	University of Nevada, Reno: Photoelectrochemical Hydrogen Generation from Water Using TiSi ₂ -TiO ₂ Nanotube Core-Shell Structure	160
II.G.9	University of South Dakota: USD Catalysis Group for Alternative Energy	164
II.G.10	University of Nebraska, Omaha: Novel Photocatalytic Metal Oxides	170
II.G.11	University of Nevada, Reno: Solar Thermal Hydrogen Production	173
II.G.12	National Renewable Energy Laboratory: Photoelectrochemical Materials: Theory and Modeling	176
II.G.13	Synkera Technologies Inc.: Nanotube Array Photoelectrochemical Hydrogen Production	181
II.H	Biological	185
II.H.1	National Renewable Energy Laboratory: Biological Systems for Hydrogen Photoproduction	185
II.H.2	National Renewable Energy Laboratory: Fermentation and Electrohydrogenic Approaches to Hydrogen Production	190
II.H.3	J. Craig Venter Institute: Hydrogen from Water in a Novel Recombinant Oxygen-Tolerant Cyanobacterial System	195
II.H.4	University of California, Berkeley: Maximizing Light Utilization Efficiency and Hydrogen Production in Microalgal Cultures	200
II.H.5	Purdue University: Purdue Hydrogen Systems Laboratory: Hydrogen Production	203
II.I	Production Analysis	207
II.I.1	National Renewable Energy Laboratory: H ₂ A Production Model Updates	207
II.J	Production	211
II.J.1	Giner Electrochemical Systems, LLC: Unitized Design for Home Refueling Appliance for Hydrogen Generation to 5,000 psi	211
II.J.2	Proton Energy Systems: Hydrogen by Wire - Home Fueling System	215
II.J.3	University of Texas, Arlington: Value-Added Hydrogen Generation with CO ₂ Conversion	218
II.J.4	Physical Optics Corporation: Photochemical System for Hydrogen Generation	225
II.K	Basic Energy Sciences	228
II.K.1	Stanford University: SISGR: Using <i>In vitro</i> Maturation and Cell-free Evolution to Understand [Fe-Fe]hydrogenase Activation and Active Site Constraints	228
II.K.2	University of Washington: Phototrophic metabolism of organic compounds generates excess reducing power that can be redirected to produce H ₂ as a biofuel	232
II.K.3	University of Georgia: Fundamental Studies of Recombinant Hydrogenases	234
II.K.4	University of Washington: Prospects for Hydrogen Production from Formate by <i>Methanococcus maripaludis</i>	237
II.K.5	National Renewable Energy Laboratory: Structural, Functional, and Integration Studies of Solar-Driven, Bio-Hybrid, H ₂ -Producing Systems	240
II.K.6	University of Oklahoma: Genes Needed For H ₂ Production by Sulfate Reducing Bacteria	242

II.	Hydrogen Production (Continued)	
II.K	Basic Energy Sciences (Continued)	
II.K.7	University of Missouri: Genetics and Molecular Biology of Hydrogen Metabolism in Sulfate-reducing Bacteria	245
II.K.8	National Renewable Energy Laboratory: Regulation of H ₂ and CO ₂ Metabolism: Factors Involved in Partitioning of Photosynthetic Reductant in Green Algae	248
II.K.9	University of Rochester: Excited State Dynamics in Semiconductor Quantum Dots	250
II.K.10	Princeton University: Theoretical Research Program on Bio-inspired Inorganic Hydrogen Generating Catalysts and Electrodes	253
II.K.11	Virginia Polytechnic Institute and State University: Photoinitiated Electron Collection in Mixed-Metal Supramolecular Complexes: Development of Photocatalysts for Hydrogen Production	257
II.K.12	University of California, Santa Cruz: Hydrogen Generation Using Integrated Photovoltaic and Photoelectrochemical Cells	260
II.K.13	University of Pennsylvania: Modular Designed Protein Constructions for Solar Generated H ₂ from Water	264
II.K.14	University of Alabama, Tuscaloosa: Protein-Templated Synthesis and Assembly of Nanostructures for Hydrogen Production	267
II.K.15	Brookhaven National Laboratory: Catalyzed Water Oxidation by Solar Irradiation of Band-Gap-Narrowed Semiconductors	270
II.K.16	Stony Brook University: Quantum theory of Semiconductor-Photo-Catalysis and Solar Water Splitting	273
II.K.17	University of Arizona: Formation and Characterization of Semiconductor Nanorod/Oxide Nanoparticle Hybrid Materials: Toward Vectorial Electron Transport in Hybrid Materials	275
II.K.18	University of Wyoming: Combinatorial methods for the Improvement of Semiconductor Metal Oxide Photoelectrodes	279
II.K.19	Pennsylvania State University: A Hybrid Biological-Organic Half-Cell for Generating Dihydrogen	281
II.K.20	California Institute of Technology: Fundamental Optical, Electrical, and Photoelectrochemical Properties of Catalyst-Bound Silicon Microwire Array Photocathodes for Sunlight-Driven Hydrogen Production	283
II.K.21	National Renewable Energy Laboratory: New Directions for Efficient Solar Water Splitting Based on Two Photosystems and Singlet Fission Chromophores	286
III.	Hydrogen Delivery	291
III.0	Hydrogen Delivery Sub-Program Overview	293
III.1	Sandia National Laboratories: Hydrogen Embrittlement of Structural Steels	299
III.2	Argonne National Laboratory: Hydrogen Delivery Infrastructure Analysis	303
III.3	Oak Ridge National Laboratory: Vessel Design and Fabrication Technology for Stationary High-Pressure Hydrogen Storage	307
III.4	National Renewable Energy Laboratory: Hydrogen Delivery Analysis	312
III.5	Lawrence Livermore National Laboratory: Demonstration of Full-Scale Glass Fiber Composite Pressure Vessels for Inexpensive Delivery of Cold Hydrogen	316
III.6	Savannah River National Laboratory: Fiber Reinforced Composite Pipeline	322
III.7	Lincoln Composites, Inc.: Development of High Pressure Hydrogen Storage Tank for Storage and Gaseous Truck Delivery	326
III.8	Concepts NREC: Development of a Centrifugal Hydrogen Pipeline Gas Compressor	331
III.9	Mohawk Innovative Technologies, Inc.: Oil-Free Centrifugal Hydrogen Compression Technology Demonstration	338
III.10	FuelCell Energy, Inc.: Electrochemical Hydrogen Compressor	342
III.11	Praxair, Inc.: Advanced Hydrogen Liquefaction Process	345
III.12	University of Illinois at Urbana-Champaign: A Combined Materials Science/Mechanics Approach to the Study of Hydrogen Embrittlement of Pipeline Steels	349
III.13	Oak Ridge National Laboratory: Composite Technology for Hydrogen Pipelines	354

III.0	Hydrogen Delivery (Continued)	
III.14	Lawrence Livermore National Laboratory: Thermodynamic Modeling of Rapid Low Loss Cryogenic Hydrogen Refueling	358
III.15	Oak Ridge National Laboratory: Integrity of Steel Welds in High-Pressure Hydrogen Environment	362
III.16	Argonne National Laboratory: Hydrogen Pipeline Compressors	367
III.17	Prometheus Energy: Active Magnetic Regenerative Liquefier	371
IV.	Hydrogen Storage	375
IV.0	Hydrogen Storage Sub-Program Overview	377
IV.A	Metal Hydride	383
IV.A.1	Savannah River National Laboratory: Amide and Combined Amide/Borohydride Investigations	383
IV.A.2	Northwestern University: Efficient Discovery of Novel Multicomponent Mixtures for Hydrogen Storage: A Combined Computational/Experimental Approach	388
IV.A.3	University of Hawaii: Fundamental Studies of Advanced High-Capacity, Reversible Metal Hydrides	393
IV.A.4	Ohio State University: Lightweight Metal Hydrides for Hydrogen Storage	398
IV.A.5	University of Illinois at Urbana-Champaign: Reversible Hydrogen Storage Materials - Structure, Chemistry, and Electronic Structure	403
IV.A.6	Brookhaven National Laboratory: Aluminum Hydride	409
IV.A.7	Savannah River National Laboratory: Electrochemical Reversible Formation of Alane	413
IV.A.8	Sandia National Laboratories: Tunable Thermodynamics and Kinetics for Hydrogen Storage: Nanoparticle Synthesis Using Ordered Polymer Templates	416
IV.A.9	National Institute of Standards and Technology: Neutron Characterization in Support of the DOE Hydrogen Storage Sub-Program	420
IV.B	Chemical Hydrogen Storage	425
IV.B.1	University of Oregon: Hydrogen Storage by Novel CBN Heterocycle Materials	425
IV.B.2	Los Alamos National Laboratory: Fluid Phase Chemical Hydrogen Storage Materials	429
IV.C	Hydrogen Sorption	432
IV.C.1	Texas A&M University: A Biomimetic Approach to Metal-Organic Frameworks with High H ₂ Uptake	432
IV.C.2	University of California, Los Angeles: A Joint Theory and Experimental Project in the Synthesis and Testing of Porous COFs/ZIFs for On-Board Vehicular Hydrogen Storage	439
IV.C.3	University of Missouri: Multiply Surface-Functionalized Nanoporous Carbon for Vehicular Hydrogen Storage	444
IV.C.4	Northwestern University: New Carbon-Based Porous Materials with Increased Heats of Adsorption for Hydrogen Storage	450
IV.C.5	Argonne National Laboratory: Hydrogen Storage through Nanostructured Porous Organic Polymers (POPs)	455
IV.C.6	Pennsylvania State University: Hydrogen Trapping through Designer Hydrogen Spillover Molecules with Reversible Temperature and Pressure-Induced Switching	459
IV.C.7	National Renewable Energy Laboratory: Weak Chemisorption Validation	464
IV.C.8	State University of New York, Syracuse: Nanostructured Activated Carbon for Hydrogen Storage	470
IV.C.9	University of California, Los Angeles: Hydrogen Storage in Metal-Organic Frameworks	474
IV.D	H ₂ Storage Engineering Center of Excellence	479
IV.D.1	Savannah River National Laboratory: Hydrogen Storage Engineering Center of Excellence	479
IV.D.2	National Renewable Energy Laboratory: System Design, Analysis, Modeling, and Media Engineering Properties for Hydrogen Energy Storage	486
IV.D.3	Los Alamos National Laboratory: Chemical Hydride Rate Modeling, Validation, and System Demonstration	491

IV.	Hydrogen Storage (Continued)	
IV.D	H2 Storage Engineering Center of Excellence (Continued)	
IV.D.4	Jet Propulsion Laboratory: Key Technologies, Thermal Management, and Prototype Testing for Advanced Solid-State Hydrogen Storage Systems	494
IV.D.5	Savannah River National Laboratory: SRNL Technical Work Scope for the Hydrogen Storage Engineering Center of Excellence: Design and Testing of Metal Hydride and Adsorbent Systems	498
IV.D.6	Pacific Northwest National Laboratory: Systems Engineering of Chemical Hydride, Pressure Vessel, and Balance of Plant for On-Board Hydrogen Storage	503
IV.D.7	United Technologies Research Center: Advancement of Systems Designs and Key Engineering Technologies for Materials-Based Hydrogen Storage	511
IV.D.8	General Motors Company: Optimization of Heat Exchangers and System Simulation of On-Board Storage Systems Designs	517
IV.D.9	Ford Motor Company: Ford/BASF-SE/UM Activities in Support of the Hydrogen Storage Engineering Center of Excellence	522
IV.D.10	Oregon State University: Microscale Enhancement of Heat and Mass Transfer for Hydrogen Energy Storage	530
IV.D.11	Lincoln Composites, Inc.: Development of Improved Composite Pressure Vessels for Hydrogen Storage	534
IV.E	Storage Testing, Safety and Analysis	538
IV.E.1	United Technologies Research Center: Quantifying and Addressing the DOE Material Reactivity Requirements with Analysis and Testing of Hydrogen Storage Materials and Systems	538
IV.E.2	Argonne National Laboratory: System Level Analysis of Hydrogen Storage Options	544
IV.E.3	TIAX, LLC: Cost Analyses of Hydrogen Storage Materials and On-Board Systems	550
IV.E.4	Sandia National Laboratories: Analysis of H ₂ Storage Needs for Early Market Non-Motive Fuel Cell Applications	554
IV.E.5	National Renewable Energy Laboratory: Analysis of Storage Needs for Early Motive Fuel Cell Markets	558
IV.E.6	Southwest Research Institute®: Standardized Testing Program for Solid-State Hydrogen Storage Technologies	562
IV.E.7	H2 Technology Consulting LLC: Best Practices for Characterizing Engineering Properties of Hydrogen Storage Materials	567
IV.E.8	Hydrogen Education Foundation: Administration of H-Prize for Hydrogen Storage	571
IV.F	Tanks	576
IV.F.1	Oak Ridge National Laboratory: High Strength Carbon Fibers	576
IV.F.2	Oak Ridge National Laboratory: Lifecycle Verification of Polymeric Storage Liners	581
IV.G	Cross-Cutting	585
IV.G.1	Purdue University: Purdue Hydrogen Systems Laboratory: Hydrogen Storage	585
IV.G.2	University of Nevada, Las Vegas: HGMS: Glasses and Nanocomposites for Hydrogen Storage	590
IV.G.3	Delaware State University: Hydrogen Storage Materials for Fuel Cell-Powered Vehicles	593
V.	Fuel Cells	597
V.0	Fuel Cells Sub-Program Overview	599
V.A	Analysis/Characterization	605
V.A.1	National Renewable Energy Laboratory: Analysis of Laboratory Fuel Cell Technology Status – Voltage Degradation	605
V.A.2	Directed Technologies, Inc.: Mass-Production Cost Estimation for Automotive Fuel Cell Systems	609
V.A.3	Argonne National Laboratory: Drive-Cycle Performance of Automotive Fuel Cell Systems	614
V.A.4	Oak Ridge National Laboratory: Characterization of Fuel Cell Materials	621

V.	Fuel Cells (Continued)	
V.A	Analysis/Characterization (Continued)	
V.A.5	National Institute of Standards and Technology: Neutron Imaging Study of the Water Transport in Operating Fuel Cells	626
V.A.6	Los Alamos National Laboratory: Technical Assistance to Developers	631
V.A.7	National Renewable Energy Laboratory: Enlarging the Potential Market for Stationary Fuel Cells Through System Design Optimization	634
V.A.8	Argonne National Laboratory: Fuel Cell Testing at the Argonne Fuel Cell Test Facility: A Comparison of U.S. and EU Test Protocols.	637
V.B	Impurities.	640
V.B.1	National Renewable Energy Laboratory: Effect of System Contaminants on PEMFC Performance and Durability.	640
V.B.2	University of Connecticut: The Effects of Impurities on Fuel Cell Performance and Durability	644
V.B.3	Hawaii Natural Energy Institute: The Effect of Airborne Contaminants on Fuel Cell Performance and Durability	649
V.B.4	Clemson University: Effects of Impurities on Fuel Cell Performance and Durability	654
V.B.5	Los Alamos National Laboratory: Effects of Fuel and Air Impurities on PEM Fuel Cell Performance	659
V.C	Membranes	662
V.C.1	3M Company: Membranes and MEAs for Dry, Hot Operating Conditions.	662
V.C.2	Giner Electrochemical Systems, LLC: Dimensionally Stable Membranes (DSMs)	667
V.C.3	Giner Electrochemical Systems, LLC: Dimensionally Stable High Performance Membrane (SBIR Phase III)	671
V.C.4	Case Western Reserve University: Poly(p-Phenylene Sulfonic Acids): PEMs with Frozen-In Free Volume	675
V.C.5	Vanderbilt University: NanoCapillary Network Proton Conducting Membranes for High Temperature Hydrogen/Air Fuel Cells.	680
V.C.6	Colorado School of Mines: Novel Approaches to Immobilized Heteropoly Acid (HPA) Systems for High Temperature, Low Relative Humidity Polymer-Type Membranes	685
V.C.7	FuelCell Energy, Inc.: High-Temperature Membrane with Humidification-Independent Cluster Structure	690
V.C.8	Ion Power Inc.: Corrugated Membrane Fuel Cell Structures	694
V.C.9	University of Central Florida: Lead Research and Development Activity for DOE's High Temperature, Low Relative Humidity Membrane Program	696
V.D	Catalysts.	699
V.D.1	3M Company: Advanced Cathode Catalysts and Supports for PEM Fuel Cells	699
V.D.2	UTC Power: Highly Dispersed Alloy Catalyst for Durability	708
V.D.3	3M Company: Durable Catalysts for Fuel Cell Protection During Transient Conditions	714
V.D.4	National Renewable Energy Laboratory: Extended, Continuous Pt Nanostructures in Thick, Dispersed Electrodes	719
V.D.5	Argonne National Laboratory: Nanosegregated Cathode Catalysts with Ultra-Low Platinum Loading.	723
V.D.6	Brookhaven National Laboratory: Contiguous Platinum Monolayer Oxygen Reduction Electrocatalysts on High-Stability Low-Cost Supports.	729
V.D.7	Los Alamos National Laboratory: The Science and Engineering of Durable Ultralow PGM Catalysts	734
V.D.8	Lawrence Berkeley National Laboratory: Molecular-Scale, Three-Dimensional Non-Platinum Group Metal Electrodes for Catalysis of Fuel Cell Reactions.	738
V.D.9	National Renewable Energy Laboratory: Tungsten Oxide and Heteropoly Acid Based System for Ultra-High Activity and Stability of Pt Catalysts in PEM Fuel Cell Cathodes	745
V.D.10	Illinois Institute of Technology: Synthesis and Characterization of Mixed-Conducting Corrosion Resistant Oxide Supports	752

V.	Fuel Cells (Continued)	
V.D	Catalysts (Continued)	
V.D.11	Northeastern University: Development of Novel Non-PGM Electrocatalysts for Proton Exchange Membrane Fuel Cell Applications	756
V.D.12	General Motors Company: High-Activity Dealloyed Catalysts	760
V.D.13	University of South Carolina: Development of Ultra-Low Platinum Alloy Cathode Catalyst for PEM Fuel Cells	764
V.D.14	Los Alamos National Laboratory: Engineered Nano-Scale Ceramic Supports for PEM Fuel Cells.	770
V.D.15	Pacific Northwest National Laboratory: Development of Alternative and Durable High Performance Cathode Supports for PEM Fuel Cells	777
V.E	Degradation Studies	783
V.E.1	Argonne National Laboratory: Polymer Electrolyte Fuel Cell Lifetime Limitations: The Role of Electrocatalyst Degradation.	783
V.E.2	Los Alamos National Laboratory: Durability Improvements Through Degradation Mechanism Studies	788
V.E.3	E. I. du Pont de Nemours and Company: Analysis of Durability of MEAs in Automotive PEMFC Applications	794
V.E.4	Ballard Power Systems: Development of Micro-Structural Mitigation Strategies for PEM Fuel Cells: Morphological Simulations and Experimental Approaches.	797
V.E.5	Nuvera Fuel Cells, Inc.: Durability of Low Platinum Fuel Cells Operating at High Power Density.	802
V.E.6	UTC Power: Improved Accelerated Stress Tests Based on FCV Data	806
V.E.7	Los Alamos National Laboratory: Accelerated Testing Validation.	810
V.F	Transport Studies	814
V.F.1	CFD Research Corporation: Water Transport in PEM Fuel Cells: Advanced Modeling, Material Selection, Testing, and Design Optimization	814
V.F.2	Sandia National Laboratories: Development and Validation of a Two-Phase, Three-Dimensional Model for PEM Fuel Cells.	818
V.F.3	Giner Electrochemical Systems, LLC: Transport in PEMFC Stacks	822
V.F.4	General Motors Company: Investigation of Micro- and Macro-Scale Transport Processes for Improved Fuel Cell Performance	827
V.F.5	Plug Power Inc.: Air-Cooled Stack Freeze Tolerance	833
V.F.6	Nuvera Fuel Cells, Inc.: Transport Studies Enabling Efficiency Optimization of Cost-Competitive Fuel Cell Stacks.	837
V.F.7	Lawrence Berkeley National Laboratory: Fuel Cell Fundamentals at Low and Subzero Temperatures	841
V.G	Portable Power	846
V.G.1	National Renewable Energy Laboratory: Novel Approach to Advanced Direct Methanol Fuel Cell (DMFC) Anode Catalysts	846
V.G.2	Arkema Inc.: Novel Materials for High Efficiency Direct Methanol Fuel Cells	850
V.G.3	University of North Florida: New MEA Materials for Improved Direct Methanol Fuel Cell (DMFC) Performance, Durability, and Cost	854
V.G.4	Los Alamos National Laboratory: Advanced Materials and Concepts for Portable Power Fuel Cells.	858
V.H	Hardware	863
V.H.1	TreadStone Technologies, Inc.: Low-Cost PEM Fuel Cell Metal Bipolar Plates	863
V.H.2	Argonne National Laboratory: Metallic Bipolar Plates with Composite Coatings.	867
V.I	Innovative Concepts.	872
V.I.1	Los Alamos National Laboratory: Resonance-Stabilized Anion Exchange Polymer Electrolytes	872

I. INTRODUCTION

I.0 Introduction

The Department of Energy Hydrogen and Fuel Cells Program (the Program) conducts comprehensive efforts to enable the widespread commercialization of hydrogen and fuel cell technologies in diverse sectors of the economy. The Program is coordinated across the Department of Energy (DOE or the Department), including activities in the offices of Energy Efficiency and Renewable Energy (EERE), Science (SC), Nuclear Energy (NE), and Fossil Energy (FE), and it is aligned with DOE's strategic vision and goals—its efforts will help to secure U.S. leadership in clean energy technologies and advance U.S. economic competitiveness and scientific innovation.

With emphasis on applications that will most effectively strengthen our nation's energy security and improve our stewardship of the environment, the Program engages in research, development, and demonstration (RD&D) of critical improvements in the technologies, as well as diverse activities to overcome economic and institutional obstacles to commercialization. The Program addresses the full range of challenges facing the development and deployment of hydrogen and fuel cell technologies by integrating basic and applied research, technology development and demonstration, and other supporting activities.

In Fiscal Year (FY) 2011, Congress appropriated approximately \$150 million for the DOE Hydrogen and Fuel Cells Program.¹ The Program is organized into distinct sub-programs focused on specific areas of RD&D, as well as other activities to address non-technical challenges. More detailed discussions of Program activities and plans can be found in EERE's *Fuel Cell Technologies Program Multi-Year RD&D Plan*; FE's *Hydrogen from Coal RD&D Plan*; and SC's *Basic Research Needs for the Hydrogen Economy*. All of these documents are available at www.hydrogen.energy.gov/program_plans.html.

In the past year, the Program made substantial progress toward its goals and objectives. Highlights of the Program's accomplishments are summarized below. More detail can be found in the sub-program chapters of this report.

PROGRAM PROGRESS AND ACCOMPLISHMENTS

Fuel Cells

The Fuel Cells sub-program continued to make progress toward meeting targets through advancements achieved in both catalysis and membrane R&D. Technological advances in several component areas led to significant improvements in performance and durability, with reduced cost. In FY 2011, the catalyst utilization in polymer electrolyte membrane (PEM) automotive fuel cell systems improved from 2.8 kW/g in 2008 to 5.6 kW/g in 2011 (as measured in units of kW per gram of platinum group metal).² This exceeds the Program's 5.5 kW/g target set for FY 2011 and has contributed to reducing the high-volume manufacturing cost of fuel cells. This cost is currently projected to be \$49/kW (assuming manufacturing volumes of 500,000 units/year), which represents a more than 30% cost reduction since FY 2008.³

¹ This includes \$98 million for the Fuel Cell Technologies Program within the Office of Energy Efficiency and Renewable Energy, \$38 million for hydrogen and fuel cell-related research in the Basic Energy Sciences program within the Office of Science, \$12 million for hydrogen production R&D in the Office of Fossil Energy and \$2.8 million for hydrogen production R&D in the Office of Nuclear Energy.

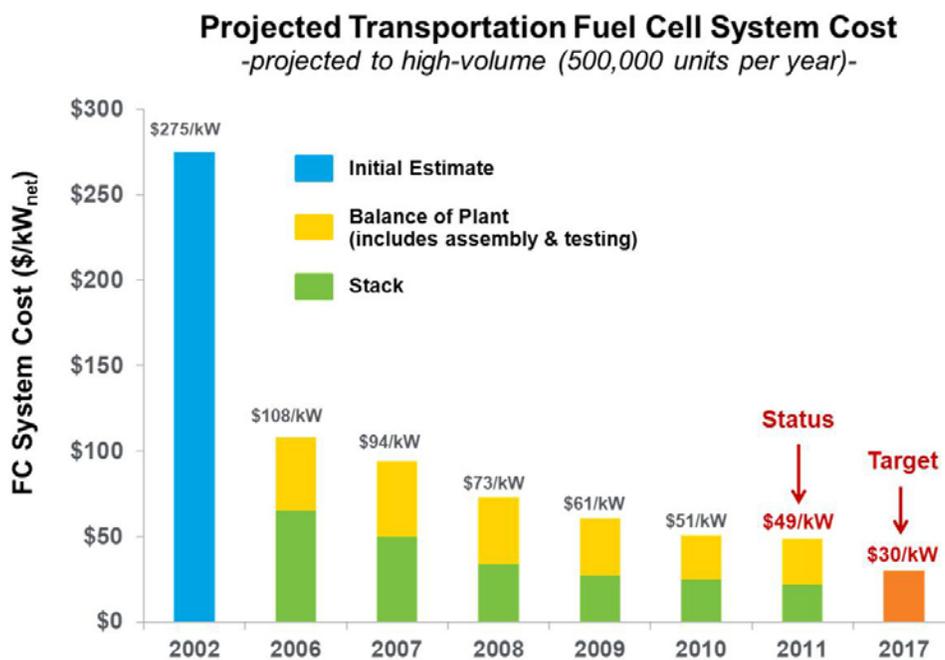

FIGURE 1. Current Modeled Cost of an 80-kW Automotive Fuel Cell System Based on Projection to High-Volume Manufacturing (500,000 Units/Year)⁴

FY 2011 also saw the development of a perfluoroimide acid membrane, for higher-temperature operation (120°C) that meets most DOE targets, including most membrane resistance targets. Progress over the last year enabled a 40% reduction in membrane resistance at 120°C and 40 kPa water vapor, with an additional 13% reduction still required to meet the 2017 DOE target of 0.02 ohm cm².⁵ Efforts in FY 2011 also led to the development of solid-oxide fuel cell (SOFC) systems for remote power and micro-combined heat and power applications with increased durability, enabling more than 12,000 hours of operation of an SOFC system.⁶ This advance represents a significant step toward production of an SOFC system for widespread commercialization and builds on the performance improvements demonstrated in FY 2010.

Hydrogen Production

The FY 2011 Hydrogen Production sub-program continued to focus on developing technologies that enable the long-term viability of hydrogen as an energy carrier for a diverse range of end-use applications, including stationary power, backup power, specialty vehicles, transportation, and portable power. In FY 2011, the sub-program continued to make progress in several key areas, including autothermal reforming of bio-derived liquids, electrolysis, photoelectrochemical (PEC) hydrogen production, and biological hydrogen production.

In the area of bio-derived liquids, increases in process efficiency from 47% to 62% and increases in yield from 7.4 g to 10.1 g hydrogen per 100 g bio-oil were achieved for bench-scale tests of catalytic steam reforming of pyrolysis oil as a result of improvements in catalyst performance through the use of a 0.5% Pt/Al₂O₃ BASF catalyst.⁷ Progress in the area of electrolysis included demonstration of a PEM electrolyzer incorporating advanced low-cost membrane electrode assemblies (MEAs) with chemically etched supports.⁸ Due to improvements in MEAs and flow fields and reductions in catalyst loading, the projected capital cost of electrolyzer stacks was reduced to less than \$400/kW, representing a cost reduction of more than 10% relative

Projected High-Volume Cost of Hydrogenⁱ – Status

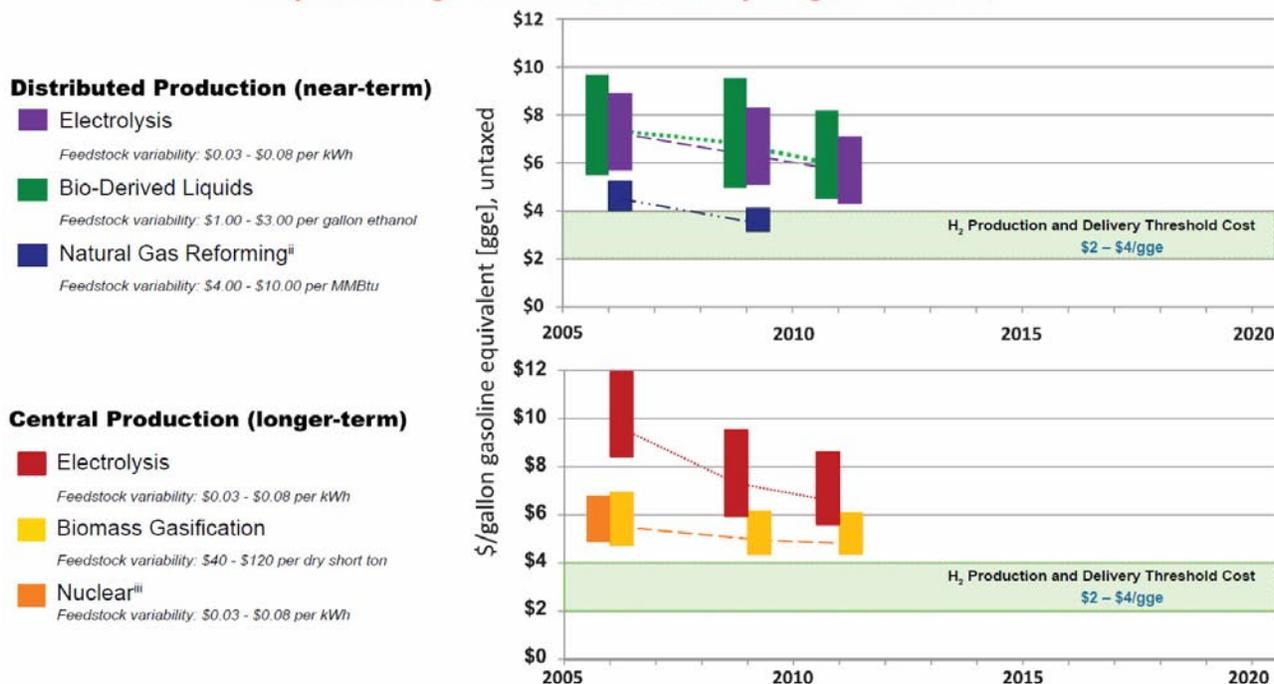

FIGURE 2. Hydrogen Production and Delivery Cost Status. Significant progress has already been made in several hydrogen production pathways. The Hydrogen Threshold Cost represents the cost at which hydrogen fuel cell electric vehicles are projected to become competitive on a cost-per-mile basis with competing vehicles (gasoline hybrid-electric vehicles) in 2020. Notes: (i) Costs shown include all delivery and dispensing costs, but do not include taxes. A cost of \$1.80 for forecourt compression, storage, and dispensing is included for distributed technologies, and \$2.60 is included as the total cost of delivery (including transportation, compression, storage, and dispensing) for centralized technologies. All delivery costs are based on the Hydrogen Pathways Technical Report (NREL, 2009). Projections of distributed costs assume station capacities of 1,500 kg/day, with 500 stations built per year. Projections of centralized production costs assume capacities of $\geq 50,000$ kg/day. Cost ranges for each pathway are shown in 2007 dollars, based on high-volume projections from H2A analyses, reflecting variability in major feedstock pricing and a bounded range for capital cost estimates. (ii) DOE funding of natural gas reforming projects was completed in 2009 due to achievement of the threshold cost. Incremental improvements will continue to be made by industry. (iii) High-temperature electrolysis activities are ongoing under the Next Generation Nuclear Plant Program.

to 2010 projections.⁹ In the area of PEC hydrogen production, the Program demonstrated exceptional stability in quantum-confined MoS₂ nanoparticle photocatalysts with bandgaps optimized at 1.8 eV, showing stable operation over 10,000 voltage cycles of accelerated lifetime testing. In complementary work, novel macroporous scaffolds, which are transparent and conductive, were developed as electrode substrates to support PEC photocatalyst materials, such as MoS₂, in high-efficiency devices.¹⁰ Finally, in the area of biological hydrogen production, the gene mutation responsible for the decrease in chlorophyll antenna size, previously observed to increase light utilization efficiency to 15% from 3% in wild-type organisms, was identified and characterized. Efforts to identify the mutation responsible for light utilization of up to 25% are ongoing, along with R&D to optimize hydrogen production in microalgal cultures.¹¹

⁹ See Report I.I.E.1, “PEM Electrolyzer Incorporating an Advanced Low-Cost Membrane,” and Report I.I.E.2, “High Performance, Low Cost Hydrogen Generation from Renewable Energy,” in the Hydrogen Production chapter of this volume.

¹¹ See Report I.I.H.4, “Maximizing Light Utilization Efficiency and Hydrogen Production in Microalgal Cultures,” in the Hydrogen Production chapter of this volume.

Hydrogen Delivery

Hydrogen Delivery sub-program activities continued to focus on reducing the cost and increasing the energy efficiency of hydrogen delivery, to enable the widespread use of hydrogen as an energy carrier. In FY 2011, the sub-program continued to make progress in all major areas, including the following examples. A design trade study for a 5,000 pounds per square inch (psi) vessel was completed; this showed a projected 33% increase in capacity at 15°C and ~10% reduction in capital cost (on a per kilogram of transported hydrogen basis).¹² In addition, burst testing on fiber reinforced polymer pipe with 40% through-wall flaws was also completed and demonstrated a 3x margin above the rated pressure for the pipe. Researchers also showed that industry-standard compression fittings will meet Department of Transportation requirements for joint leakage between pipe segments.¹³ FY 2011 also saw the development of a two-stage electrochemical hydrogen compressor that achieved 420 bar of compression.¹⁴

Hydrogen Storage

In FY 2011, the Hydrogen Storage sub-program's materials-discovery projects developed a number of new materials and improved the performance of other materials. Key accomplishments in FY 2011 include: characterization of high surface area sorbents with specific surface areas greater than 6,000 m² per gram and excess hydrogen sorption capacities exceeding 8% by weight at 77 K;¹⁵ demonstration of cycling of Mg(BH₄)₂ at hydrogen capacities greater than 12% by weight under high-temperature and high-pressure conditions;¹⁶ demonstration of alane slurry with 60% capacity by weight and with kinetics exceeding non-slurried alane;¹⁷ and determination that thermal stability of ionic liquids is dominated by choice of cation. The Hydrogen Storage Engineering Center of Excellence (HSECoE) completed a baseline assessment of storage system models for reversible metal hydrides, cryo-sorbents, and both solid- and liquid-phase off-board regenerable chemical hydrogen storage material systems. The HSECoE assessed these models against the full set of DOE onboard storage targets. Also in FY 2011, the sub-program increased its emphasis on reducing the cost of compressed hydrogen gas storage tanks by initiating new efforts on low-cost, high-strength carbon fiber. Inexpensive storage vessels for compressed hydrogen gas are considered the most likely near-term hydrogen storage solution for the initial commercialization of fuel cell electric vehicles (FCEVs), as well as for other early market applications.

Manufacturing R&D

FY 2011 saw a number of advances in manufacturing of fuel cells and storage systems. Ballard made several improvements that resulted in significant improvement in quality yields and a gas diffusion layer cost reduction of over 60%, while increasing manufacturing capacity nearly four-fold.¹⁸ For example, they improved thickness and basis weight uniformity of gas diffusion layers by adding mass flow meters to the "Many-at-a-Time" coating equipment. W.L. Gore reduced membrane thickness, eliminated membrane backers, reduced scrap with better coating process, and eliminated finishing operations such as electrode and membrane edge trim (Gore previously demonstrated, using their cost model, that a new three-layer membrane electrode assembly process has the potential to reduce membrane electrode assembly cost by 25%).¹⁹ And Quantum saved 17.4 kg of composite from the baseline (all fiber wound) high-pressure hydrogen storage vessel (a 23% savings).²⁰

²⁰ See Report VI.9, "Development of Advanced Manufacturing Technologies for Low Cost Hydrogen Storage Vessels," in the Manufacturing R&D chapter of this volume.

In conjunction with the National Renewable Energy Laboratory, the Manufacturing R&D sub-program also held a workshop to prioritize challenges and barriers to manufacturing hydrogen and fuel cell systems and components and to identify R&D activities that government can support to overcome barriers.

Basic Research

The Basic Energy Sciences program within the DOE Office of Science supports fundamental scientific research addressing critical challenges related to hydrogen storage, hydrogen production, and fuel cells. This basic research complements the applied R&D projects supported by other offices in the Program.

Progress in any one area of basic science is likely to spill over to other areas and bring advances on more than one front. The subjects of basic research most relevant to the Program's key technologies are:

- *Hydrogen Storage*: Nanostructured materials; theory, modeling, and simulation to predict behavior and design new materials; and novel analytical and characterization tools.
- *Fuel Cells*: Nanostructured catalysts and materials; integrated nanoscale architectures; novel fuel cell membranes; innovative synthetic techniques; theory, modeling, and simulation of catalytic pathways, membranes, and fuel cells; and novel characterization techniques.
- *Hydrogen Production*: Longer-term approaches such as photobiological and direct photochemical production of hydrogen.

By maintaining close coordination between basic science research and applied R&D, the Program ensures that discoveries and related conceptual breakthroughs achieved in basic research programs will provide a foundation for the innovative design of materials and processes that will lead to improvements in the performance, cost, and reliability of fuel cell technologies and technologies for hydrogen production and storage. This is accomplished in various ways—for example, through monthly coordination meetings between the participating offices within DOE, and at the researcher level by having joint meetings with participation from principal investigators who are funded by the participating offices.

Technology Validation

The Technology Validation sub-program demonstrates, tests, and validates hydrogen and fuel cell technologies and uses the results to provide feedback to the Program's R&D activities. The Technology Validation sub-program has been focused on conducting learning demonstrations that emphasize co-development and integration of hydrogen infrastructure with FCEVs to permit industry to assess progress toward technology readiness. As the vehicle and infrastructure demonstrations in are coming to a close, the sub-program is increasing its focus on other areas, such as combined hydrogen, heat, and power (tri-generation or CHHP) as well as stationary power applications.

The Program's vehicle and infrastructure demonstrations in the National Hydrogen Learning Demonstration have deployed 155 FCEVs and 24 hydrogen fueling stations to date. Over the course of the demonstration, the vehicles have traveled more than 3 million miles. Vehicles and infrastructure in these demonstrations have validated the status of several key technologies in integrated systems under real-world operating conditions, including vehicular fuel cell efficiency of up to 59%, projected durability of 2,500 hours (nearly 75,000 miles) with less than 10% degradation, a range of more than 250 miles between refueling (the Program has validated one vehicle—not in the Learning Demonstration—that is capable of traveling more than 430 miles on a single fill), and refueling times of approximately five minutes for 4 kg of hydrogen. The Technology Validation sub-program also collected and analyzed data from over 45,000 fuel cell fork truck lift refuelings at Defense Logistics Agency sites.

A major accomplishment in FY 2011 was demonstrating the world's first fuel cell energy station that produces electric power and hydrogen from wastewater treatment gas.²¹ The energy station provides hydrogen as a transportation fuel to the public and electric power to the wastewater treatment facility; it also has the potential to operate in "trigeneration" (or combined-heat-hydrogen-and-power) mode, if waste heat from the fuel cell is captured and provided to the facility. The energy station began operation at the Orange County Sanitation District's facility in Fountain Valley, California, sending hydrogen to a fueling station for FCEVs

²¹ See Report VII.4, "Validation of an Integrated Hydrogen Energy Station," in the Technology Validation chapter of this volume.

first in February 2011. The combined co-production efficiency of hydrogen and power was 54% at the energy station, exceeding DOE's target of 50% for FY 2011.

Safety, Codes and Standards

The Safety, Codes and Standards sub-program continued to support critical R&D to establish key requirements and address knowledge gaps in safety, codes and standards. Building on work from previous years, the sub-program continued to facilitate collaborative activities among relevant stakeholders in an effort to harmonize domestic and international regulations, codes, and standards. Significant accomplishments include the development of *National Fire Protection Association (NFPA) 2: Hydrogen Technologies Code*, which consolidates all building codes and requirements for hydrogen installations in the United States into a single document. NFPA 2 also includes a qualitative risk assessment introduced by DOE for separation distances for hydrogen bulk storage. Another achievement was the development of an international hydrogen fuel specification standard (ISO TC 197 WG 12), which was led by the United States and ensures performance and durability of PEM fuel cells. In addition, a final draft of a Global Technical Regulation for hydrogen-fueled vehicles has been submitted to the United Nations Economic Commission for Europe. The sub-program also took a leadership role in international coordination by co-organizing the International Conference on Hydrogen Safety in California with Sandia National Laboratories.

Education

The Education sub-program facilitates hydrogen and fuel cell demonstrations and supports commercialization by providing technically accurate and objective information to key target audiences both directly and indirectly involved in the use of hydrogen and fuel cells. FY 2010 appropriations supported these activities.

To support early market outreach, the Education sub-program implemented several end-user, state and local government, and safety and code official education activities. Accomplishments include the development of a model to analyze the economic impacts on early market deployment of fuel cells in primary power, backup power, and material-handling applications through a user-friendly spreadsheet tool used to calculate impacts on production, installation, and utilization at a regional or national level. The tool will be available for beta testing at the end of 2011. Videos were also developed to be aired on TV and posted online to YouTube and other sites, including the development of two segments for MotorWeek entitled "Hydrogen and Fuel Cells Emerging Markets" and "Vehicles and Infrastructure Update." In FY 2011, the sub-program also organized, publicized, and facilitated 10 webinars on hydrogen and fuel cell topics of interest to state policymakers, local leaders, and end users, including: "The Top 5 Fuel Cell States: Why Local Policies Mean Green Growth," "Hydrogen and First Responders," "Financing Fuel Cell Installations," and others.

Systems Analysis and Integration

Systems Analysis supports decision-making by providing a greater understanding of technology gaps, options, and risks. Analysis is also conducted to assess cross-cutting issues, such as integration with the electrical sector and use of renewable fuels. Particular emphasis is given to assessing stationary fuel cell applications, fuel quality impacts on fuel cell performance, resource needs, and potential infrastructure options.

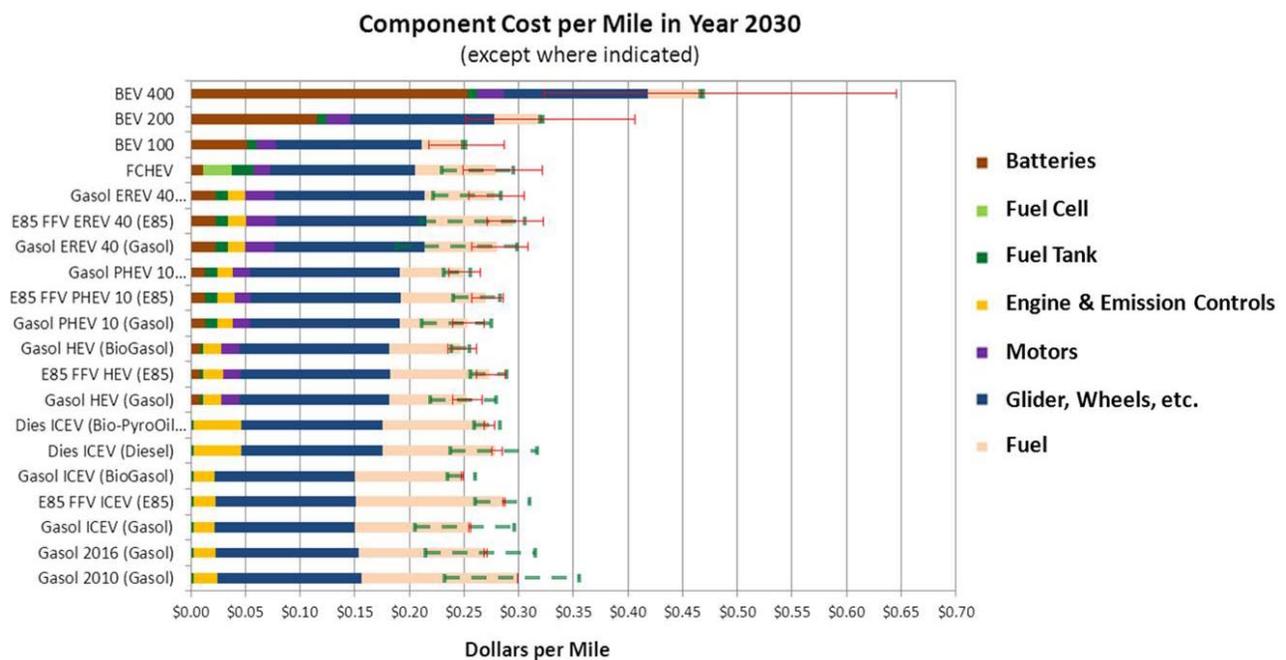

Accomplishments in FY 2011 include the development of a hydrogen cost threshold in the range of \$2-\$4/gasoline gallon equivalent (in 2007 dollars) to assist DOE in focusing and prioritizing R&D options. The cost threshold represents the cost at which hydrogen FCEVs are projected to become competitive on a cost-per-mile basis with the competing fuel/vehicle combination—gasoline in hybrid-electric vehicles. A graphical representation of the hydrogen threshold, relative to current projected production and delivery costs is shown in Figure 2 in the "Hydrogen Production" section of this Introduction. Also in FY 2011, a comparison of cost estimates for non-automotive fuel cells showed a 50% or greater reduction in costs between 2008 and 2010.²² Despite these large cost reductions, the analysis concluded that the continuation or enhancement of current policies such as the investment tax credit and government procurement combined with progress by industry will be necessary to establish a viable domestic fuel cell industry. In addition,

²² Greene, David et al. "Status and Outlook for the U.S. Non-Automotive Fuel Cell Industry: Impacts of Government Policies and Assessment of Future Opportunities" Oak Ridge National Laboratory, May 2011.

infrastructure analysis revealed that synergies between fuel cells for stationary power generation and transportation could be realized in the early phases of market adoption of hydrogen for light-duty fuel cell vehicles. Model results that indicate hydrogen produced from combined hydrogen, heat, and power systems could result in smaller stations with higher capital utilization and lower hydrogen cost; this hydrogen could supplement hydrogen supplied from distributed natural gas-based steam methane reforming, particularly for the early years of FCEV penetration scenarios where hydrogen demand and station sizes are initially small.

In FY 2011, the Systems Analysis sub-program collaborated with counterparts in the DOE Vehicle Technologies Program and the DOE Biomass Program to prepare and release an EERE-wide request for information (RFI) on the total cost of operation of future light-duty vehicles, including petroleum fuels and alternative fuels pathways, based on three levels of technology success. Comments from the public were requested on the projected cost reductions and the financial analysis approach used in estimating the cost per mile for each pathway. Responses to the RFI are due on December 16, 2011. Figure 3 shows the preliminary EERE estimates of costs per mile that were released for comments under the RFI.

Life-Cycle Costs of Advanced Vehicles – *PRELIMINARY ANALYSIS*

BEV – battery electric vehicle; FCHEV – fuel cell hybrid electric vehicle; Gasol – gasoline; EREV – extended range electric vehicle; FFV – flexible fuel vehicle; PHEV – plug-in hybrid electric vehicle; HEV – hybrid electric vehicle; ICEV – internal combustion engine vehicle

FIGURE 3. Preliminary EERE Estimates of the Life-Cycle Costs of Several Advanced Vehicle Pathways. Error bars illustrate the sensitivity of costs per mile to fuel prices (green) and vehicle technology success (red).

Market Transformation

To ensure that the benefits of its efforts are realized in the marketplace, the Program continued to facilitate the growth of early markets for fuel cells used in portable, stationary, and specialty-vehicle applications. Market transformation activities are helping to reduce the cost of fuel cells by enabling economies of scale through early market deployments and by overcoming a number of barriers, including the lack of operating performance data, the need for applicable codes and standards, and the need for user acceptance. FY 2011 activities primarily involved project startup and kickoff from FY 2010 appropriations. The Market Transformation sub-program is currently focused on building on past successes in material handling equipment (e.g., lift trucks) and emergency backup power applications, which received support from Recovery Act

funding. These Recovery Act projects are highly leveraged with an average of over half the funds or cost share provided by partner resources, and they are providing valuable data on the status of the technologies in real-world operation that will be used to validate the benefits and potential needs for further R&D. (For more information on Recovery Act projects, see “American Recovery and Reinvestment Act Projects” under the “Other Program Activities” section of this Introduction.) The Market Transformation sub-program is seeking to expand on the success of these activities by exploring other potential and emerging applications for market viability.

Specific accomplishments in FY 2011 include a joint effort by the Department of Defense’s (DOD’s) U.S. Army Corps of Engineers and the Program, which was conducted under the Memorandum of Understanding (MOU) signed between DOE and DOD in July 2010. The project consists of installation of emergency backup power fuel cells at eight DOD locations across the country. Additionally, demonstration and testing of fuel cell-powered mobile lighting prototypes were conducted at the National Aeronautic and Space Administration Kennedy Space Center and the San Francisco International Airport, among others. Activities conducted at entertainment industry events such as the 2011 Golden Globe Awards and 2011 Grammy Awards ceremonies had the added value of exposing fuel cell technology to the public.²³ Also in FY 2011, a total of 22 hydrogen-powered buses were deployed at federal facilities and national labs across the country to demonstrate hydrogen buses and infrastructure with widespread public visibility. The 12-passenger buses are used for special events, campus tours, new employee orientations, and as part of shuttle bus fleets. The buses were shown to thousands of attendees at special events throughout the year. During FY 2011, the technical viability of using landfill gas (LFG) as a cost-effective source of hydrogen production was demonstrated at BMW’s assembly plant in South Carolina. Once fully implemented, this project will represent a “first-of-its-kind” LFG-to-hydrogen production project in the nation, and serve as a model for future adoption of renewable biogas as a feedstock for hydrogen production.²⁴ Finally, in FY 2011, the substantial effects of market transformation became apparent in the material-handling equipment sector when successful DOE projects led industry to plan deployments of more than 3,000 fuel cell forklifts with no additional DOE funding.²⁵

OTHER PROGRAM ACTIVITIES

American Recovery and Reinvestment Act Projects

The American Recovery and Reinvestment Act (Recovery Act or ARRA) has been a critical component of the Program’s efforts to accelerate the commercialization and deployment of fuel cells in the market. With approximately \$41.9 million from the Recovery Act and \$54 million in cost-share funding from industry participants—for a total of nearly \$96 million—this funding is supporting the deployment of up to 1,000 fuel cell systems in emergency backup power, material handling, and combined heat and power applications. Twelve projects were competitively selected to develop and deploy a variety of fuel cell technologies including polymer electrolyte, solid oxide, and direct-methanol fuel cells in stationary, portable, and specialty vehicle applications. In FY 2011, ARRA investments led to 610 additional fuel cell deployments into the market. As of the end of September 2011, more than 460 fuel cell lift trucks and more than 370 fuel cell backup-power systems for cellular communications towers and stationary backup-power systems had been deployed, and over 80% of the ARRA project funds had been spent by the projects. A total of 46 direct jobs have been created or retained as a result of the Fuel Cell Technologies ARRA projects (if supply chain and other indirect jobs are included, the total jobs created or retained is estimated to be more than 180 from these ARRA projects alone). These projects are helping to build a competitive domestic supply base, reduce costs, and demonstrate the economic and performance benefits of fuel cells as a competitive option for stationary, portable, and specialty vehicle applications.

Tracking the Commercialization of Technologies

One indicator of the robustness and innovative vitality of an R&D program is the number of patents applied for and granted, and the number of technologies commercialized. The Program continued to assess the commercial benefits of Program funding by tracking the commercial products and technologies developed with the support of the EERE Fuel Cell Technologies Program. DOE-funded R&D has resulted in more

²³ See Report X.1, “Fuel Cell Mobile Lighting,” in the Market Transformation chapter of this volume.

²⁵ DOE Hydrogen and Fuel Cells Program Record #11017, http://hydrogen.energy.gov/program_records.html.

than 310 patents and more than 60 emerging technologies while 30 hydrogen and fuel cell technologies have entered the market.²⁶ DOE also tracks the impact of its funding in terms of industry revenues and investment—for example, \$70 million in funding for specific projects that were tracked was found to have led to more than \$200 million in industry revenues and investment.

INTERNATIONAL ACTIVITIES

International Partnership for Hydrogen and Fuel Cells in the Economy

The United States is a founding member of the International Partnership for Hydrogen and Fuel Cells in the Economy²⁷ (IPHE), which includes 17 member countries (Australia, Brazil, Canada, China, France, Germany, Iceland, India, Italy, Japan, New Zealand, Norway, the Republic of Korea, the Russian Federation, South Africa, the United Kingdom, and the United States) and the European Commission. The IPHE is a forum for governments to work together to advance worldwide progress in hydrogen and fuel cell technologies. IPHE also offers a mechanism for international R&D managers, researchers, and policymakers to share program strategies. In FY 2011, the 15th Steering Committee Meeting was held in Vancouver, Canada, on May 13 and 14. An IPHE Roundtable with Stakeholders is planned for November 17 in Berlin, along with the 16th Steering Committee Meeting also in Berlin on November 18th.

International Energy Agency

The United States is also involved in international collaboration on hydrogen and fuel cell R&D through the International Energy Agency (IEA) implementing agreements; the United States is a member of both the Advanced Fuel Cells Implementing Agreement²⁸ (AFCIA) and the Hydrogen Implementing Agreement²⁹ (HIA). These agreements provide a mechanism for member countries to share the results of research, development, and analysis activities. The AFCIA currently includes six annexes: Molten Carbonate Fuel Cells, Polymer Electrolyte Fuel Cells, Solid Oxide Fuel Cells, Fuel Cells for Stationary Applications, Fuel Cells for Transportation, and Fuel Cells for Portable Power. The participating countries are Australia, Austria, Belgium, Canada, Denmark,

²⁹ www.ieahia.org

Finland, France, Germany, Italy, Japan, South Korea, the Netherlands, Mexico, Sweden, Switzerland, Turkey, and the United States. The IEA HIA is focused on RD&D and analysis of hydrogen technologies. It includes 11 tasks: Hydrogen Safety, Biohydrogen, Fundamental and Applied Hydrogen Storage Materials Development, Small-Scale Reformers for On-site Hydrogen Supply, Wind Energy and Hydrogen Integration, High-Temperature Production of Hydrogen, Advanced Materials for Hydrogen from Water Photolysis, Near-Market Routes to Hydrogen by Co-Gasification with Biomass, Large Scale Hydrogen Delivery Infrastructure, Distributed and Community Hydrogen for Remote Communities, and Global Hydrogen Systems Analysis. The United States participates in all of these tasks. Members of the HIA are Australia, Canada, Denmark, the European Commission, Finland, France, Germany, Greece, Iceland, Italy, Japan, South Korea, Lithuania, the Netherlands, New Zealand, Norway, Spain, Sweden, Switzerland, Turkey, United Nations Industrial Development Organization-International Center for Hydrogen Energy Technologies, and the United States.

EXTERNAL COORDINATION, INPUT, AND ASSESSMENT

Hydrogen and Fuel Cell Technical Advisory Committee (HTAC)

As required by the Energy Policy Act of 2005, HTAC was created in 2006 to advise the Secretary of Energy on issues related to the development of hydrogen and fuel cell technologies and to provide recommendations regarding DOE's programs, plans, and activities, as well as on the safety, economic, and environmental issues related to hydrogen and fuel cells. HTAC members include representatives of domestic industry, academia, professional societies, government agencies, financial organizations, and environmental groups, as well as experts in the area of hydrogen safety.

HTAC met three times in FY 2011. In March 2011, HTAC released its third annual report, which summarizes hydrogen and fuel cell technology domestic and international progress in RD&D projects; commercialization activities; and policy initiatives. More information about HTAC, including its annual reports, is available at: http://www.hydrogen.energy.gov/advisory_htac.html

Federal Agency Coordination—the Interagency Task Force and the Interagency Working Group

The Hydrogen and Fuel Cell Interagency Task Force (ITF), mandated by the Energy Policy Act of 2005, includes senior representatives from federal agencies supporting hydrogen and fuel cell activities, with the DOE/EERE serving as chair. Recently efforts by the ITF focus on facilitating federal deployment of hydrogen and fuel cells in emerging technology applications such as stationary power and specialty vehicles. In June 2011, DOE hosted the first ITF meeting of this administration. During this meeting, Deputy Secretary of Energy Daniel Poneman announced a DOE and DOD collaboration with the Army Corps of Engineers to deploy emergency backup power units for critical loads at eight DOD locations across the nation. In addition, ITF members provided feedback on the recently drafted *Interagency Action Plan*.

The Hydrogen and Fuel Cell Interagency Working Group (IWG), co-chaired by DOE and the White House Office of Science and Technology Policy, continues to meet monthly to share expertise and information about ongoing programs and results, to coordinate the activities of federal entities involved in hydrogen and fuel cell RD&D, and to ensure efficient use of taxpayer resources.

DOD-DOE MOU Workshops

DOD and DOE entered into an MOU for the purpose of coordinating efforts to enhance national energy security and demonstrate federal government leadership in transitioning to a low-carbon economy. A key focus area of the MOU is DOD-DOE collaboration on a broad range of innovative, technology-driven solutions to reduce petroleum use, among other objectives.⁵⁰ As a large developer and end user of technology, DOD will aim to speed the movement of innovative energy technologies and technical expertise from DOE's research laboratories to military end users, using military installations as test beds and early markets. Activities undertaken through this collaboration can also help DOD installations meet the requirements of additional regulations that affect their strategies for energy use.

⁵⁰ *Memorandum of Understanding between U.S. Department of Energy and U.S. Department of Defense*, DOE and DOD, July 22, 2010, www.energy.gov/news/documents/Enhance-Energy-Security-MOU.pdf.

In support of this MOU, the Program held a series of workshops with DOD and other stakeholders focusing on hydrogen and fuel cell activities. The “Waste-to-Energy Using Fuel Cells” workshop was held on January 13, 2011, the “Shipboard Auxiliary Power Unit” workshop was held on March 29, 2011, and the “Aircraft Petroleum Use Reduction” workshop was held on September 30, 2010. Presentations and outcomes can be found in the Market Transformation section of the Program’s workshops Web page, which is located at http://www1.eere.energy.gov/hydrogenandfuelcells/wkshp_proceedings.html.

The National Academies

The National Research Council (NRC) of the National Academies provides ongoing technical and programmatic reviews and input to the Hydrogen and Fuel Cells Program. The NRC has conducted independent reviews of both the Program³¹ and the R&D activities of the U.S. DRIVE Partnership.³² On May 19, 2011, Secretary Chu announced U.S. DRIVE, a cooperative partnership with industry to accelerate the development of clean, advanced, energy-efficient technologies for cars and light trucks and the infrastructure needed to support their widespread use. Formerly known as the FreedomCAR and Fuel Partnership, U.S. DRIVE (Driving Research and Innovation for Vehicle efficiency and Energy sustainability) works together on an extensive portfolio of advanced automotive and energy infrastructure technologies, including batteries and electric-drive components, advanced combustion engines, lightweight materials, and hydrogen and fuel cell technologies.

FY 2011 Annual Merit Review and Peer Evaluation

The Program’s Annual Merit Review (AMR) took place May 9-13, 2011, providing an opportunity for the Program to obtain an expert peer review of the projects it supports and to report its accomplishments and progress. For the third time, this meeting was held in conjunction with the annual review of DOE’s Vehicle Technologies Program. During the AMR, reviewers evaluate the Program’s projects and make recommendations; DOE uses these evaluations, along with other review processes, to make project funding decisions for the upcoming fiscal year. The review also provides a forum for promoting collaborations, the exchange of ideas, and technology transfer. This year, more than 1,700 participants attended, and the Hydrogen and Fuel Cells Program had 207 oral presentations and 87 poster presentations. More than 200 of the Program’s projects were peer-reviewed, and there were 210 contributing reviewers. The report summarizing the results and comments from these reviews is available at http://www.hydrogen.energy.gov/annual_review11_report.html. In 2012, the AMR will be held May 14-18 in Arlington, Virginia.

IN CLOSING...

The Program will continue to pursue a broad portfolio of RD&D activities for fuel cell applications across multiple sectors. Efforts will span the full spectrum of technology readiness, including: early market applications that are already viable or are expected to become viable in the next few years, such as forklifts, backup power, and portable power applications; mid-term markets that are expected to emerge in the 2012-2015 timeframe, such as residential combined heat and power systems, auxiliary power units, fleet vehicles, and buses; and longer-term markets that are expected to emerge in the 2015-2020 timeframe, including light-duty passenger vehicles and other transportation applications. The Program will also continue to pursue activities to enable commercialization and stimulate the markets for hydrogen and fuel cells as they achieve technology readiness. Supporting these markets will not only help to achieve the economic, environmental, and energy security benefits that fuel cells provide in those specific applications, but it will complement the Program’s longer-term R&D efforts by helping to increase current sales and manufacturing volumes, providing essential cost reductions—through economies of scale—for many of the same technologies that will be used in longer-term applications. Supporting earlier markets can also reduce many non-technological barriers to the deployment of hydrogen and fuel cell technologies and lay the groundwork for the larger infrastructure and

supply base that will be needed for fuel cell vehicles. Communication and outreach remain critical to all these efforts, and the Program actively pursues opportunities to publicize its activities and progress, releasing more than 70 news items in FY 2011, including DOE press releases, progress alerts, success stories, and blogs.

Finally, a major undertaking in FY 2011 was the complete revision of the Program's strategic plan (the *Hydrogen and Fuel Cells Program Plan*),³³ which outlines the strategy, activities, and plans of the DOE Hydrogen and Fuel Cells Program, covering hydrogen and fuel cell activities within the EERE Fuel Cell Technologies Program and the DOE offices of Nuclear Energy, Fossil Energy, and Science. It describes the Program's activities, the specific obstacles addressed by each sub-program, the strategies employed, key milestones, and future plans for each sub-program and the Program as a whole. The last time the *Plan* had been updated was in 2006 (then it was known as the *Hydrogen Posture Plan*). The new version reflects extensive input from stakeholders, the Hydrogen and Fuel Cell Technical Advisory Committee, and public feedback on the draft version that was posted online for public comment.

We are pleased to present the U.S. Department of Energy's *2011 Hydrogen and Fuel Cells Program Annual Progress Report*. The report is divided into chapters and is organized by technology area (e.g., fuel cells, hydrogen storage, etc.). Each chapter opens with an overview written by a DOE technology development manager that summarizes the progress and accomplishments of the previous fiscal year. The projects outlined in this document represent the work of the many innovative scientists and engineers supported by DOE. They are the ones responsible for the progress and technical accomplishments reported in this year's *Annual Progress Report*. We would like to recognize them for their hard work, commitment, and continued progress.

II. HYDROGEN PRODUCTION

II.0 Hydrogen Production Sub-Program Overview

The Hydrogen Production sub-program supports research and development (R&D) of technologies that will enable the long-term viability of hydrogen as an energy carrier for a diverse range of end-use applications including stationary power (e.g., backup power and combined-heat-and-power systems), transportation (e.g., specialty vehicles, cars, trucks, and buses), and portable power. A variety of feedstocks and technologies are being pursued.

Three DOE offices are engaged in R&D relevant to hydrogen production:

- The Fuel Cell Technologies Program, within the Office of Energy Efficiency and Renewable Energy (EERE), is developing technologies for distributed and centralized renewable production of hydrogen. Distributed production options under development include reforming of bio-derived renewable liquids and electrolysis of water. Centralized renewable production options include water electrolysis integrated with renewable power generation (e.g., wind, solar, hydroelectric, and geothermal power), biomass gasification, solar-driven high-temperature thermochemical water splitting, direct photoelectrochemical water splitting, and biological processes.
- The Office of Fossil Energy (FE) is advancing the technologies needed to produce hydrogen from coal-derived synthesis gas, including co-production of hydrogen and electricity. Separate from the Hydrogen and Fuel Cells Program, FE is also developing technologies for carbon capture and sequestration, which will ultimately enable hydrogen production from coal to be a near-zero-emissions pathway.
- The Office of Science's Basic Energy Sciences (BES) program conducts research to expand the fundamental understanding of biological and biomimetic hydrogen production, photoelectrochemical water splitting, catalysis, and membranes for gas separation.
- The Office of Nuclear Energy (NE) is conducting efforts in development of high-temperature electrolysis, under the Next Generation Nuclear Plant (NGNP) project, which also includes evaluations of other end-user applications and energy transport systems. The Nuclear Hydrogen Initiative was discontinued as a separate program in Fiscal Year (FY) 2009 after the selection of steam electrolysis as the hydrogen production pathway most compatible with the NGNP.

Goal

The goal of the Hydrogen Production sub-program's portfolio is to develop low-cost, highly efficient hydrogen production technologies that utilize diverse domestic sources of energy, including renewable resources (EERE), coal with sequestration (FE), and nuclear power (NE).

Objectives¹

The objective of the EERE hydrogen production portfolio is to reduce the cost of hydrogen dispensed at the pump to a cost that is competitive with gasoline, on a cents-per-mile basis (based on current analysis, this translates to a hydrogen threshold cost of \$2-4 per gallon gasoline equivalent [gge]). Technologies are being researched to achieve this goal in timeframes appropriate to their current stages of development.

The objectives of FE's efforts in hydrogen production are documented in the *Hydrogen from Coal Program Research, Development and Demonstration Plan* (September 2009). They include proving the feasibility of a near-zero emissions, high-efficiency plant that will produce both hydrogen and electricity from coal and reduce the cost of hydrogen from coal by 25 percent compared with current technology, by 2016.

FY 2011 Technology Status

The current projected cost of hydrogen from several production pathways is shown in Figure 1. The current status of cost and performance for several other hydrogen production pathways, as determined by independent reviews, are shown in Table 1. These reviews, along with cost projections from the Hydrogen

¹Note: Targets and milestones are under revision; therefore, individual progress reports may reference prior targets.

Projected High-Volume Cost of Hydrogenⁱ – Status

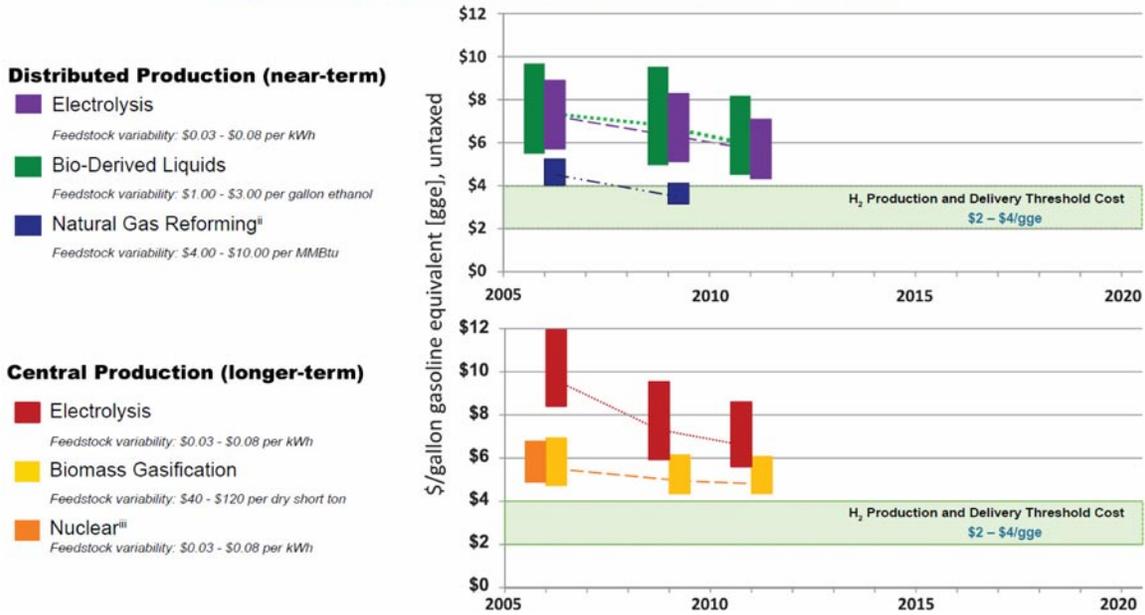

FIGURE 1. Hydrogen Production and Delivery Cost Status. Significant progress has already been made in several hydrogen production pathways. The Hydrogen Threshold Cost represents the cost at which hydrogen fuel cell electric vehicles are projected to become competitive on a cost-per-mile basis with competing vehicles (gasoline hybrid-electric vehicles) in 2020. Notes: (i) Costs shown include all delivery and dispensing costs, but do not include taxes. A cost of \$1.80 for forecourt compression, storage, and dispensing is included for distributed technologies, and \$2.60 is included as the total cost of delivery (including transportation, compression, storage, and dispensing) for centralized technologies. All delivery costs are based on the Hydrogen Pathways Technical Report (NREL, 2009). Projections of distributed costs assume station capacities of 1,500 kg/day, with 500 stations built per year. Projections of centralized production costs assume capacities of $\geq 50,000$ kg/day. Cost ranges for each pathway are shown in 2007 dollars, based on high-volume projections from H2A analyses, reflecting variability in major feedstock pricing and a bounded range for capital cost estimates. (ii) DOE funding of natural gas reforming projects was completed in 2009 due to achievement of the threshold cost. Incremental improvements will continue to be made by industry. (iii) High-temperature electrolysis activities are ongoing under the Next Generation Nuclear Plant Program.

Analysis (H2A) model, were also used in the development of the Hydrogen Production sub-program’s chapter of the *Multi-Year Research, Development and Demonstration Plan (MYRD&D Plan)*, where they were used as the basis for establishing the status of the different technologies and for determining appropriate pathway-independent targets. The 2006 report *Distributed Hydrogen Production from Natural Gas*² provided the basis for DOE to discontinue R&D of steam methane reforming for hydrogen production—verifying that the use of existing steam methane reforming technologies in distributed hydrogen production could meet the cost target at high-volume production. Targets for hydrogen production efforts in FE, along with information on the status of the technologies, are documented separately in the *Hydrogen from Coal Program Research Development and Demonstration Plan* (2009).

² Distributed Hydrogen Production from Natural Gas, National Renewable Energy Laboratory, October 2006, <http://www.hydrogen.energy.gov/pdfs/40382.pdf>.

TABLE 1. Recent Independent Reviews of Production Pathway Costs

Pathway	Report	Status ¹
Steam Methane Reforming²	<i>Distributed Hydrogen Production from Natural Gas</i> , NREL, October 2006	\$2.75–\$3.05/gge
Electrolysis³	<i>Current (2009) State-of-the-Art Hydrogen Production Cost Estimate Using Water Electrolysis</i> , NREL, September 2009	Distributed: \$4.90–\$5.70/gge ~75% membrane efficiency (proton exchange membrane [PEM]) Central (Wind): \$2.70–\$3.50/gge ~75% membrane efficiency (PEM)
Photoelectrochemical (PEC) Production⁴	<i>Technoeconomic Analysis of Photoelectrochemical (PEC) Hydrogen Production</i> , Directed Technologies Inc., December 2009	\$4–\$10/gge (projected cost assuming technology reaches technology readiness); promising PEC materials identified, but durability issues remain
Biological Production⁵	<i>Technoeconomic Boundary Analysis of Biological Pathways to Hydrogen Production</i> , Directed Technologies Inc., September 2009	\$3–\$12/gge (projected cost assuming technology readiness) 15% solar-to-chemical energy efficiency by microalgae
Biomass Gasification	<i>Hydrogen Production Cost Estimate Using Biomass Gasification</i> , Independent Panel Review [DRAFT], NREL, April 2011	Preliminary results: feedstock costs, capital costs, and financing structure are primary influences on overall cost.
Solar Thermochemical Production⁶	<i>Cost Analyses on Solar-Driven High Temperature Thermochemical Water-Splitting Cycles</i> , TIAX, February 2011	Hybrid Cycles: \$3.90–\$5.40 (in 2025) Hi-Temp Cycles: \$2.40–\$4.70 (in 2025)

¹ Based on H2A V.2.1 using 2005\$ inputs for costs, with the exception of the 2011 Solar Thermochemical Production study which used 2007\$ inputs.

⁴ *Technoeconomic Analysis of Photoelectrochemical (PEC) Hydrogen Production*, Directed Technologies Inc., December 2009, http://www1.eere.energy.gov/hydrogenandfuelcells/pdfs/pec_technoeconomic_analysis.pdf.

⁵ *Technoeconomic Boundary Analysis of Biological Pathways to Hydrogen Production*, Directed Technologies Inc., September 2009, <http://www1.eere.energy.gov/hydrogenandfuelcells/pdfs/46674.pdf>.

⁶ *Cost Analyses on Solar-Driven High Temperature Thermochemical Water-Splitting Cycles*, TIAX, February 2011, http://www1.eere.energy.gov/hydrogenandfuelcells/pdfs/solar_thermo_h2_cost.pdf.

This year an updated version of H2A (H2A version 3) was published with updated economic data and assumptions; this version also converts all costs to 2007 dollars. Updated economic and cost-sensitivity analyses are currently being performed using H2A version 3, incorporating the most up-to-date information on pathway technologies and technology-readiness projections. These analyses will serve as the basis for updating the status information in Table 1 and will be used to revise pathway-specific targets in an updated version of the *MYRD&D Plan*.

FY 2011 Accomplishments

Biomass Gasification

- The National Renewable Energy Laboratory (NREL) completed the initial draft of an independent panel review of costs for hydrogen production from biomass gasification and performed an analysis of near-term markets for hydrogen from biomass gasification.
- The United Technologies Research Center (UTRC) demonstrated a novel slurry-based fuel-flexible and carbon-neutral biomass reforming process that exceeded 2012 targets in both projected cost and plant efficiency (current status: \$1.54/gge and 51.1% efficiency, respectively).
- The Gas Technology Institute completed a membrane design for a one-step, shift-separation membrane reactor for close-coupling with a biomass gasifier. The module demonstrated a flux rate of 80+ standard cubic feet per hour (SCFH)/ft² and is capable of 125 SCFH/ft². Economic analysis indicates that the technology can meet the production threshold cost target of <\$2.00/gge.

Bio-Derived Liquid Pathways

- In the area of autothermal reforming of bio-derived liquids, NREL replaced their catalyst with a better-performing commercial catalyst and reduced the amount of hydrogen oxidized to H₂O during reforming, resulting in increased yield from 7.4 g hydrogen to 10.1 g hydrogen per 100 g bio-oil during short-term, bench-scale tests of catalytic steam reforming at ~650°C, and increased process efficiency from 47% to 62%.
- Pacific Northwest National Laboratory (PNNL) evaluated the feasibility of aqueous phase reforming (APR) of pyrolysis oil and demonstrated successful reforming of most oil components, but also identified key challenges in reforming the acetic acid component. H₂A analysis indicated APR of bio-oil is economically feasible only with complete reforming of all oil components.
- Argonne National Laboratory (ANL) demonstrated a more-than-threefold increase in hydrogen production rate by using a Rh-based catalyst coating on an BaFe_{0.9}Zr_{0.1}O_x (BFZ1) oxygen transport membrane (OTM) compared to that of a lanthanum strontium cobalt iron oxide (LSCF) OTM tube with a BaFe_{0.9}Zr_{0.1}O_x (BFZ1).

Separation Processes

- Pall Corporation demonstrated durable, high-performance palladium alloy membranes for hydrogen separation and purification, achieving 270 SCFH/ft² flux in pure H₂/N₂, 400 pounds per square inch operation, 88% hydrogen recovery, 99.99% hydrogen permeate quality, and a projected cost of <\$1,000/ft², meeting or exceeding the 2012 targets for dense metallic membranes.
- Media and Process Technologies developed hydrogen-selective membranes/modules based on thin-film palladium for use as reactors/separators for distributed hydrogen production, with field tests demonstrating >99% CO conversion, >99.9% hydrogen purity and >83% hydrogen recovery, meeting or exceeding the 2012 targets for dense metallic membranes.
- The University of Cincinnati developed methods and techniques to prepare zeolite membranes for water gas-shift reactions for hydrogen production. High hydrogen permeance (1.26 x 10⁻⁷ mol m⁻² s⁻¹ Pa⁻¹) and H₂/CO₂ separation factor improvements from 4.95 to 25.3 were observed for bilayer membranes modified to include a yttria-stabilized zirconia intermediate diffusion barrier layer.

Electrolysis Hydrogen Production

- Giner Electrochemical Systems (GES) demonstrated a proton exchange membrane (PEM) electrolyzer incorporating advanced low-cost membrane electrode assemblies using dimensionally stable membranes with chemically etched supports, which exhibited lifetimes over 1,000 hours operating at 80°C. GES additionally demonstrated significantly reduced hydrogen embrittlement in C/Ti cell separators, indicating expected lifetimes of more than 60,000 hours. Projected stack capital costs of <\$0.70/gge based on these improvements meets a critical Program milestone.
- Proton Onsite (formerly Proton Energy Systems) demonstrated new catalyst application techniques for lower-cost hydrogen production, with 55% reduction of catalyst loading on the anode and >90% reduction of catalyst loading on the cathode, with negligible effect on stack performance. Projected stack capital costs of <\$0.70/gge based on these improvements meets a critical Program milestone.
- NREL completed more than 2,000 hours of testing on a PEM electrolysis system. The system generated 13 kg of hydrogen per day, running continuously, with full stack-monitoring capabilities and with stacks operating on wind power for stack-decay analysis.

Photoelectrochemical (PEC) Hydrogen Production

- Stanford University demonstrated exceptional stability in their quantum-confined 1.8 eV MoS₂ nanoparticle photocatalysts for PEC hydrogen production, showing stable operations over 10,000 voltage cycles of accelerated lifetime testing. Stanford also developed a high-surface-area macroporous scaffold, which is transparent and conducting, as an efficient electrode substrate for the MoS₂ photocatalysts and other PEC materials.

- NREL validated new benchmark levels of solar-to-hydrogen (STH) conversion efficiency in the 16%–18% range in optimized photoelectrode systems using high-quality III-V semiconductor materials in multi-junction configurations.
- Lawrence Livermore National Laboratory (LLNL), Los Alamos National Laboratory (LANL), the University of Nevada, Las Vegas (UNLV), and NREL worked collaboratively to complete the initial phase of a “III-V Surface Validation Study” to optimize STH performance and enhance lifetime of III-V semiconductor PEC interfaces in aqueous solutions. Ab initio quantum molecular dynamic models of the interface were created by LLNL, and the initial phase of model validation was completed using materials synthesized by NREL/LANL and characterized by UNLV using state-of-the-art spectroscopic facilities.
- MV Systems with the University of Hawaii at Manoa demonstrated 4.3% STH efficiency and device lifetimes exceeding 250 hours in multi-junction devices based on thin-film copper-gallium-diselenide semiconductors, representing a new benchmark in this low-cost class of PEC photoelectrode devices, and representing progress toward the 2010 Program target of stabilized 10% STH.
- The Midwest Optoelectronic Company accelerated development of efficient low-cost substrate-type PEC systems based on multi-junction thin film Si photoelectrodes; they also supplied multi-junction thin-film silicon devices for integration with novel Suncatalytix thin-film catalysts into solar water-splitting demonstration systems. This project demonstrates effective coordination between EERE and Advanced Research Projects Agency-Energy activities.

Biological Hydrogen Production

- University of California, Berkeley successfully characterized the function of a gene that regulates antenna size in chlorophyll (*Tla2*), and cloned another for further analysis (*Tla3*). These findings will be applied to reducing chlorophyll antenna size to increase the utilization efficiency of incident solar light energy.
- NREL—through their collaboration with the University of Manitoba, Canada—used a custom-designed plasmid, along with improved transformation protocols, to obtain two mutant lines of *C. thermocellum*. These lines will serve as the foundation for future genetic engineering efforts with *C. thermocellum* for fermentative hydrogen production.
- The J. Craig Venter Institute, in collaboration with NREL, successfully expressed and purified a stable recombinant hydrogenase. This is a significant step in transferring a more oxygen-tolerant hydrogenase from photosynthetic bacteria into hydrogen producing cyanobacteria.
- NREL used computational methods to understand the geometries and energies of the gas diffusion barrier protecting the hydrogen cluster in two hydrogenases. This information guided mutagenesis techniques to randomize the amino acid residues around the diffusion barriers with the aim of reducing the oxygen sensitivity of hydrogenase.

Solar-Thermochemical Hydrogen Production

- The University of Colorado demonstrated atomic layer deposition thin-film ferrite-based materials with a peak production rate 100 times faster than that in the bulk material, with the thin-film materials remaining active for up to 30 water splitting cycles, with no signs of deactivation.
- Sandia National Laboratories developed a reactor system concept capable of annual average STH production efficiency in excess of 20% with a heat-to-hydrogen conversion efficiency of 40%, predicting through system models that annual average STH efficiency could reach 23%.
- ANL identified two membranes for the electrolysis step of the hybrid Cu-Cl cycle that are chemically and thermally stable at 80°C for over 36 hours, addressing the key barrier to this cycle.
- SAIC reduced the voltage of their electrolysis cell at 80°C to levels similar to those previously demonstrated at 130°C in order to optimize the electrolysis step in their hybrid sulfur-ammonia cycle; they also demonstrated the feasibility of molten salt storage for continuous operation.
- TIAX LLC completed a report analyzing the costs of solar-driven high temperature thermochemical water-splitting cycles and identifying the key cost drivers for the reaction cycles.

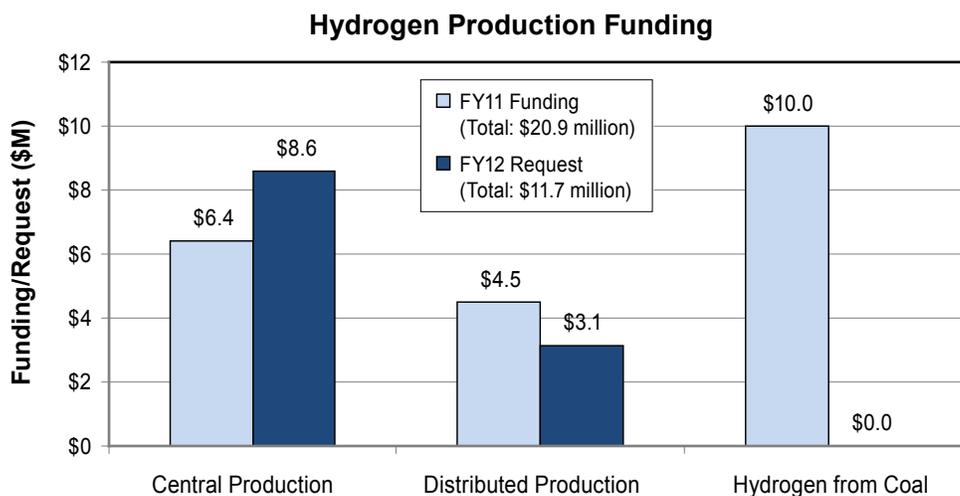

Fossil Energy—Hydrogen from Coal

In FY 2011, the first H₂/CO₂ separation membranes were exposed to coal derived syngas under gasification conditions.

- The National Energy Technology Laboratory's Office of Research and Development in collaboration with Worcester Polytechnic Institute (WPI) and UTRC have obtained over 1800 hours of membrane coupon exposures at the National Carbon Capture Center (NCCC.) Preliminary analysis indicates a stable body-centered-cubic Pd-alloy phase under gasification conditions.
- WPI has completed over 750 hours of membrane tests at the NCCC. Tests have demonstrated stable hydrogen flux levels and hydrogen purity in excess of 99.9%.
- UTRC has completed over 500 hours of membrane tests on the TRIG (transport gasifier) at the Energy & Environmental Research Center. Tests have demonstrated stable hydrogen flux levels and hydrogen purity in excess of 99.9%.
- The Colorado School of Mines has demonstrated reasonable flux and moderate selectivity using a non-precious metal membrane under laboratory conditions.

Budget

The FY 2011 DOE appropriation provided \$20.9 million for continued R&D efforts in hydrogen production. EERE received \$10.9 million, providing \$6.4 million for R&D of centralized renewable hydrogen production and \$4.5 million for R&D of distributed renewable hydrogen production; FE received \$10.0 million for R&D of hydrogen production from coal.

The President's FY 2012 budget request for EERE provides \$11.7 million for hydrogen production, with an emphasis on materials and processes for hydrogen from renewable resources.

FY 2012 Plans

- Continue emphasis on addressing major challenges in hydrogen production. Performance and durability enhancements in materials and systems will remain a priority, and cost reductions will be achieved through process optimization for all production pathways and technologies. Additional efforts will also address reducing the cost of materials and capital equipment.
- Continue EERE coordination with the Office of Science, which plans approximately \$50 million in basic research related to hydrogen and fuel cell technologies. Through Basic Science activities, a fundamental understanding of issues related to hydrogen production—particularly in the longer-term R&D areas of PEC

and biological processes—can help address the challenges of hydrogen production. Coordination of the PEC-related fundamental research activities in the Office of Science’s Solar Fuels Innovation Hub with the hydrogen production systems-oriented PEC R&D in EERE will be a high priority.

- Complete fabrication of a prototype alkaline electrolyzer unit capable of providing 30 kg of hydrogen per day at 6,500 psi; complete field testing of a prototype PEM electrolyzer capable of providing 12 kg of hydrogen per day at 300-400 psi; and initiate transition of electrolysis production pathways to the “technology validation” stage.
- Complete lifetime measurements of GaInP₂/GaAs devices for PEC production of hydrogen and determine the durability benchmarked against the target of a 100-hour operational lifetime at 10% efficiency.
- Demonstrate 100 hours of total catalyst operation in an integrated bench-scale system for production of pure hydrogen from steam reforming of pyrolysis oil at a rate of 100 liters per hour and with a yield of 10 g of hydrogen from 100 g of bio-oil.
- Operate a microalgae system continuously for two months, with the culture being induced to anaerobiosis with prolonged hydrogen production through use of a physiological switch activated by sulfur deprivation.
- Demonstrate—on-sun, using the NREL High Flux Solar Furnace—the cobalt ferrite/alumina “hercynite” thermochemical reaction cycle with 1,300°C reduction/1,000°C oxidation thermochemical redox cycling to split water, with hydrogen production of >100 micromoles per gram of active material.
- Continue coordination with deployment projects funded by American Recovery and Reinvestment Act to gain lessons learned related to hydrogen production technologies.

understanding the causes of catalyst deactivation. This improved understanding is aimed at reducing operating costs, which will lower cost of hydrogen production. The following are our technical targets:

- Cost: \$3.80/gge in 2012 and \$3.00 in 2017 (\$3.00/kg H₂)
- Catalyst life: 100 h without loss of selectivity

FY 2011 Accomplishments

- Completed a series of acidity characterization studies with Pt-Re catalysts. Verified that the amount of acid sites as measured by ammonia temperature programmed desorption (NH₃TPD) correlated with the amount of Re added to the catalyst, making clear the role of Re in the generation of acid sites on the catalyst surface.
- Showed the presence of Bronsted acid sites on Pt-Re/SiO₂ catalysts after exposure to water vapor by infrared studies and pyridine adsorption. This sheds more light on the character of the acidity with this particular metal combination.
- A cell was constructed to allow measurements of the Pt-Re/C catalyst under operating conditions in X-ray absorption experiments, to be carried out at the Brookhaven National Laboratory Synchrotron source. Preliminary experiments (not in situ) were carried out, demonstrating operability of the system and indicating areas for upgrading the hardware.
- APR studies of aqueous-soluble bio-oil components were carried out with the Pt-Re/C catalyst. We showed successful reforming of most oxygenated species, but also identified difficulty in reforming acetic acid, which is a component present in significant concentration.
- H₂A analysis indicates that the DOE H₂ production target of \$3.00/kg H₂ can be achieved, but only with virtually complete reforming of all the components present in the bio-oil to H₂ and CO₂.

Fiscal Year (FY) 2011 Objectives

- Evaluate and develop bio-derived liquids aqueous phase reforming (APR) technology for hydrogen production, with a specific focus on aqueous-soluble bio-oil, that can meet the DOE 2017 cost target of <\$3.00/gasoline gallon equivalent (gge).
- Identify and control the catalyst composition, reaction pathways, and catalyst preparation methods to enhance hydrogen selectivity, productivity, and catalyst life.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) Reformer Capital Cost
- (C) Operation & Maintenance
- (D) Feedstock Issues
- (E) Greenhouse Gas Emissions

Technical Targets

For production of hydrogen from bio-derived liquids, we have been focusing on identifying the specific role of the different catalyst components, delineating the mechanistic pathways leading to desired and undesired products, and

Introduction

The conversion of biomass-derived liquids to hydrogen is attractive because of the near carbon-neutral footprint it provides, and availability of such feedstocks in many regions of the U.S. We have previously targeted sugars and sugar alcohols, along with other polyols such as glycerol, as feedstocks. In FY 2011, we made a transition to bio-oil as a feedstock, specifically water-soluble bio-oil which contains a large fraction of oxygen-containing functionality, but is overall a more complex mixture that can be expected to raise some new challenges. Much of our catalyst development

work in the APR area has focused on understanding the correlation between catalyst function and performance. Our primary catalyst system has comprised Pt-Re/C, which is a highly active catalyst. We continued work with this same catalyst as we changed feedstock.

Approach

For the APR of bio-oil, we used our standard testing conditions of relatively low temperatures (225-265°C) and sufficient pressure (about 30 bar) to maintain the system in the liquid phase. We started by first identifying and assembling a slate of representative components known to be present in the aqueous-soluble bio-oil, and testing them individually for performance. We then combined these individual components into a single feed, and again compared performance, giving us insight into whether there might be interactions between components that could not be predicted from the individual component studies. This would provide us with guidance regarding what kind of modifications might be required for our catalyst.

For catalyst characterization, we focused primarily on identifying and quantifying the acidity that is developed with the Pt-Re/C catalyst, a result of Pt-Re interactions under both reduced and aqueous phase conditions. This provided insights into the nature of the acidity and how to develop approaches to mitigate the effects of this acidity, including the possibility of complete catalyst modification/substitution.

Results

Our original list of representative compounds was selected based on a literature report from the Huber group [1]. This list is provided in Figure 1. Subsequently, we found that furfural and guaiacol, two of the identified components, were insoluble in water at ambient temperature at the concentrations

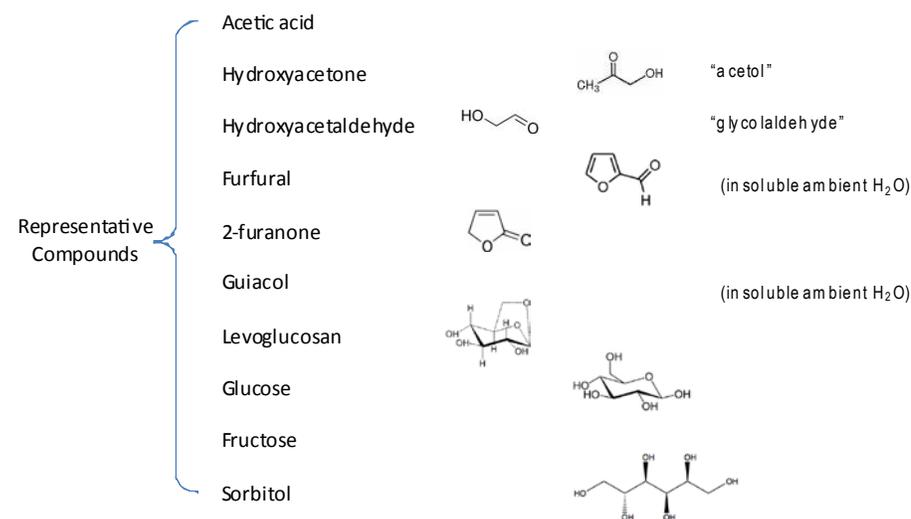

FIGURE 1. Initial List of Representative Compounds for Study of Bio-Oil APR

necessary for APR studies. We later made substitutions for these compounds: furfuryl alcohol for furfural, and p-methoxyphenol for guaiacos, but these two components were not present in our first pass screening studies.

Figure 2 provides a graphical comparison of the performance of the other components under APR testing conditions. Glycerol is added for comparison. Two feedstocks show poor H₂ selectivity (levoglucosan and fructose), and two showed virtually no selectivity (acetic acid and furanone). The poor selectivity of the first two we believe can be improved significantly through an adjustment in reaction conditions to lower flow rates and possibly carrying out the reaction at higher temperature. The performance of the latter two compounds is more problematic. Acetic acid is present in significant concentration, and we must find a way to increase the reactivity of the catalyst system or find an alternate catalyst system to handle acetic acid. Furanone is structurally more difficult in principle since both unsaturation and ring-opening must be contended with, and hydrogen is not initially present to remove the unsaturation. This may be alleviated by co-feeding hydrogen, and we expect furanone and similar molecules may only be tackled effectively by focusing on hydrogenolysis to form methane, rather than relying on catalytic conversions for hydrogen production. Furanone is present at significantly lower concentration than is acetic acid, thus it is only a very minor constituent. However, acetic acid is present at much higher concentrations, pointing to the primary importance in focusing on effective APR of acetic acid.

In Figure 3 we see the effect of acetic acid on the APR of glycerol. Both components were present at 10 wt% in the feed. It can be seen that the addition of acetic acid reduces the conversion of glycerol. Thus, it is not only that acetic acid is unreactive, but that it also inhibits the conversion of other feed molecules, presumably by strongly adsorbing on the catalyst surface and thereby making fewer active catalyst sites available. It can be seen that this is an effect specifically of the acetic acid and is not an effect of general acidity—addition of nitric acid has virtually no apparent effect on either activity or selectivity in the APR of glycerol.

In Figure 4 we show the results of characterization of the Pt-Re/C catalyst for surface acidity by ammonia TPD. This acidity has been responsible for generation of a significant byproduct alcohol and alkane production from glycerol to the detriment of H₂ production. It is clear that the acidity correlates with Re loading, although there is also some acidity present just with Pt/C. However, this acid strength

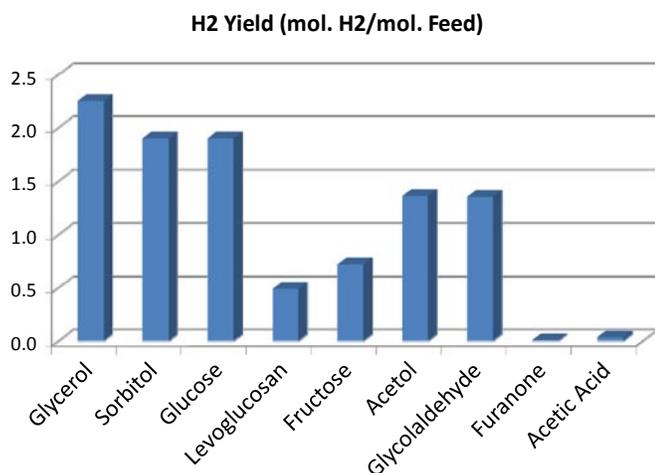

FIGURE 2. H₂ selectivity from the APR of representative bio-oil compounds with Pt-Re/C catalyst. Conditions: 225°C, 420 psig, 0.1 mL/min flow rate, all feeds present at the same molar concentration.

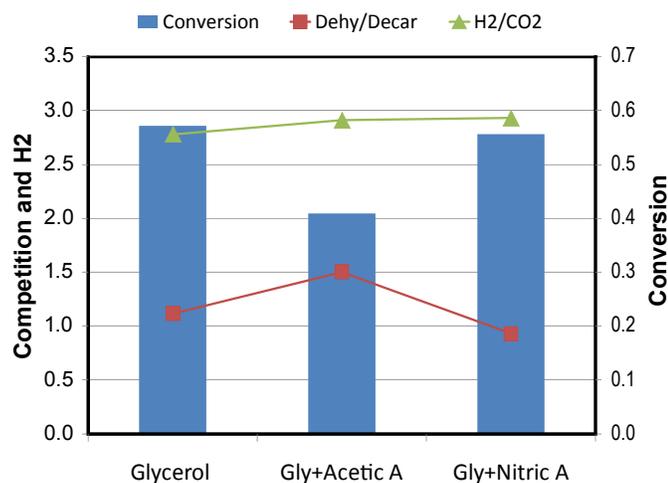

FIGURE 3. Effect of Acetic Acid and Dilute Nitric Acid on the APR of Glycerol with Pt-Re/C

(evidenced by a lower temperature peak) is significantly less than that obtained with the Pt-Re system. Finding methods to decrease or obviate this acidity is important to improve H₂ selectivity in APR. It is interesting to note that despite the surface acidity generated on the catalyst surface by Re, this is not sufficient to repel acetic acid, so that the acetic acid maintains an inhibitory effect on catalyst performance. This points to the possibility of the acid sites being distinct and different from the metal sites present on the catalyst.

Conclusions and Future Directions

We have shifted feedstocks this FY from glycerol and sorbitol to aqueous fraction bio-oil. This shift was necessitated in order to work with cheaper biomass-derived

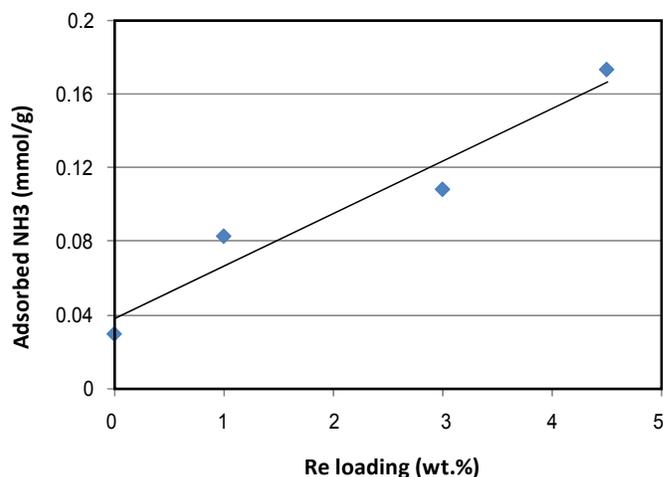

FIGURE 4. Correlation between Re Loading and Total Catalyst Surface Acidity as Measured by TPD of Ammonia

feedstocks that had a greater probability to meet the DOE target of \$3.00/gge in 2017. We developed a slate of representative bio-oil components and found that there are some significant challenges with this new feedstock, notably the low activity and apparent poisoning effect of acetic acid. In FY 2012, we will focus especially on catalyst development in order to improve the reactivity of bio-oil, especially dealing with the presence of acetic acid. One strategy that we intend to investigate is to increase the C-C bond breaking activity of our catalyst, for example by adding Ru to Pt/C, as well as evaluating alternate supports. One possibility is that in order to increase C-C cleavage activity we may also increase hydrogenolysis, leading to greater methane co-production. This might require co-feeding hydrogen. We believe that this may not be a negative outcome, since it will be possible to steam reform by-product methane (at higher temperature) using known technology. Such an approach would of course have to still meet the H₂ production cost targets, which will require H₂A analysis and verification.

Project Start Date: October 1, 2004

Projected End Date: Project continuation and direction determined annually by DOE

Fiscal Year (FY) 2011 Objectives

- By 2012, develop and demonstrate distributed reforming technology for producing hydrogen from bio-oil at \$3.80/kilogram (kg) purified hydrogen.
- By 2011, develop a prototype that incorporates the key operations: bio-oil injection, catalytic auto-thermal reforming, water-gas shift, and hydrogen isolation.
- By 2010, demonstrate the process of auto-thermal reforming of bio-oil including a long-term catalyst performance, yields of hydrogen, and mass balances.
- Develop the necessary understanding of process chemistry, bio-oil compositional effects, catalyst chemistry, and deactivation and regeneration strategy to form a process definition basis for automated distributed reforming to meet the DOE targets.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program's Multi-Year Research, Development and Demonstration Plan:

- (A) Fuel Processor Capital
- (C) Operation & Maintenance
- (D) Feedstock Issues

Technical Targets

gge – gasoline gallon equivalent

FY 2011 Accomplishments

- Demonstrated 60 hours of hydrogen production by auto-thermal reforming of bio-oil using a commercial (BASF) 0.5 Pt/Al₂O₃ catalyst in the bench-scale reactor system.
- Demonstrated catalyst regenerability in several reforming/regeneration cycles.
- Optimized process conditions and achieved the hydrogen production of 10.1 g/100 g bio-oil with 90% bio-oil to gas conversion.
- Based on those results, the total production cost in a 1,500 kg/day hydrogen plant, was estimated at \$2.75/gge and the total delivered cost at \$4.63/gge.
- Constructed an integrated bench-scale system for producing 100 L/h of pure hydrogen by reforming bio-oil.

Introduction

Renewable biomass is an attractive near-term alternative to fossil resources because it has near zero life-cycle carbon dioxide (CO₂) impact. Recent assessments have shown that more than one billion tons of biomass could be available in the United States each year at less than \$50/ton [1]. This biomass could be converted to 100 million tons of hydrogen, enough to supply the light-duty transportation needs of the United States. This work addresses the challenge of distributed hydrogen production with the target of hydrogen cost of \$3.80/kg by 2012 [2]. Pyrolysis is used to convert biomass to a liquid that can be transported more efficiently and has the potential for automated operation of the conversion system [3,4]. "Bio-oil" can then be converted to hydrogen and CO₂ in a distributed manner at fueling stations.

The objective of this project is to develop a system that will provide distributed production of hydrogen from bio-oil at filling stations. To accomplish this we are developing a simple fixed-bed reactor suitable for unsupervised automated operation.

Approach

Research is focused on developing a compact, low-capital-cost, low/no maintenance reforming system to enable achievement of the cost and energy efficiency targets for distributed reforming of renewable liquids. In this project, we are evaluating the following steps in the process:

- Bio-oil volatilization using ultrasonic atomization. We need to control physical and chemical properties of the liquid (e.g., viscosity), so blending with alcohol may be necessary.
- Heterogeneous auto-thermal reforming of bio-oil derived gas and vapor. Precious metal catalysts appear to be the most effective in the application to bio-oil and its partial oxidation products.

Early in the project, experiments were carried out using a micro-scale, continuous flow, tubular reactor coupled with a molecular beam mass spectrometer (MBMS) for analyzing

the product gas composition. In the last two years, we conducted a series of tests using a bench-scale reactor system that allowed for a longer-duration steady-state operation and provided more reliable data for mass balance calculations. In the bench-scale auto-thermal reforming tests carried out in 2011 we used two types of commercial (BASF) platinum catalyst: alumina-supported pellets and a monolith, both with 0.5% Pt. The experiments were carried out in the systems shown in Figure 1. Poplar pyrolysis bio-oil diluted with 10 wt% methanol was fed at 60 g/h using a membrane pump to the top of the 34 mm internal diameter, 45 cm long tubular quartz reactor. The bottom section of the reactor contained a fixed bed comprising 100 g of pelletized catalyst or 55 g of the monolith. In the freeboard, the liquid in the form of a very fine mist produced by a 60 kHz ultrasonic nozzle contacted air and steam; steam was produced by a home-made micro-generator. The excess steam and some liquid organics were collected in two condensers. The outlet gas flow rate was measured by a dry test meter. The concentrations of CO₂, CO, and CH₄ in the product gas were monitored by a non-dispersive infrared analyzer (NDIR Model 300 from California Analytical Instruments); the hydrogen concentration was tracked by a thermal conductivity detector (TCD) TCM4. In addition, the gas was analyzed every four minutes by an on-line Varian (Model 4900) micro

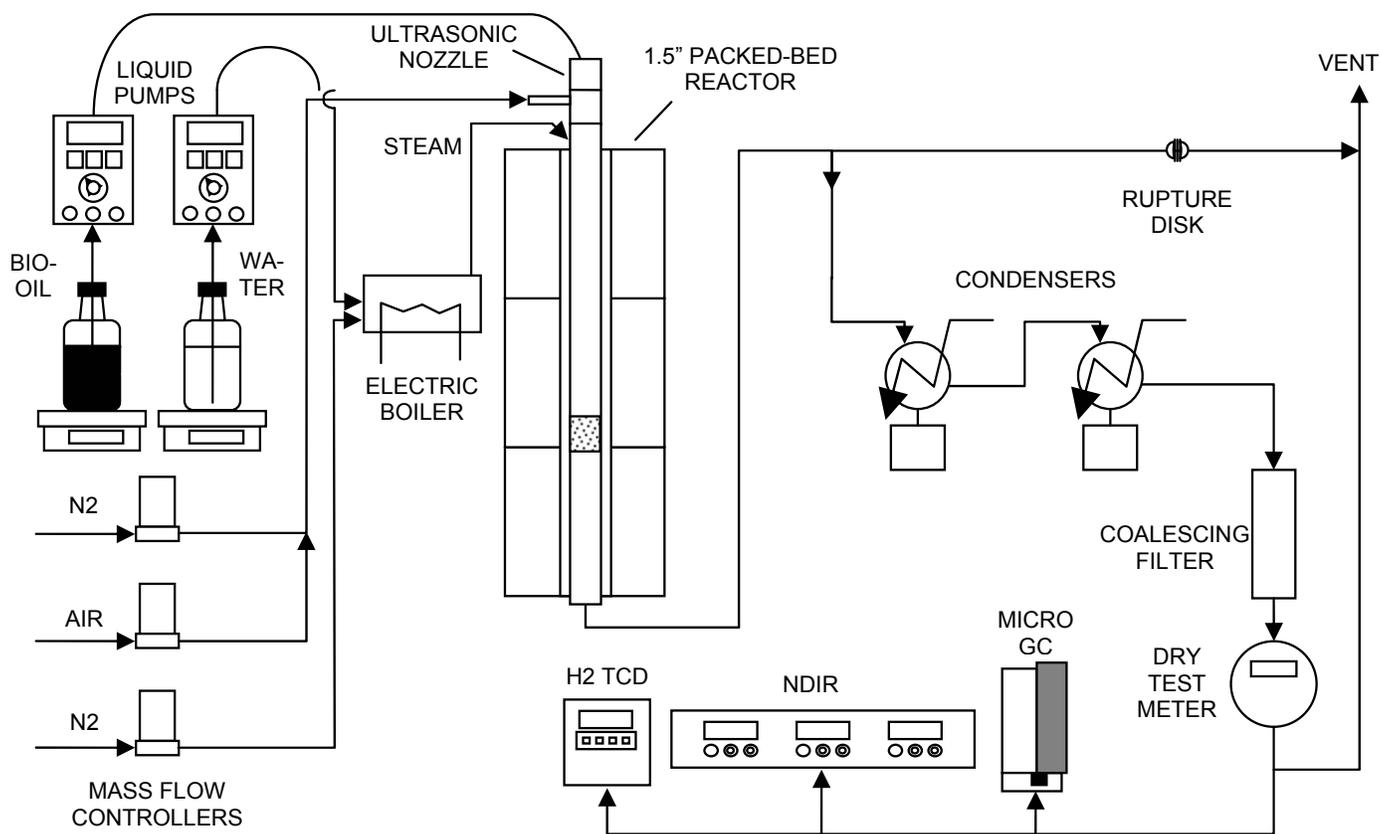

FIGURE 1. Schematic of the Bench-Scale Auto-Thermal Reforming System

gas chromatograph (GC), which provided concentrations of H₂, CO, CO₂, CH₄, C₂H₄, O₂, and N₂. The temperatures in the system, as well as the flows, were recorded and controlled by an OPTO 22 data acquisition and control system. Based on the flows and compositions of the process streams, mass balances as well as the yields of hydrogen generated from the feed were calculated.

Last year, we applied the conditions that assured the optimal system operation in the micro-scale tests: process temperature of 800-850°C, oxygen-to-carbon ratio (O/C)=1.5, molar steam-to-carbon ratio S/C=1.6, and methane-equivalent space velocity equal to 5,200 h⁻¹. This year, using the 0.5% Pt/Al₂O₃ catalyst from BASF, we varied O/C and steam to carbon ratio (S/C) to find the optimal conditions for maximizing the hydrogen yield while still operating in the auto-thermal range.

Results

A series of auto-thermal reforming tests included production and regeneration cycles. After each hydrogen production test, the catalyst was regenerated by air oxidation and reused in the subsequent tests carried out at the same process conditions. Figure 2 shows the product gas composition as a function of time for one of the experiments. The results of the tests are summarized in Table 2.

Despite a lower carbon-to-gas conversion, the increase in S/C and the decrease in O/C resulted in higher hydrogen yields because a larger part of bio-oil reacted by steam reforming that forms more hydrogen than partial oxidation. The increase in space velocity had a negative impact on both carbon-to-gas conversion and hydrogen yield. Based on those tests, the optimum process conditions that will assure an autothermal operation and high hydrogen yields are temperature 850°C, O/C of 0.9-1, S/C=3, and weight hourly space velocity (WHSV)=0.6. Assuming those reactor conditions and performances, the hydrogen production cost estimated using H2A for a 1,500 kg H₂/day plant is \$2.75/gge and the cost of delivered hydrogen is \$4.63/gge.

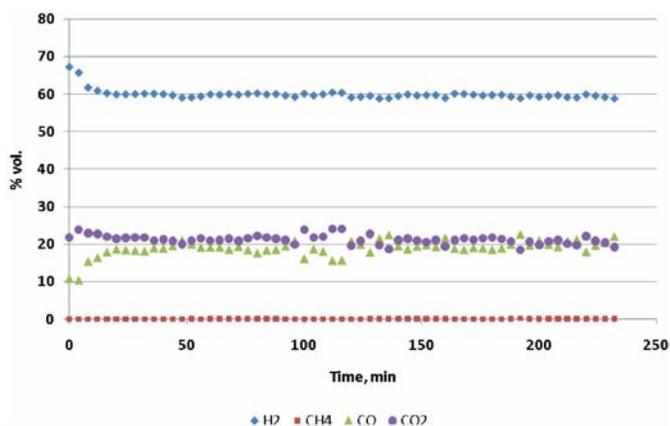

FIGURE 2. Product Gas Composition from Auto-Thermal Reforming of Poplar Bio-Oil Using BASF 0.5% Pt/Al₂O₃ Pelletized Catalyst

TABLE 2. Hydrogen Yields Produced at Different Process Conditions Using 0.5 Pt/Al₂O₃ at 850°C

WHSV (g/h bio-oil/g cat)	O/C (mol/mol)	S/C (mol/mol)	Hydrogen yield (g H/100 g bio-oil)	C-to-gas Conversion, %
0.6	0.5	3	10.3	72
	0.89	3	10.1	86
	1.6	1.6	7.0	90
1.2	0.85	2.8	5.9	76
2.4	1.5	3	5.6	80
	0.9	3	4.1	60
4.8	1.3	2.8	4.7	80

The monolith platinum catalyst of nominally the same composition as the pellets did not perform as well as the packed bed. During all the tests, the product gas composition as a function of time (Figure 3) changed more than in the packed bed experiments. Especially, the water-gas shift activity decreased with time that was observed as the increase in the concentration of CO and the decrease of CO₂. As before, the highest yields of hydrogen were obtained for lower values of WHSV, lower O/C, and higher S/C. However, these yields as well as carbon to gas conversion were lower than those achieved in the packed bed reactor at the same conditions. In the best case, for O/C=1, S/C=5, and G_{C1}HSV=2,000 h⁻¹ the hydrogen yield was 8.5 g/100 g bio-oil and the carbon to gas conversion was 80% compared to respectively 10.1 g/100 g bio-oil and 90% carbon conversion for the packed bed reactor. The reason might be shorter residence time of the bio-oil vapors and especially of the carbon solids in the channels of the monolith than in the packed bed.

The construction of an integrated system for producing 100 L/h of hydrogen by auto-thermal reforming of bio-oil was completed. The main components of the system include

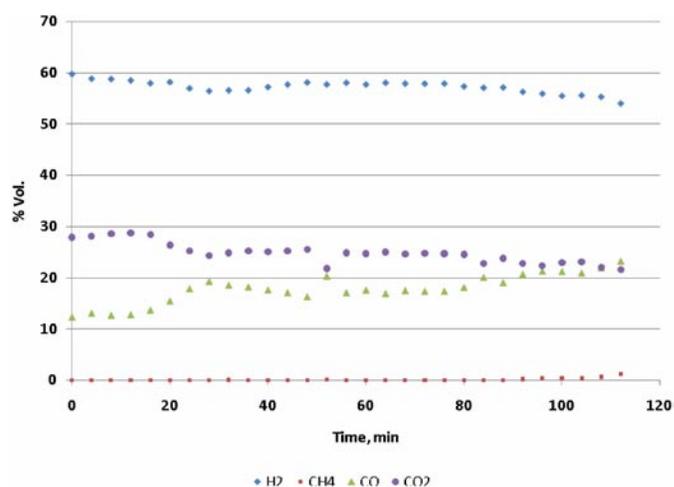

FIGURE 3. Product Gas Composition from Auto-Thermal Reforming of Poplar Bio-Oil Using BASF 0.5% Pt/Al₂O₃ Monolith Catalyst

a bio-oil evaporator, reforming reactor, water-gas shift convertor, and hydrogen separator.

Conclusions and Future Direction

- Bench-scale reactor tests of catalytic auto-thermal reforming of bio-oil performed using 90 wt% bio-oil/10 wt% methanol mixtures produced hydrogen yields of 10 g/100 g bio-oil with 90% of carbon-to-gas conversion.
- The optimal process conditions for the bench-scale system are: temperature 850°C, O/C of 0.9-1, S/C=3, and WHSV=0.6 (BASF 0.5%Pt/Al₂O₃ catalyst).
- The construction of a prototype system including bio-oil evaporator/filter, catalytic reformer, water-gas shift reactor, and electrochemical hydrogen separator was completed. The system will produce 100 L/h of pure hydrogen. The performance of that prototype will be tested in FY 2012 and will help to make a go/no go decision on further process development.

direction determined annually by DOE

Technical Targets

This project is developing compact dense ceramic membranes that transport pure oxygen to efficiently and cost-effectively produce hydrogen by reforming renewable liquid fuels such as EtOH and bio-oil. Cost-effective small-scale reformer technology will be developed to integrate process steps, thereby minimizing unit size, capital cost, energy use, and operating cost and helping to meet DOE technical targets:

Production Unit Energy Efficiency:	72% (lower heating value, LHV) by 2012 65-75% (LHV) by 2017
Production Unit Capital Cost (un-installed):	\$1.0M by 2012 \$600K by 2017
Total Hydrogen Cost:	\$3.80/gge (delivered) at the pump by 2012 <\$3.00/gge (delivered) at the pump by 2017

A preliminary techno-economic analysis in FY 2010 estimated a cost of ≈\$3.40/gge for producing hydrogen by reforming EtOH with an OTM.

Fiscal Year (FY) 2011 Objectives

Develop a compact ceramic membrane reactor that meets the DOE 2017 cost target of <\$3.00/gasoline gallon equivalent (gge) for producing hydrogen by reforming renewable liquids. Specific objectives for FY 2011 were:

- Use oxygen transport membrane (OTM) to reform ethanol (EtOH) at ≤700°C in presence of catalyst.
- Perform detailed Design for Manufacturing and Assembly and H2A analyses to assess benefits of approach.

Technical Barriers

This project addresses the following technical barriers from the Production section (3.1.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) Reformer Capital Costs
- (B) Reformer Manufacturing
- (C) Operation and Maintenance
- (N) Hydrogen Selectivity
- (P) Flux
- (R) Cost

FY 2011 Accomplishments

- Significantly increased EtOH conversion using BaFe_{0.9}Zr_{0.1}O_x (BFZ1), an OTM that gives significantly higher oxygen flux at low temperature (≈500°C), but analysis of the products indicated the need for a suitable catalyst to increase hydrogen production.
- Used Rh-based catalyst on a small (1.3 cm²) BFZ1 disk to nearly quadruple the hydrogen production rate compared to that of a much larger (15.3 cm²) lanthanum strontium cobalt iron oxide (LSCF) tube.
- Estimated a hydrogen production cost of \$3.40/kg H₂ for a station with a 1,500 kg H₂/day capacity, (analysis by DTI).

Introduction

Others have shown that supplying oxygen with an OTM reduced the costs of methane reforming by ≈30-40% and energy consumption by ≈30%. Supplying oxygen during EtOH reforming increases EtOH conversion and enhances catalyst performance by preventing coke formation [1]. An OTM can supply high-purity oxygen for EtOH reforming by separating it from air without using a separate gas separation unit. Because the OTM is a mixed conductor, the oxygen transport requires neither electrodes nor external power circuitry, i.e., the process is non-galvanic. The oxygen flux

through the membrane depends on the membrane's electron and oxygen-ion conductivities, its surface oxygen exchange kinetics, and the oxygen partial pressure (p_{O_2}) gradient across the membrane.

The goal of this subtask is to develop a dense OTM that provides oxygen for efficiently and economically producing hydrogen through the reforming of renewable liquid fuels such as EtOH and bio-oil. To assess the potential for reducing the cost and energy consumption associated with EtOH reforming, DTI performed a detailed system analysis to determine the cost and energy benefits of using an OTM to supply high-purity oxygen from air. While generating the necessary data for DTI's system analysis, we continued developing OTMs that transport oxygen at an industrially significant rate at low temperature ($\approx 500^\circ\text{C}$) and possess sufficient mechanical and chemical stability under the large stresses that develop from having air on one side of the OTM and carbonaceous fuels on the other side.

Approach

In order to be cost-effective during the reforming of renewable liquids, an OTM must efficiently transport oxygen. For efficient oxygen transport, an OTM must have an appropriate combination of electronic and ionic conductivity; therefore, we use conductivity measurements to identify promising membrane materials. If a material has sufficient conductivity ($>10^{-1} \text{ ohm}^{-1}\text{-cm}^{-1}$), we measure its hydrogen production rate, which is directly related to its oxygen transport rate. In order to increase the oxygen transport rate, we adjust the OTM's composition, decrease its thickness, coat it with porous layers to increase its active area, and modify its microstructure to overcome limitations from surface reaction kinetics. With promising OTMs, catalysts are used to promote reforming reactions. We measure the hydrogen production rate under various reaction conditions for periods up to $\approx 1,000$ h to evaluate the chemical stability of OTMs, because OTMs must be stable for extended periods to cost-effectively produce hydrogen. Because OTMs must be available in a shape with a large surface area, e.g. tubes, we fabricate small tubular OTMs and test their performance. In order to assess the expected cost- and energy-benefits of reforming renewable liquids with an OTM, we shared our oxygen flux data to an independent party, DTI, who conducted a detailed system analysis.

Results

BFZ1 powder was prepared by conventional solid-state synthesis using BaCO_3 , Fe_2O_3 , and ZrO_2 as starting materials. Stoichiometric amounts of starting materials were ball-milled for 1-3 days with zirconia media in isopropyl alcohol (IPA). After drying the mixture, it was heated in ambient air at $800\text{-}850^\circ\text{C}$ for 10-20 h and then ball-milled as before for one day. The dried powder was heated again in ambient air at $880\text{-}900^\circ\text{C}$ for 10-20 h, and then was ball-milled again.

Although the microstructure of BFZ1 thin films is acceptable, they have shown a tendency to crack during EtOH reforming conditions; therefore, an EtOH reforming experiment was done using a relatively thick (0.67 mm) BFZ1 disk. A disk (1 inch diameter) was uniaxially pressed from BFZ1 powder and was then sintered at $1,340^\circ\text{C}$ for 10 h in 100 ppm H_2 /balance N_2 . To deposit Rh-catalyst on one face of the disk, rhodium nitrate ($\text{Rh}(\text{NO}_3)_3 \cdot 2\text{H}_2\text{O}$, Alfa Aesar, 99.9%) was dissolved in deionized water, and then a binder and BFZ1 powder was added to the solution. Heating the solution with binder and powder at $<80^\circ\text{C}$ while stirring gave a viscous paste that was painted onto the surface of the BFZ1 disk. The painted disk was dried in air and installed for an EtOH reforming test at 600°C .

A glass ring was used to seal the Rh-coated BFZ1 disk to the test fixture by heating overnight at 650°C while flowing He on the Rh-catalyst side and air on the other side. After obtaining a seal at 650°C , the tube was cooled to 600°C for the EtOH reforming test. The EtOH partial pressure (p_{EtOH}) was fixed on the Rh-coated side of the disk by bubbling ultrahigh purity He or N_2 through absolute EtOH at 23°C ($p_{\text{EtOH}} \approx 0.067 \text{ atm}$), while air was flowed on the other side of the disk. During the measurements, both gases flowed at a rate of 200 ml/min. The concentrations of products from EtOH reforming were measured with an Agilent gas chromatograph.

Figure 1 shows cross-sectional and plan views of a BFZ1 disk coated with catalyst. An EtOH reforming test with the sample shown in Figure 1 was unsuccessful, because a gas-tight seal was not made. EtOH reforming results were obtained with a second sample. The sample shown in Figure 1 was heated overnight at 930°C , because a gold ring was used to make a gas seal rather than a glass ring. Other than being heated to higher temperature in order to make a seal, the unsuccessful sample (Figure 1) was identical to the sample used in the successful reforming test. The porous catalyst-containing layer on top of the BFZ1 disk had a thickness of $\approx 10 \mu\text{m}$. The BFZ1 disk itself had several isolated pores but the pores did not appear to be interconnected.

An EtOH reforming test was conducted at 600°C with a Rh catalyst-coated BFZ1 disk. Table 1 summarizes the results for the BFZ1 disk coated with catalyst along with data that was the reported previously [2] for an LSCF thin-film tube not coated with catalyst. Figure 2 compares the total production rates for the products of EtOH reforming with the BFZ1 disk and the LSCF thin-film tube. Figure 3 plots the relative hydrogen production rates, i.e., the ratios of the hydrogen production rate to the production rates for the other products of reforming.

The carbon balance and EtOH conversion of BFZ1 were 90.9% and 28.0%, respectively. The EtOH conversion for the BFZ1 disk was lower than that of the LSCF thin-film tube due to the disk's smaller active area (≈ 1.3 vs. 15.3 cm^2). Despite its lower EtOH conversion and its smaller active area, the total hydrogen production rate of BFZ1 was

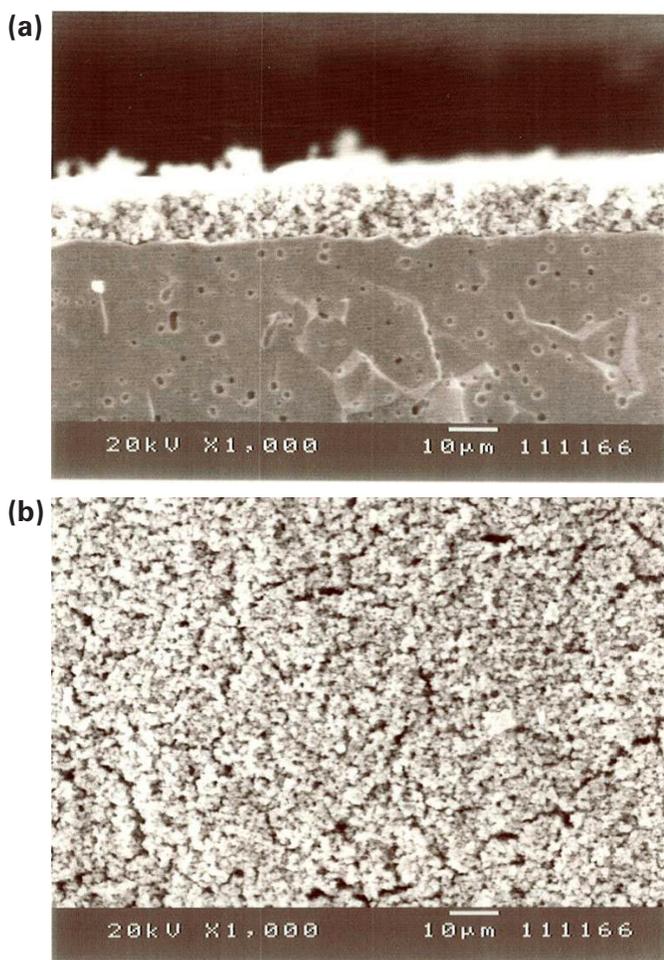

FIGURE 1. Secondary electron images of a) fracture-surface and b) plan view of Rh catalyst-coated BFZ1 disk.

TABLE 1. Results of EtOH Reforming Experiments at 600°C

OTM	EtOH Reforming Results				
	OTM Thickness	HPR* (cm ³ /min)	H ₂ /Total	C Balance (%)	EtOH conversion (%)
LSCF thin-film tube	~30 μm	0.27	0.031	75.8	61.8
BFZ1 disk + Rh	0.67 mm	0.96	0.360	90.9	28.0

* HPR = hydrogen production rate

0.96 cm³/min, which is 3.6 times higher than that of the LSCF tube. Only a small amount of coke was found after the experiment with the BFZ1 disk, an observation that is consistent with the improved carbon balance for the BFZ1 disk, compared to that for the LSCF thin-film tube.

Figure 2 shows that, in addition to its higher production rate, the BFZ1 disk gave lower production rates for the major products (CO₂ and H₂O) from EtOH reforming

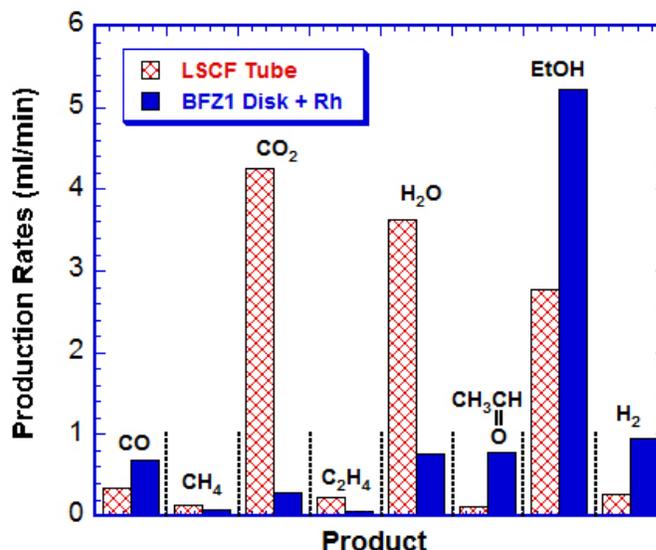

FIGURE 2. Total production rates for products of EtOH reforming at 600°C with Rh catalyst-coated BFZ1 disk (thickness=0.67 mm, active area=1.3 cm²) and LSCF tubular thin-film (thickness=0.03 mm, active area=15.3 cm²) not coated with catalyst.

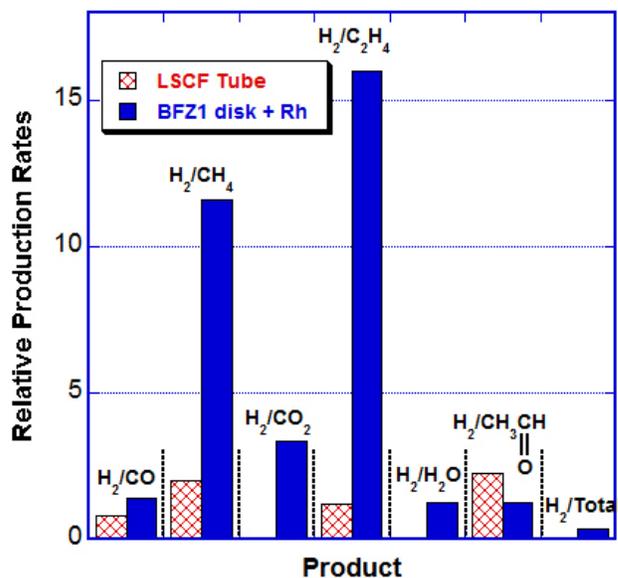

FIGURE 3. Relative production rates for products of EtOH reforming at 600°C with Rh catalyst-coated BFZ1 disk (thickness=0.67 mm, active area=1.3 cm²) and LSCF tubular thin-film (thickness=0.03 mm, active area=15.3 cm²) not coated with catalyst.

with the LSCF thin-film tube. The shift toward hydrogen production is seen more clearly in Figure 3, which plots the relative hydrogen production rates for the BFZ1 disk and LSCF tube. The catalyst-coated BFZ1 disk gave considerably higher relative hydrogen production rates for all products except acetaldehyde (CH₃CHO). The ratio of the hydrogen production rate to the sum of production rates

for all other products, given by H_2/Total in Figure 3 and Table 1, was more than an order of magnitude higher for the BFZ1 disk with catalyst than for the LSCF tube without catalyst (0.360 for Rh+BFZ1 vs. 0.031 for LSCF). The results indicate that the addition of the Rh catalyst played an important role for increasing the hydrogen selectivity and decreasing coke formation.

DTI completed a detailed techno-economic analysis of EtOH reforming with an OTM to evaluate its cost- and energy-benefits. For the analysis, Argonne provided oxygen flux and EtOH conversion data for promising OTMs. The analysis shows that the cost of the EtOH feedstock comprises a major fraction ($\approx 70\%$) the cost of producing hydrogen by EtOH reforming with an OTM. The cost of producing hydrogen by EtOH reforming with an OTM was estimated to be $\approx \$3.10$ - $\$3.60/\text{kg } H_2$, depending on the EtOH fuel efficiency.

Conclusions and Future Directions

Significant progress was made in demonstrating that a dense OTM can enhance the reforming of renewable liquids. In order to further evaluate the benefits of this approach, if funding becomes available to continue this work, we will:

- Continue testing the performance of OTMs during EtOH reforming at lower temperatures ($\approx 500^\circ\text{C}$).
- Study effect of EtOH concentration, gas flow rates, and OTM thickness.

- Evaluate effect of Rh-catalyst during EtOH reforming using tubular OTM with larger active area ($\approx 15 \text{ cm}^2$).
- Evaluate performance of other catalysts during EtOH reforming with OTM.
- Evaluate chemical stability of OTM during reforming of EtOH.
- Provide DTI with data on improved performance of OTMs to refine the cost and energy analysis and better evaluate the merits of using OTM to enhance H_2 production by EtOH reforming.

Project Start Date: May 2, 2005
Project End Date: June 3, 2011

Fiscal Year (FY) 2011 Objectives

- Develop an initial reactor and system design, with cost projections, for a biomass slurry hydrolysis and reforming process for hydrogen (H_2) production from woody biomass.
- Develop a cost-effective catalyst for liquid phase reforming of biomass hydrolysis-derived oxygenates.
- Perform a proof-of-concept demonstration of a micro-scale pilot system based on liquid-phase reforming of biomass.
- Demonstrate that the proposed H_2 production system will meet the 2012 efficiency and cost targets of 43% lower heating value (LHV) and \$1.60/kg H_2 for a 2,000 ton/day (dry wood) plant.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan [1]:

(T) Capital Costs and Efficiency of Biomass Gasification/Pyrolysis Technology

Technical Targets

This project consists of three key elements: plant and system design, catalyst research, and a proof-of-concept

demonstration. The information obtained from all three efforts will be used to demonstrate that the proposed H_2 production system will meet the DOE's 2012 Biomass Gasification/Pyrolysis Hydrogen Production energy efficiency and total H_2 cost targets of 43% (based on feedstock LHV) and \$1.60/kg H_2 , respectively. The current progress toward achieving the DOE's technical targets based on the preliminary plant and system design is shown in Table 1.

TABLE 1. Technical Progress for the Project as Measured Against the DOE's Technical Targets for Biomass Gasification/Pyrolysis Hydrogen Production

Characteristics	Units	2012 Target	Current Status
Hydrogen Cost (Plant Gate)	\$/gge	1.60	1.54 (1.31–2.11)
Total Capital Investment	\$M	150	170 (117–304)
Energy Efficiency	%	43	51.1

FY 2011 Accomplishments

- Demonstrated 100% conversion of wood using an inexpensive base metal catalyst.
- Examined the effect of base concentration on liquid phase reforming H_2 selectivity and yield.
- Developed a promoted Ni catalyst that maintains a high selectivity to H_2 with minimal base.
- Elucidated the liquid phase reforming reaction pathways for ethylene glycol over Ni and Pt via atomistic modeling.
- Demonstrated a continuous flow H_2 production system for 1 wt% wood at 50 g min^{-1} .

Introduction

This project is focused on developing a catalytic means of producing H_2 from raw, ground biomass, such as fast growing poplar trees, willow trees, or switch grass. The use of a renewable, biomass feedstock with minimal processing can enable a carbon neutral means of producing H_2 in that the carbon dioxide produced from the process can be used in the environment to produce additional biomass. For economically viable production of H_2 , the biomass is hydrolyzed and then reformed without any additional purification steps. Any unreacted biomass and other byproduct streams are burned to provide process energy. Thus, the development of a catalyst that can operate in the demanding corrosive environment and presence of potential poisons is vital to this approach.

Approach

The concept for this project is shown in Figure 1. The initial feed is assumed to be a >5 wt% slurry of ground poplar wood in dilute base. Potassium carbonate (K₂CO₃), derived from wood ash, is an effective base. Base hydrolysis of the wood is carried out at high but sub-critical pressures and temperatures in the presence of a solid catalyst. A Pd alloy membrane allows the continuous removal of pure H₂, while the retentate, including methane is used as fuel in the proposed plant.

Results

The economics of the alkali hydrolysis-based plant design using Ni-based catalysts were updated using the latest version of the H2A tool from the DOE with input from HYSYS plant models. For all cases, a Pd membrane-based separator was used to produce >99.9999% H₂ from the process for fuel cell use. For the baseline economics, the H₂ was then compressed from atmospheric pressure up to a pipeline delivery pressure of 300 psia. The use of a H₂ compression system was a more economical investment compared to using a larger Pd membrane separator operating with a 300 psia back pressure. However, the electrical demands of the plant increase significantly due to the compression system.

There were several assumptions common to the HYSYS/H2A model analyses. The wood feedstock price was set at \$41/ton to keep with the DOE’s cost target basis, although realistic feedstock prices will be higher. The cost of K₂CO₃ feed for the plant was set at \$900/ton and the design assumed that 95% of the K₂CO₃ will be recycled within the system. The reforming catalyst was assumed to be equivalent to Raney Ni at a cost of \$20/lb with catalyst replacement

occurring every three years. The reformer liquid residence time was fixed at 16 minutes with a catalyst to wood mass ratio set at a very conservative 20.

In general, the hypothetical 2,000 dry ton per day biomass plant can be run in three different modes. Table 2 shows the summary of the technoeconomic modeling results compared to the DOE targets. The first of these modes would use an inexpensive fuel source, such as natural gas, to provide the heat required to operate the endothermic hydrolysis, reforming, and H₂ separation processes. The second mode of operation assumes that the plant is operated to achieve “carbon neutrality” in terms of CO₂ emissions, not counting the secondary emissions that come from electricity provided from the grid for H₂ compression. Instead of using inexpensive fossil fuels to provide the heat required for the plant, the retentate stream from the membrane separator, which contains H₂, is burned to produce heat. This carbon neutrality comes at a cost both in terms of the H₂ cost, but the efficiency as well, as H₂ that could be delivered from the plant is diverted to heat production instead. The final mode of operation assumes that the plant is operated in a “carbon neutral; electric grid independent” mode. To achieve electric grid independence, the electrical demand from the H₂ compression system was reduced to the point that electricity generated from expanders in the plant could provide all the power needed. As a result, the delivery pressure of the H₂ was also reduced to 44.09 psia. The cost of H₂ in this scenario does not change relative to the “carbon neutral” mode, but the capital costs are lowered and the plant efficiency is reduced.

First principles atomistic modeling was previously used to gain an insight into the factors that control the activity and selectivity toward H₂ production by ethylene glycol reforming on Ni catalysts. Ethylene glycol was chosen as a model compound due to its oxygen bonding to adjacent carbons

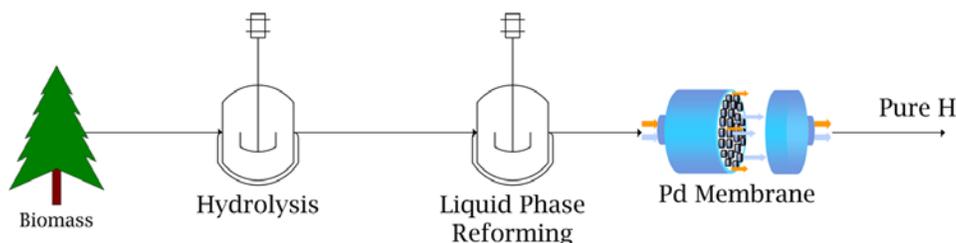

FIGURE 1. The UTRC Approach to Biomass Slurry Reforming

TABLE 2. Technoeconomic Modeling Results for Different Modes of Operation for a 2,000 Dry Tons of Wood per day Plant Compared to the DOE’s Technical Targets for Biomass Gasification/Pyrolysis Hydrogen Production

Characteristics	Units	2012 Target	Natural gas fuel mode	Carbon neutral mode	Carbon neutral, electric grid independent mode
Hydrogen Cost (Plant Gate)	\$/gge	1.60	1.27 (1.05–1.84)	1.54 (1.31–2.11)	1.54 (1.31–2.11)
Total Capital Investment	\$M	150	188 (116–370)	170 (117–304)	164 (117–283)
Energy Efficiency	%	43	56.3	51.1	46.1

which represents some fragments of biomass. The schematic diagram of reforming pathways for ethylene glycol on Ni is depicted in Figure 2. For ethylene glycol on a Ni surface, the first step after adsorption is hydroxyl bond breaking to form an ethylenedioxy intermediate. At the surface coverage considered, the activation of C-O bond in ethylenedioxy and rearrangement to form the acetaldehyde intermediate and adsorbed oxygen are thermodynamically favorable. Subsequent dehydrogenation and C-C bond scission of acetaldehyde yields the CO and CH₃ as final decomposition intermediates. CO is shifted in water to CO₂ and H₂ while the methyl is hydrogenated into methane. In a basic environment, CO can also be converted to a formate ion in solution through hydrophilic attack, consistent with the experimental observation of formic acid in the spent liquor.

To further investigate the impact of base to wood ratio on H₂ yield and selectivity, batch, single-step hydrolysis and reforming experiments were performed at EERC. The experiments were performed using a standard, unmodified

Raney nickel catalyst and potassium hydroxide base in EERC's 7.6-L autoclave system with a constant wood concentration of 8 wt%. The H₂ yield and H₂ selectivity results for the experiments are summarized in Figures 3 and 4, respectively. Consistent with previous predictions from atomistic and thermodynamic modeling for ethylene glycol, as well as batch wood reforming experiments performed at UTRC, increasing the base to wood ratio increased the selectivity of the process toward hydrogen production versus methane. However, the higher base levels decreased the H₂ yield, most likely favoring organic acid formation over gas production.

Earlier testing work used Pt-based catalysts before switching to less expensive Ni-based catalysts, and there is current interest for liquid phase reactions using precious metals. Thus, first principles atomistic modeling was used to understand the differences in reaction mechanisms. A schematic diagram of the reforming pathways for ethylene glycol on Pt is depicted in Figure 5. For ethylene glycol on the Pt surface, the first steps after adsorption are

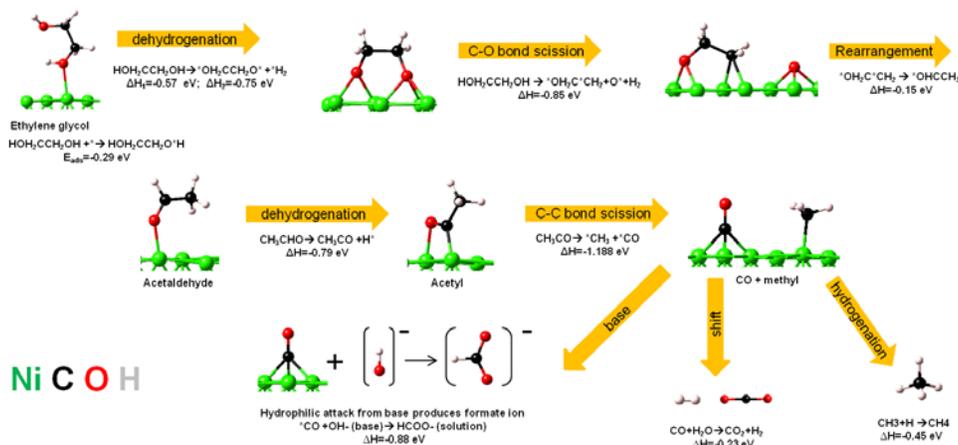

FIGURE 2. Atomistic modeling analysis of the reforming of ethylene glycol over Ni showing the intermediate reaction steps and the reaction enthalpies of their formation.

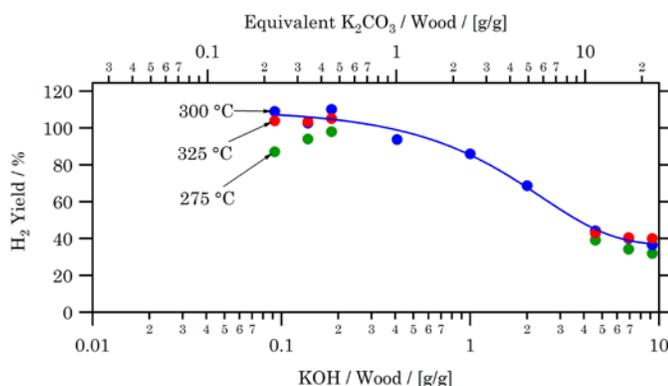

FIGURE 3. Impact of KOH to wood ratio on the H₂ yield with Raney Ni of 8 wt% hybrid poplar in a batch reactor. Also shown on the chart is the equivalent K₂CO₃ to wood ratio.

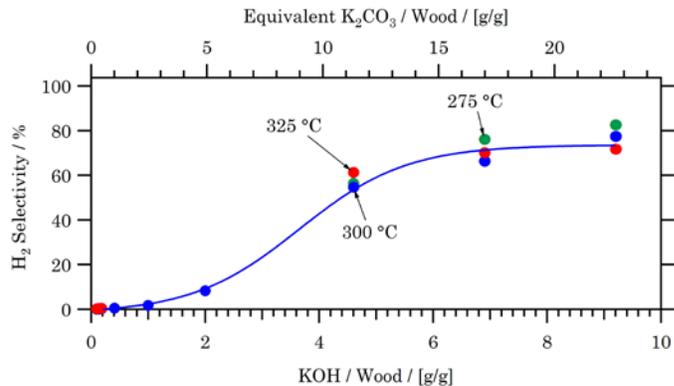

FIGURE 4. Impact of KOH to wood ratio on the H₂ selectivity with Raney Ni of 8 wt% hybrid poplar in a batch reactor. Also shown on the chart is the equivalent K₂CO₃ to wood ratio.

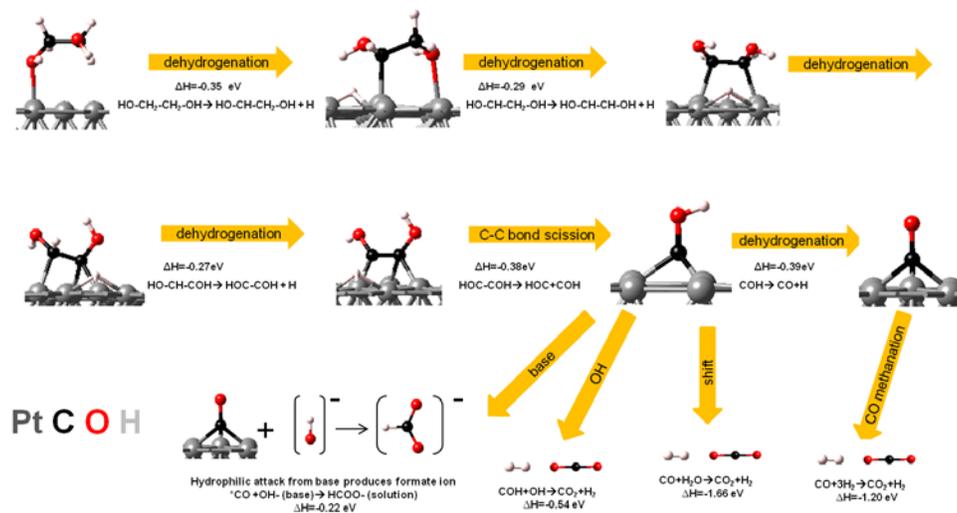

FIGURE 5. Atomistic modeling analysis of the reforming of ethylene glycol over Pt showing the intermediate reaction steps and the reaction enthalpies of their formation.

dehydrogenations. Unlike Ni catalysts, Pt appears to prefer C-C breaking rather than C-O breaking as the first step. As a result, the dehydrogenated species does not go through an ethylenedioxy intermediate as is the case with Ni, but rather undergoes a direct C-C bond scission which results in two COH species. The resulting COH groups can undergo a direct reaction with OH⁻ from the base to form CO₂ and H₂. Alternatively, the COH group can dehydrogenate further to a CO surface species which can react with hydrogen to form methane or be shifted in water to CO₂ and H₂ as happens with Ni. Also similar to the Ni case, the CO can be converted to a formate ion in solution through hydrophilic attack in a basic environment.

These modeling results offer an explanation as to why Pt-based catalysts favor reforming to H₂ while Ni prefers to form methane. Ni-based catalysts prefer to break C-O bonds, which result in both the formation of a methyl group and a CO. Pt-based catalysts prefer to break C-C bonds, resulting in only CO species. The increased preference toward CO species most likely leads to an increase in hydrogen production over methane.

Based on the successful work with base metal catalysts, the final step of the project was the construction and testing of a demonstration unit for H₂ production. This continuous flow demonstration unit consisted of wood slurry and potassium carbonate feed pump systems, two reactors for hydrolysis and reforming, and a gas-liquid separation system. The technical challenges associated with unreacted wood fines and Raney Ni catalyst retention limited the demonstration unit to using a fixed bed Raney Ni catalyst form. The lower activity of the larger particle Raney Ni in turn limited the residence time and thus the wood mass flow feed rate to 50 g min⁻¹ for a 1 wt% wood slurry. The project demonstrated continuous flow H₂ yields with unmodified, fixed bed Raney Ni, from 63% to 100% with corresponding

H₂ selectivities of 6% to 21%, for periods of several hours. The fixed bed form of the Raney Ni exhibited signs of deactivation which requires further study.

Conclusions and Future Directions

The project showed that it is possible to economically produce H₂ from woody biomass in a carbon neutral manner. However, further development work is required before this process can be commercialized. Some of the key technical areas for future projects are listed in the following.

- Further investigate catalyst kinetics for better reactor sizing.
- Demonstrate >90% base recycle in an integrated system.
- Investigate catalyst durability and higher activity base metal catalysts.
- Wood slurry pump development.
- Integration of a burner unit with the reformer.
- Demonstration of the system on a larger scale.
- Demonstration of the system with power generation (e.g., fuel cell, turbine, or internal combustion engine).

Technical Targets

This project is directed at developing a membrane reactor that can be closely-coupled with a gasification reactor while having a sufficiently high hydrogen flux to achieve a hydrogen production cost of \$2-4/gge (without delivery) per the DOE 2012 technical target.

FY 2011 Accomplishments

- Development of metallic, glass-ceramic membranes is in progress.
- Preliminary process development and economic analysis with initial candidate membrane proves economic feasibility of the process.
- Membrane module design with initial candidate membrane is finished.
- Fabrication of membrane module is in progress.

Fiscal Year (FY) 2011 Objectives

GTI together with its partners, NETL, Schott North America and ATI Wah Chang are working to determine the technical and economic feasibility of using the membrane gasifier to produce hydrogen from biomass. Specifically, the team plans to:

- Reduce the cost of hydrogen from biomass to \$2-4/gasoline gallon equivalent (gge) H₂¹ (excluding delivery).
- Develop an efficient membrane reactor that combines biomass gasification, reforming, shift reaction and H₂ separation in one step.
- Develop hydrogen-selective membrane materials compatible with the biomass gasification conditions.
- Demonstrate the feasibility of the concept in a bench-scale biomass gasifier.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section of the Hydrogen, Fuel Cells and Infrastructure Technologies Program Multi-Year Research, Development and Demonstration Plan:

¹ From presentation on 2011 Annual Merit Review by DOE.

Introduction

GTI has developed a novel concept of membrane reactor for clean, efficient, and low cost production of hydrogen from biomass-derived syngas. Our approach is presented in Figure 1 and shows conventional hydrogen production from biomass gasification and a hydrogen-selective membrane closely coupled with a reforming or gasification reactor for direct extraction of hydrogen from the syngas.

The specific objective of the project is to develop high temperature metallic or glass membranes that can be used closely-coupled with a biomass gasifier. The technical feasibility of using the membrane reactor to produce hydrogen from a biomass gasifier will be evaluated. GTI with its project team (Schott Glass, NETL, and Wah Chang) has been evaluating potential membranes (metal, ceramic and glass) suitable for high temperature, high pressure, and the harsh environment of a biomass gasifier. The project team has been screening and testing each type of material, investigating its thermal and chemical stability, and conducting durability tests.

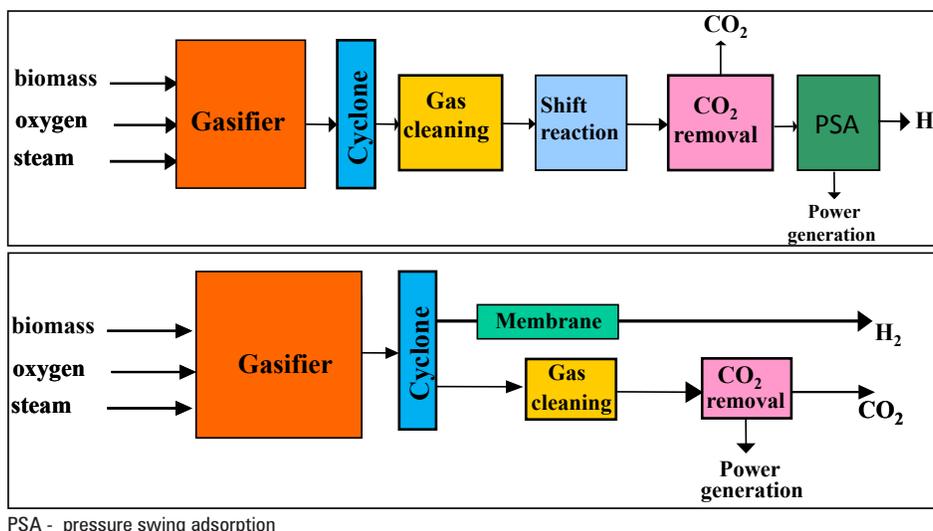

FIGURE 1. Conventional Hydrogen Production from Biomass Gasification and Biomass Gasifier with Close-Coupled Membrane

Approach

To conduct commercially successful research, GTI has developed a plan where efforts are concentrated in four major areas: membrane material development, membrane module development, membrane process development and membrane gasifier scale up. The initial focus of the project has been concentrated on membrane material development. Metallic and glass-based membranes have been identified as hydrogen selective membranes under the conditions of the biomass gasification, temperatures above 700°C and pressures up to 30 atmospheres. Membranes are synthesized by arc-rolling for metallic type membranes and incorporating Pd into a glass matrix for glass membranes. Testing for hydrogen permeability properties has been completed and the effects of hydrogen sulfide and carbon monoxide were investigated for perspective membranes. The initial candidate membrane chosen in 2008 was selected for preliminary reactor design and cost estimates. The overall economics of hydrogen production from this new process will be assessed and compared with traditional hydrogen production technologies from biomass. The final deliverable of the project will be a gasification membrane reactor system that is expected to meet or exceed the DOE's cost target for hydrogen production from biomass. This will be demonstrated by a bench-scale gasification membrane reactor that can process approximately 2~10 kg/hr of woody biomass for hydrogen production.

Results

GTI and partners from NETL and Schott continued researching new candidates for hydrogen-selective membranes.

NETL is pursuing a new approach for hydrogen permselective Pd alloys for high temperature use.

Superpermeable alloys have desirable characteristics for hydrogen membrane applications including high permeability, high temperature strength and cost, but are very susceptible to poisoning of surface catalytic sites and surface corrosion. A good method to counter these effects is by coating the alloy with a second alloy such as one containing Pd to provide catalytic activity and corrosion protection. Unfortunately, such coatings are likely to be unstable at the temperatures of interest. Therefore, alternative methods of protecting these materials are needed. One possibility being investigated is an inorganic, nonmetallic coating that can protect these alloys at the conditions of interest. Potential inorganic coating systems are being investigated in the literature and synthesis of new tertiary alloy formulations based on Pd metal is in progress.

Two new Pd-based ternary alloys are being fabricated. The alloying components were selected to attempt to improve high temperature strength and alter surface chemistry to improve impurity resistance. A new niobium/tantalum alloy has been identified that may offer high temperature stability under the conditions of interest. These alloys offer good resistance to the corrosive conditions of the post-gasifier environment, however, their hydrogen permeability is not known. More information on the characteristics of these alloys is currently being sought. If they continue to look promising, samples will be acquired or synthesized for testing. Also, 55 wt% Ni-Pt and PdPtAl synthesized earlier in the presence of H₂S is being tested. Due to membrane testing relocations, very restricted membrane testing facilities have been available for several months.

Schott continued development of glass ceramic membranes based on results of membranes synthesized by them and tested by GTI. A new melting protocol was completed to produce larger quantities of material with

greater homogeneous properties for permeability testing. Total conductivity was measured. Electrical conductivity results indicated Schott has fabricated highly-conducting samples; however, this is likely a necessary condition, though not sufficient, to ensure H permeation. Only direct permeation measurements can address this point.

Glass membranes were obtained from Schott and tested for hydrogen permeation. Unfortunately, these new samples, processed using similar means as in 2008, did not yield measurable H permeation at 800°C during testing at GTI. Schott plans to focus on other Pd-containing glass-ceramics, including Pd-Cu and Pd-Ag alloys, and subsequent submittal of these materials for testing by GTI.

GTI continued to test membranes fabricated by GTI and other team members as they become available. The initial candidate membrane Pd-Cu was tested for long-term stability at 800°C in syngas (20% hydrogen, 20% carbon monoxide, 10% carbon dioxide, 10% water and 0.03 % of hydrogen sulfide with balance of helium) atmosphere. The membrane has 83% of initial hydrogen permeation flux after 22 hours. The test was stopped due to a sealing failure. New sealing techniques that can withstand a sour atmosphere were researched.

$Pd_{90}Ta_{10}$ and $Pd_{60}Cu_{20}Ni_{20}$ foils were tested for hydrogen permeation. The results show lower hydrogen permeability as compared with initial candidate membrane ($Pd_{80}Cu_{20}$). Also, $Pd_{80}Cu_{20}$ with thickness 5 microns was purchased. Based on reverse dependence of hydrogen permeation with thickness, we expect to increase hydrogen flux four times. GTI continues to search for a new more promising alloy.

The design of a membrane module that is compatible with the biomass gasifier was completed. The module must be reliable, durable and cost-effective. The membrane module is of planar design for the initial candidate membrane ($Pd_{80}Cu_{20}$). Calculations were made to ensure no diffusion limitation for hydrogen permeation process and uniform gas distribution. Sealing was developed to withstand high temperatures and high pressures of operation. A support was designed to ensure high mechanical stability. Wah Chang assisted in review of membrane module design and their suggestions were incorporated to the membrane module design. Figure 2 shows membrane module inside the pressure vessel.

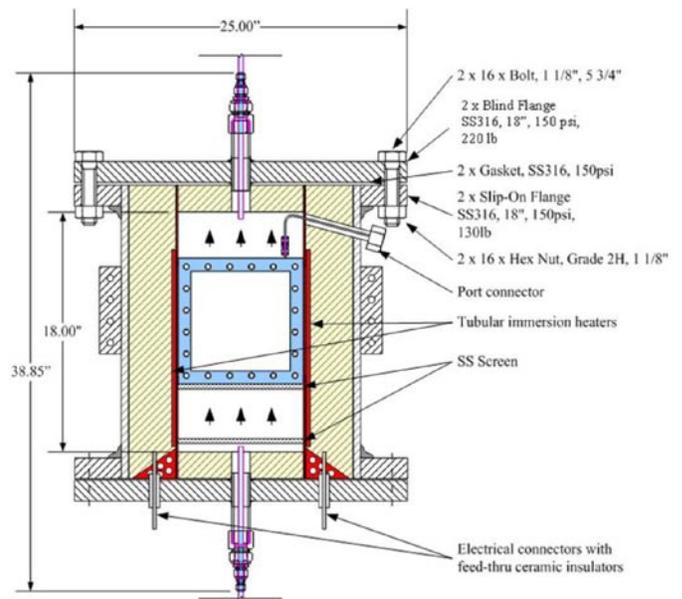

FIGURE 2. Membrane Module Unit in Pressure Vessel

A preliminary techno-economic analysis was performed to determine the potential economic viability of hydrogen production from biomass gasification using an initial candidate membrane- $Pd_{80}Cu_{20}$ foil. Estimating the costs of the process compared to the conventional technology can determine the economic feasibility of a project. Also the analysis is useful in directing research toward areas in which improvements will result in the greatest cost reductions. As the economics of a process are evaluated throughout the life of the project, advancement toward the final goal of commercialization can be measured.

Figure 3 shows the modeling software sequence for process development and costing. RENU GAS[®] modeling software output such as syngas composition, temperature, pressure, etc was used as input data for the HYSYS[®] software. The HYSYS model of the process was used to determine the membrane area needed at the specified process conditions for a given level of hydrogen recovery. The Aspen model of the process was then used to determine the stream flow rates and/or process heat duties for all the process steps so that equipment sizes could be estimated.

Contract Number: DE-PS36-05GO15043

Subcontractors:

- University of Cincinnati, Cincinnati, OH
- Arizona State University, Tempe, AZ
- Ohio State University, Columbus, OH

Start Date: July 1, 2005

Projected End Date: October 30, 2011

Fiscal (FY) 2011 Objectives

- To synthesize chemically and thermally stable silicalite membranes with hydrogen permeance $>5 \times 10^{-7} \text{ mol/m}^2 \cdot \text{s} \cdot \text{Pa}$ and H_2/CO_2 selectivity >50 .
- To fabricate tubular silicalite membranes and membrane reactor module suitable for membrane reactor applications.
- To identify experimental conditions for the water-gas shift (WGS) reaction in the zeolite membrane reactor that will produce a hydrogen stream with at least 94% purity and a CO_2 stream with 97% purity.

Technical Barriers

This project addresses the following technical barriers from the Production section (3.1) Hydrogen Production of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) Reformer Capital Costs
- (C) Operation and Maintenance (O&M)
- (K) Durability
- (N) Hydrogen Selectivity
- (P) Flux

Technical Targets

This project is focused on fundamental studies of zeolite membrane reactor for WGS reaction for hydrogen production. Insights gained from these studies will be applied towards the development of low-cost, high-efficiency technology for distributed and central hydrogen production that meets the following DOE 2010 hydrogen storage targets:

- Cost: \$0.4/kg
- Flux rate: 200 scfh/ft²
- Hydrogen recovery: $>80\%$
- Hydrogen quality: 99.5%
- Operating capability: 400 psi
- Durability: 26,280 hr

FY 2011 Accomplishments

- Modified silicalite/Zeolite Socony Mobil (ZSM)-5 bilayer membrane synthesized on the yttria-stabilized zirconia (YSZ)-coated alumina porous supports for H_2/CO_2 separation factor improvement.
- MFI (zeolite structure code) membranes have negligible water vapor permeance with $\text{H}_2/\text{H}_2\text{O}$ selectivity of about 100, and the presence of water vapor has minimum effect on H_2 permeance and H_2/CO_2 selectivity.
- High H_2/CO_2 separation factor (25) and considerable H_2 permeance ($1.26 \times 10^{-7} \text{ mol m}^{-2} \text{ s}^{-1} \text{ Pa}^{-1}$) were obtained on the modified silicalite/ZSM-5 bilayer membrane.
- Developed alumina tubular porous supports coated with YSZ barrier layer for stability improvement of tubular MFI zeolite membranes.
- Conducted WGS reactions in the modified disk MFI zeolite membrane reactor at pressures up to 6 atm to enhance the CO-conversion and hydrogen recovery.
- Developed and characterized the most effective catalysts for high-temperature (HT) WGS in the presence of 400 ppm H_2S .

Introduction

Gasification of biomass or heavy feedstock to produce hydrogen fuel gas using current technology includes partial oxidation to produce syngas, the WGS reaction to convert carbon monoxide with water to hydrogen, separation of hydrogen from the product stream, and removal of water vapor and other impurities (such as H_2S)

from the CO₂ containing stream. Commercially, WGS is normally conducted in two or more reactor stages with inter-cooling to maximize conversion for a given catalyst volume. Complete conversion of WGS is possible in a single membrane reactor at high temperatures (~400°C). The membrane removes product hydrogen from the reactor, facilitating higher conversion at a given temperature.

This project is focused on experimental and theoretical studies of the synthesis of a new hydrogen permselective and thermally/chemically stable zeolite membrane and its use in the membrane reactor for the WGS reaction to produce hydrogen and CO₂ rich streams. The membrane reactor system is designed for operation with feeds containing sulfur or other biomass residual contaminants. The zeolite membrane consists of a continuous thin (1-3 μm), aluminum-free silicalite film without intercrystalline micropores on a support with macroporous zirconia and mesoporous silicalite intermediate layers. These composite silicalite membranes in disk and tubular geometries were prepared by a unique technique that combines several synthesis methods including a template-free secondary growth step. Research efforts were also directed towards development of the cost-effective microwave method to synthesize the MFI (a zeolite structure code) zeolite (silicalite and high Si/Al ratio ZSM-5) membranes in disk and tubular geometries.

A new catalyst was developed for the WGS reaction under membrane reactor conditions. The final research task is to perform experimental and modeling studies on the performance of the WGS reaction in the membrane reactors with the silicalite membranes and the catalyst developed in this project. The results obtained in this project will enable development of a large-scale one step membrane reactor process for the WGS reaction for cost-effective production of hydrogen to below \$0.40/kg.

Approach

The approach used in this project is to study fundamental issues related to synthesis of high quality, stable zeolite membranes and a membrane reactor for WGS reaction and hydrogen separation. The details of project are to: (1) synthesize disk-shaped and tubular supports with desired intermediate layers and silicalite membranes with a template-free hydrothermal synthesis method; (2) optimize the hydrothermal synthesis condition and perform thorough permeation and separation characterization of silicalite and ZSM-5 membranes; (3) perform chemical vapor deposition for improvement of H₂ permselectivity; (4) develop a microwave synthesis approach to more efficiently and cost-effectively synthesize high quality silicalite membranes; (5) obtain a new WGS catalyst with activity and selectivity comparable to the best available commercial catalyst with improved chemical stability for SO₂ and H₂S containing WGS reaction stream; and (6) develop methods to fabricate a tubular membrane support with desired intermediate layers

and a membrane module and sealing system for a tubular membrane reactor that can be operated in WGS conditions.

Results

In order to obtain modified MFI zeolite membrane with high H₂/CO₂ separation factor, considerable H₂ permeance and high chemical and thermal stability, a silicalite/ZSM-5 bilayer membrane consisting of a ZSM-5 top thin layer and a silicalite bottom thick layer was synthesized on an alumina support coated with a YSZ intermediate barrier layer. The YSZ barrier layer was used to prevent the diffusion of Al³⁺ from the alumina porous support into zeolite membrane to improve the stability of the zeolite membrane. The synthesized silicalite/ZSM-5 membrane was modified through catalytic cracking deposition of methyl-diethoxy silane (MDES) carried by equimolar H₂/CO₂ mixture gas at 450°C to improve the H₂/CO₂ separation factor of the membrane.

Figure 1 shows the variations of H₂, CO₂ permeance and H₂/CO₂ separation factor during the on-stream catalytic cracking deposition (CCD) modification of the silicalite/ZSM-5 bilayer membrane at 450°C under H₂/CO₂ reducing environment. The H₂/CO₂ separation factor of the membrane was improved from 4.95 to 25.3 after CCD modification for one hour and got stabilized, indicating that the CCD modification process was fast which is consistent with the previous observation on modification of MFI zeolite disk membranes. The H₂ permeance decreased from 1.85 × 10⁻⁷ mol·m⁻²·s⁻¹·Pa to 1.26 × 10⁻⁷ mol·m⁻²·s⁻¹·Pa with only a reduction rate of 31.9%. The significant improvement of H₂/CO₂ factor with only modest reduction in H₂ permeance is ascribed to the unique structure of the silicalite/ZSM-5 bilayer membrane. Because CCD of MDES precursor only occurred in the ZSM-5 top thin layer instead of the entire

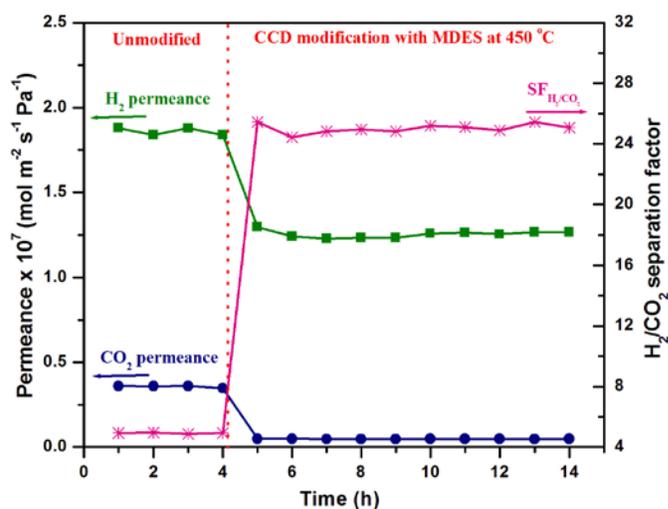

FIGURE 1. On-stream CCD modification of the stability improved silicalite/ZSM-5 bilayer membrane on YSZ coated alumina porous support.

diffusion channel along the membrane thickness direction, the resistance for the gas diffusion through the modified silicalite/ZSM-5 bilayer membrane is much smaller when compared to the membrane with the entire diffusion channel modified with MDES precursor. As a result, the H_2/CO_2 separation factor of the modified bilayer membrane was improved significantly with only modest reduction in H_2 permeance. The silicalite/ZSM-5 bilayer membrane is being shifted to the tubular porous supports with a YSZ intermediate barrier layer for stability improvement.

Understanding the effects of water vapor on gas permeation and separation properties of MFI zeolite membranes was important to the use of the zeolite membranes in WGS. The effects of water vapor on H_2 and CO_2 permeation and separation properties of ZSM-5 (Si/Al~80) zeolite and aluminum-free silicalite membranes were studied by comparing permeation properties of H_2 and CO_2 with the feed of equimolar H_2/CO_2 binary and $H_2/CO_2/H_2O$ ternary mixtures in 300°C-550°C. For both membranes, water vapor permeance was very low, with H_2/H_2O selectivity about 100. The presence of water vapor lowers H_2 and CO_2 permeance to the same extent, resulting in negligible effect on the H_2/CO_2 separation factor. The suppression effect of water vapor on H_2 and CO_2 permeation is larger for the less hydrophobic ZSM-5 zeolite membrane than for the hydrophobic silicalite membrane, and, for both membranes, is stronger at lower temperatures and higher water vapor partial pressures.

The modified silicalite/ZSM-5 bilayer membrane with improved H_2/CO_2 separation property was packed with a catalyst under WGS reaction conditions to examine the long-term stability of the membrane. Figure 2 presents the variations of CO-conversion and H_2 recovery of the modified disk membrane reactor during the long-term stability testing under WGS reaction conditions. The

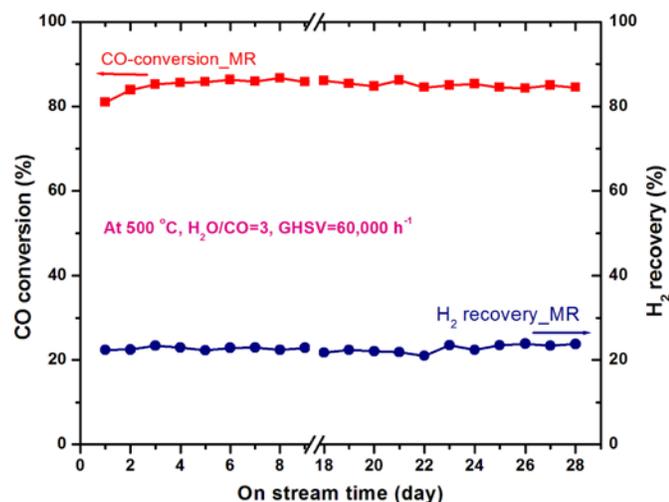

FIGURE 2. Results of stability tests (CO-conversion and H_2 recovery) of the modified silicalite/ZSM-5 bilayer/YSZ membrane disk under water gas shift reaction conditions, (at 500°C, $H_2O/CO=3$, $GHSV=60,000 h^{-1}$).

stability testing was conducted at 500°C, gas hourly space velocity ($GHSV$)=60,000, and $H_2O/CO=3$. As can be seen from this figure, the CO-conversion increased from 81% to 85% for the first a few days because the catalyst was not fully activated initially. After that, the CO-conversion kept constant at a value of 85% over the entire long-term stability testing period, indicating that the activity of the catalyst was very stable at high temperature under WGS reaction conditions. The H_2 recovery increased from 22.6% to 23.5% with an increase rate of only 3.9% over the stability testing for 28 days. These results also reveal that the modified silicalite/ZSM-5 bilayer membrane reactor with an YSZ intermediate barrier layer was very stable under WGS reaction conditions.

To make good quality $\alpha-Al_2O_3$ tubular supports with YSZ barrier layer for stability improvement of tubular MFI zeolite membranes, the deposition of YSZ support layers was investigated with commercial tubular $\alpha-Al_2O_3$ carriers from Pall Corporation. The carrier tubes have inner and outer diameters of 7 and 10 mm, respectively, and a specified nominal pore size of 800 nm. A 10 wt% YSZ dispersion was first prepared by dispersing 8 mol% yttria YSZ (TZ-8Y, Tosoh Co.) in an aqueous suspension adjusted to pH 2 with HNO_3 . The dispersion was then ultrasonically mixed with a Branson Digital sonifier (Branson Ultrasonics Corp.) for approximately 20 min and screened with 20 μm nylon mesh to remove any agglomerates and external contaminants. A polyvinyl alcohol (PVA) solution was prepared by mixing 3 wt% PVA (Celvol® 125, Celanese Chemicals) with pH 2 HNO_3 . The YSZ dispersion was then mixed with the PVA solution in a 3:2 volume ratio and flow coated onto the tubular carriers with an actuator speed of 10 mm/s and residence time of 30 s. The coating procedure was repeated a second time after waiting 30 s. The coated tubes were allowed to dry overnight at room temperature and calcined at 1,000°C for 3 hr with heating and cooling rates of 1.67°C/min.

Scanning electron microscopy (SEM) cross-sections of the YSZ-coated Pall carriers are shown in Figure 3. Figure 3 (a) illustrates the multilayer structure of the modified Pall carriers. A single continuous YSZ coating is observed on top of the two layer $\alpha-Al_2O_3$ substrate (with an 18 μm thick top layer). From the high magnification SEM cross-section in Figure 3(b), the thickness of the YSZ coating is estimated to be approximately 3 μm . After performing a surface analysis of the coated Pall carrier (Figure 3(c)), the YSZ coating was found to have a much smoother surface than the uncoated carrier (Figure 3(d)). The YSZ-coated tubular alumina porous supports have good quality for MFI zeolite membrane synthesis.

During the reporting period, the work on catalysts was focused on screening the best catalysts for HTWGS reactions in the presence of 400 ppm H_2S . Several different kinds of ferrite-based HTWGS catalysts were synthesized according to the procedure reported in the previous annual report. The best HTWGS catalysts that can be used at

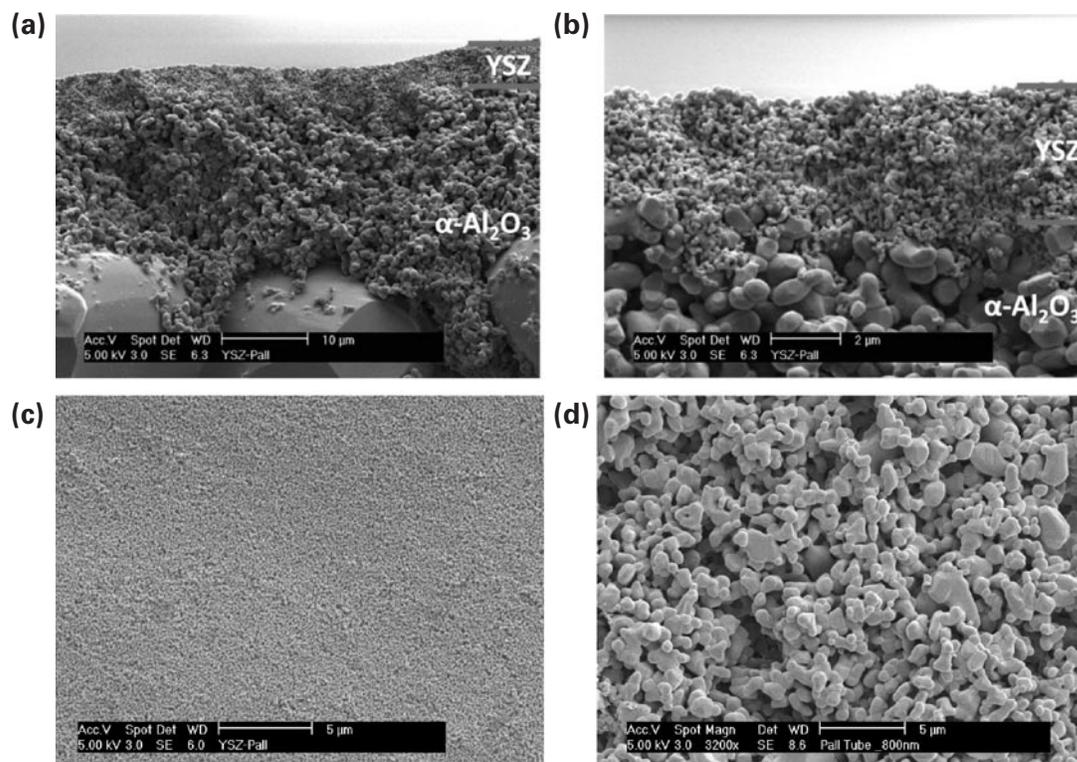

FIGURE 3. Microstructure of the YSZ coated and uncoated alumina tubular support. (a) SEM cross-section of an YSZ coating on a Pall tubular α - Al_2O_3 carrier, (b) High magnification SEM cross-section of YSZ coating on a Pall tubular carrier, (c) SEM surface image of an YSZ coating on a Pall tubular carrier, and (d) SEM surface image of an uncoated Pall tubular carrier.

relatively low and high $\text{H}_2\text{O}/\text{CO}$ ratios in the presence of H_2S were selected and tested, respectively.

HTWGS reaction has been carried out over the catalysts at temperature 500°C and compared with commercial catalyst. WGS reaction was performed at low steam to CO ratio ($\text{H}_2\text{O}/\text{CO}=1.5$) in the presence of 400 ppm of sulfur. A relatively high space velocity of $60,000\text{ h}^{-1}$ was maintained in all the experiments. On the whole, the WGS operating conditions were chosen to mimic conditions found in a membrane reactor. Before the reaction, all the ferrite catalysts are activated in the presence of process gas at 400°C for 4 h. The activation process was described in our previous reports. WGS activity profile of Fe/Ce/Cr and commercial catalysts for 30 days time on stream experiment is presented in Figure 4(a) at steam to CO ratio of 1.5 and 400 ppm of H_2S . Remarkably, Fe/Ce/Cr catalyst exhibited excellent stability for 30 days. There is no decrease in CO conversion within the permissible error during the 30 days of reaction. On the other hand commercial catalyst started to deactivate from the 4th day onwards. The deactivation continued up to the 13th day and the catalyst became stable. Hence, our shift activity results show that our Fe/Ce/Cr catalyst exhibits better stability compared to the commercial catalyst at specific activation and reaction conditions. The excellent stability of Fe/Ce/Cr is due to the promotional effect of ceria and stabilization effect of chromium.

However, at high steam to CO ratio ($\text{H}_2\text{O}/\text{CO}=3.5$), the Fe/Ce catalyst exhibited the best long-term stability with/without the presence of 400 ppm H_2S in the gas stream. WGS activity profile of the Fe/Ce catalyst for 30 days time on stream experiment is presented in Figure 4(b) at a steam to CO ratio 3.5. Remarkably, the Fe/Ce catalyst exhibited excellent stability for 30 days. The CO conversion is decreased only from 84 to 80% during the 30 days of reaction. The excellent stability of Fe/Ce is because both iron and ceria undergo a facile charge transfer reaction between $\text{Fe}^{\text{III}} \leftrightarrow \text{Fe}^{\text{II}}$ and $\text{Ce}^{\text{IV}} \leftrightarrow \text{Ce}^{\text{III}}$ redox couples, respectively; the synergism between the two couples could be responsible for the improved WGS activity. Additionally, at higher temperatures, the rapid transformation of oxygen exchange between $\text{Ce}^{3+}/\text{Ce}^{4+}$ redox couple, as well as the improvement in the oxygen storage capacity of ceria will help the magnetite to keep its shift stability from CO poisoning. The experiments were also carried out in the presence of 400 ppm of sulfur to check the resistance of Fe/Ce towards sulfur. Interestingly, Fe/Ce catalyst exhibited excellent stability towards sulfur for 30 days as shown in Figure 4(c). The Fe/Ce catalysts in the presence of sulfur exhibited same activity as Fe/Ce catalyst in the absence of sulfur. Here also, the CO conversion is decreased only from 83 to 79% during 30 days of reaction. These results reveal that sulfur has no effect on the structure of Fe/Ce catalyst for the WGS reaction.

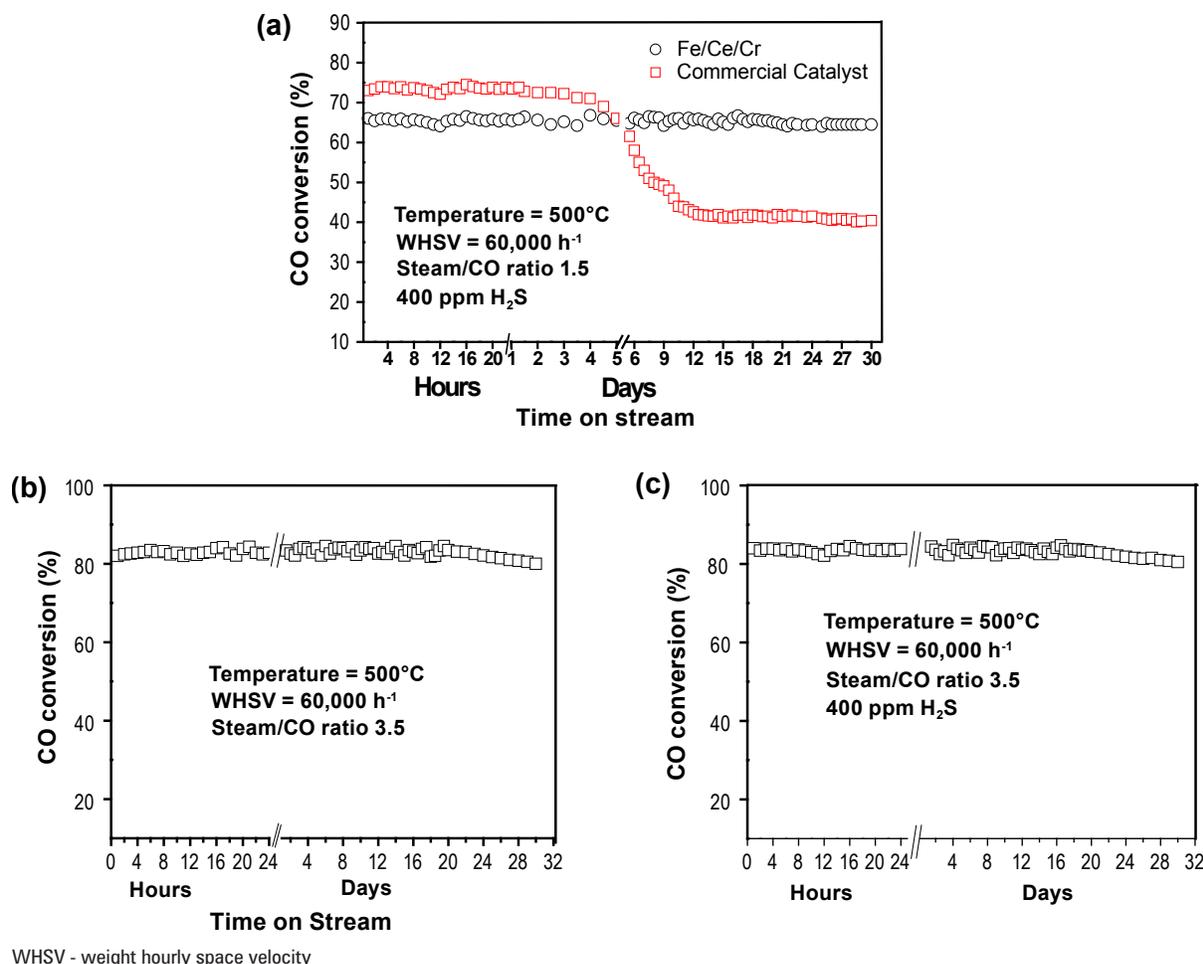

FIGURE 4. (a) Long-term stability of Fe/Ce/Cr and commercial catalysts at steam to CO ratio of 1.5 and 400 ppm of H₂S, (b) long term stability of the Fe/Ce catalyst at steam to CO ratio of 3.5 in the absence of H₂S, and (c) long term stability of the Fe/Ce catalyst for at steam to CO of 3.5 in the presence of 400 ppm of H₂S.

The work conducted on zeolite membrane reactor during the reporting period was focused on WGS reactions in the modified zeolite disk membrane reactor at different pressures (2~6 atm) with fixed GHSV and H₂O/CO ratios. MFI zeolite membranes were synthesized on the alumina porous supports with a YSZ barrier layer for stability improvement. The synthesized membranes were modified through catalytic cracking deposition of MDES precursor for H₂/CO₂ separation factor improvement. HTWGS reaction catalysts that can be used at relatively high and low H₂O/CO ratios were synthesized, respectively. The long-term stability of the catalysts was tested with/without the presence of 400 ppm H₂S in a fixed bed reactor.

The WGS reaction was performed at various feed pressures (2~6 atm) and different temperatures (400-550°C) in a modified disk MFI zeolite membrane. The permeate side pressure was kept at 1 atm. Figure 5 presents the CO conversion in the disk zeolite membrane reactor (MR) at a fixed GHSV of 7,500 h⁻¹ as a function of pressure

in comparison with the traditional reactor (TR) and the previous results obtained from a tube MR (H₂/CO₂ separation factor ~40). At all temperatures, the CO conversion in the disk MR was increased when feed pressure increased from 2 to 6 atm (constant permeate pressure of 1 atm) because high feed pressure increases ΔP_{H_2} , the driving force for H₂ permeation that in turn increases H₂ removal from the catalyst bed. In the TR, the dependence of the CO conversion on the reaction pressure was not significant, with a slight increase in CO conversion of <2%. The CO conversion in disk zeolite MR was higher than that in TR and also higher than the equilibrium CO conversions at 500°C and 550°C, indicating that faster reaction rate and higher H₂ permeance under higher temperature facilitated the WGS reaction to overcome the equilibrium CO conversion. As temperature increased, the CO conversion in disk MR increased gradually to the level of CO conversion in tube MR which has better quality than disk membrane. This suggests that the membrane quality becomes less influential on the MR performance when temperature is sufficiently high.

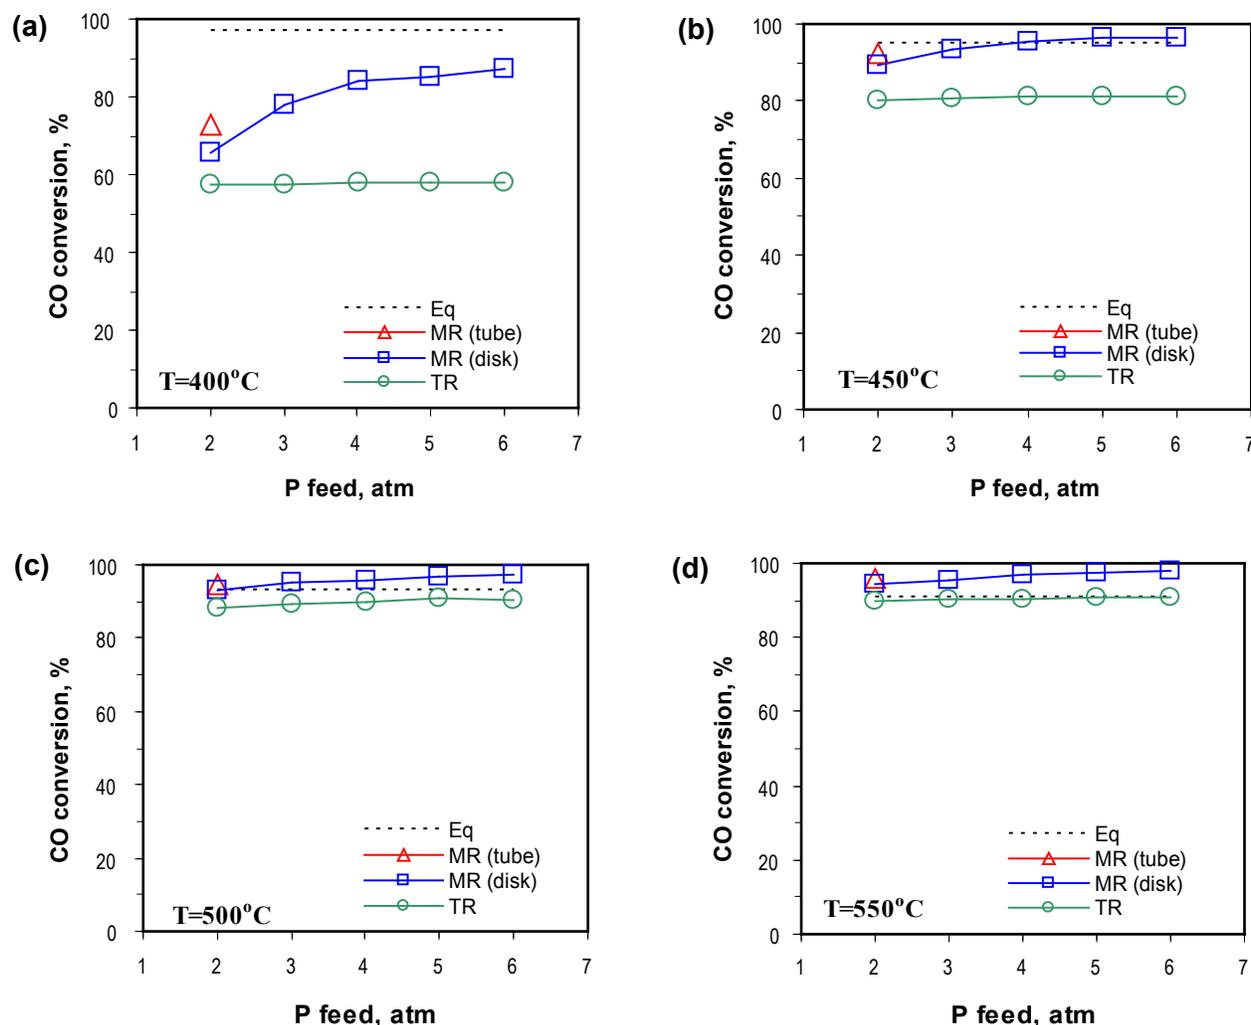

FIGURE 5. CO conversion for a fixed GHSV=7,500 h⁻¹ and various temperature of (a) 400°C, (b) 450°C, (c) 500°C and (d) 550°C: (---) equilibrium CO conversion; (Δ) CO conversion under feed pressure 1.5atm in tube MR of previous work; (□) CO conversion in disk MR; (○) CO conversion in TR.

Conclusions and Future Directions

Conclusions

- Silicalite/ZSM-5 bilayer membrane consisting of a silicalite bottom thick layer and a ZSM-5 top thin layer was synthesized on the alumina porous supports coated with YSZ barrier layer for stability improvement.
- The modified silicalite/ZSM-5 bilayer membrane exhibited high H₂/CO₂ separation factor and considerable H₂ permeance.
- Alumina tubular porous supports with YSZ barrier layer for stability improvement were obtained through optimization of a flow coating procedure.
- Several different kinds of ferrite-based catalysts were synthesized and tested in a fixed-bed reactor. The long-term stability of the best sulfur-tolerant HTWGS catalyst was tested in the presence of 400 ppm H₂S.

- WGS reactions were conducted in a modified disk membrane at pressures up to 6 atm to obtain higher CO-conversion and hydrogen recovery.

Future Work

- Test the long-term stability of the modified silicalite/ZSM-5 bilayer membrane under WGS reaction conditions in the presence of 400 H₂S.
- Synthesize and modify the silicalite/ZSM-5 bilayer membrane on the alumina tubular porous supports coated with YSZ barrier layer.
- Conduct WGS reactions in the modified MFI zeolite membrane reactor at pressures up to 20 atm.
- Perform the atmospheric kinetics by using the best catalytic system Fe/Ce/Cr for HTWGS and determine kinetic parameters for that catalyst.
- Economic evaluation of the project results to validate the scale up and operation in an industrial scale.

University of Southern California, Los Angeles, CA

Project Start Date: July 1, 2005

Projected Ended Date: December 31, 2011

Technical Targets

The WGS reaction is considered one of the least efficient unit operations for hydrogen production via steam reforming. This project focuses on developing a highly efficient, low-temperature, low-cost membrane-based WGS reaction process. 2010 Technical Target values for dense metallic membranes include:

- Flux Rate - 250 scfh/ft² at 20 psig pressure
- Membrane Material and All Module Costs - \$1,000/ft² of membrane
- Durability - 2,680 hours
- Operating Capability - 400 psi
- Hydrogen Recovery - >80% (of total gas)
- Hydrogen Quality - 99.99%

FY 2011 Accomplishments

- Verified palladium (Pd) membrane bundle performance and separation properties at pilot plant and end-user site.
- Confirmed Pd membrane bundles long term thermal cycling stability in nitrogen are similar to results for single membrane tubes (~20°C to 350°C).
- Developed a post treatment hydrogen product purity strategy that reduced 300, 70 and 10 ppm CO in hydrogen to 16, 1.2 and 0.3 ppm respectively.
- Identified a potential alloy for upgrading our Pd membrane product that will support improved stability during cooling in the presence of hydrogen.

Introduction

Membrane separation traditionally has been considered a simple, low-cost and compact process. At the same time, the WGS reaction is one of the least efficient unit operations for hydrogen production via steam reforming. This project will focus on the development of technology components associated with a WGS reactor/separator membrane process to enhance the hydrogen production efficiency for distributed hydrogen production.

Pd membranes, one set of dense metallic membranes, are capable of delivering high purity hydrogen product with a high recovery ratio. Specifically, this project will fabricate tubular Pd membranes by depositing Pd thin film over a ceramic substrate and bundling the tubes into a reactor. During 2010-2011, a test quantity of Pd membrane bundles suitable for packaging into the membrane reactor were field tested. The project target of producing a hydrogen

Fiscal Year (FY) 2011 Objectives

- Develop a highly efficient, low-temperature membrane-based bench-scale water-gas shift (WGS) reaction process, test it at pilot scale, and demonstrate the process in a field test unit.
- Screen existing membranes and modify the membranes for the proposed process and reactor.
- Determine hydrogen production costs and define system integration requirements for commercialization.
- Reduce capital and operating costs for distributed hydrogen production applications.

Technical Barriers

This project addresses the following technical barriers as presented in Section 3.1 Hydrogen Production Technical Plan, Fuel Cell Technologies Program, Multi-Year Research, Development and Demonstration Plan for 2005 to 2015 (updated October 2007):

- (K) Durability
- (L) Impurities (Hydrogen Quality)
- (M) Membrane Defects
- (N) Hydrogen Selectivity
- (P) Flux
- (R) Cost

product stream with $\ll 10$ ppm CO was achieved. Also, an evaluation of a series of Pd-alloy foils established the fundamental basis for the development of a Pd-based membrane with cooling stability in the presence of hydrogen. Further confirmation through field testing will be pursued in FY 2011-2012.

Approach

Our overall technical approach includes three steps as follows:

1. Bench-Scale Verification

- Evaluate membrane reactor: use existing membrane and catalyst via math simulation.
- Experimental verification: use upgraded membrane and existing catalyst via bench unit.
- Validate membrane and membrane reactor performance and economics.

2. Pilot Scale Testing

- Prepare membranes, module, and housing for pilot testing.
- Perform pilot-scale testing.
- Perform economic analysis and technical evaluation.
- Prepare field testing.

3. Field Demonstration

- Fabricate membranes and membrane reactors and prepare catalysts.
- Prepare site and install reactor.
- Perform field test.
- Conduct system integration study.
- Finalize economic analysis and refine performance simulation.

Results

1. Produced an 11-tube 24-Inch Length Second Generation Pd Membrane Bundle

Ceramic-based Pd membrane tubes were successfully developed and tested previously. In addition, a membrane bundling technique was developed for potting these tubes into a bundle for packaging into a membrane housing for

commercial use. Over the last year, several Pd membrane tube bundles have been produced and evaluated, and these bundles will be packaged into the membrane reactor for field testing to demonstrate the proposed WGS membrane reactor in FY 2012. Table 1 shows the performance of the four bundles produced. One of these bundles (Pd-B-4) was evaluated for its mixed gas performance. Mixed gas testing was conducted at ca. 380°C using an 80/20 vol% H₂/Ar blend. The H₂ permeance and H₂/Ar selectivity in the mixture were 7.1 and 1,220 m³/m²/hr/bar, respectively, and are consistent with the pure component result. Furthermore, the performance of these Pd membranes has been confirmed in field testing at our end-user facility using both synthetic and actual reformat.

2. Tested Thermal and Thermal Cycling Stability of Our Pd Membrane Tube Bundles

This year membrane tube bundles were subjected to thermal and thermal cycling stability testing similar to testing performed last year on Pd membrane tubes for >2,500 hours (see Figure 1). About 140 thermal cycles between 25 and 350°C have been performed. The Pd membrane bundle maintains its excellent H₂/N₂ selectivity of ~4,000. Separately the thermal stability of the membrane bundle was tested for ~400 hours. The bundle maintains its hydrogen permeance of ~15 m³/m²/hr/bar and selectivity of 10,000 – 15,000 at 350°C. This thermal stability test will be continuing into the next year. In summary, the thermal and thermal cycling stability of the Pd membrane tube bundles are excellent, similar to the tubes tested previously, and the improved performance is, in part, the result of the potting technique developed for the proposed applications.

3. Demonstrated H₂ Post-Treatment CO Reduction in the WGS-Membrane Reactor

Our previous bench-top WGS membrane reactor experimental study demonstrated the ability of our membrane to reduce CO contamination of hydrogen to 50 ppm or below, depending in part upon the degree of hydrogen recovery, and the transmembrane pressure drop. During this year, we have developed a post-treatment technique that is to be integrated into our membrane reactor to further reduce the CO level. Our experimental study demonstrated the reduction of CO from 50-300 ppm to ~0.3 to 16 ppm respectively, as illustrated in Figure 2. In

TABLE 1. Pure Component Permeance and Selectivity of the Pd Bundles Prepared and Tested during 2010-2011

Bundle ID (-)	Tube Count (#)	Temperature (°C)	Pressure (psig)	H ₂ (m ³ /m ² /hr/bar)	H ₂ /N ₂ (-)	Comments
#1	11	336	2.6	6.1	1,100	Broken
#2	14	337	2	9.8	1,600	
#3	14	338	2	7.9	780	
#4	14	337	2	6.2	1,800	

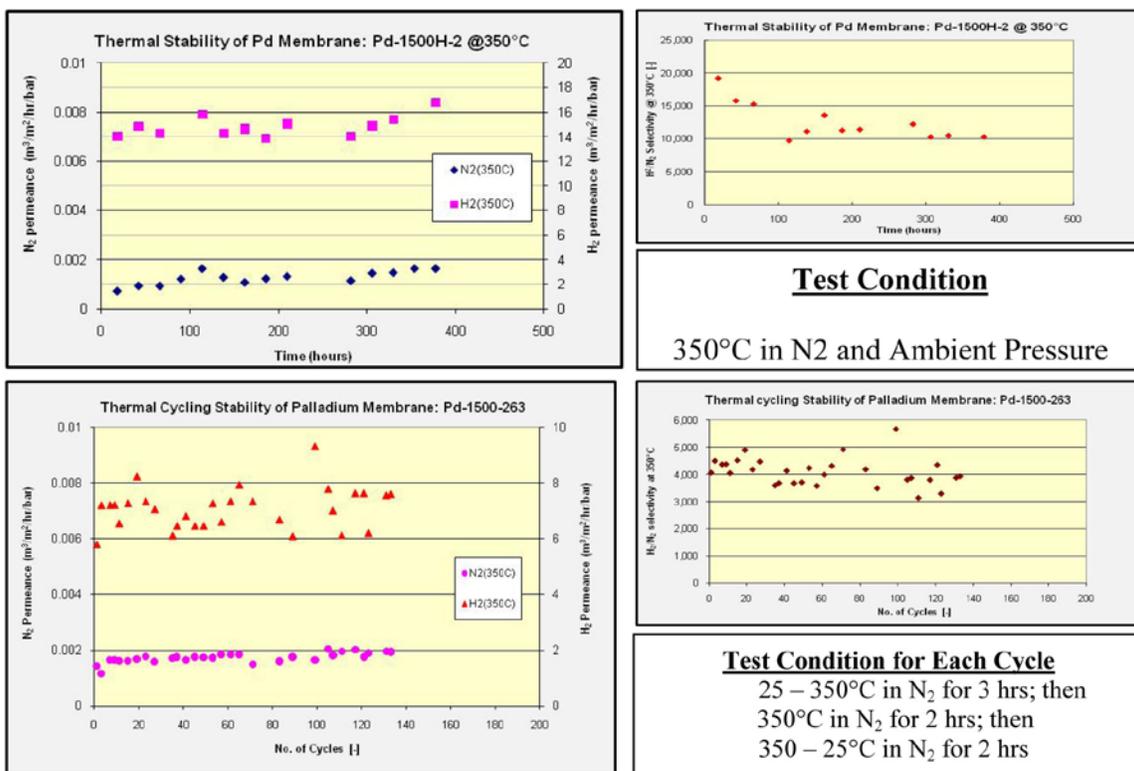

FIGURE 1. Evaluation of Thermal and Thermal Cycling Stability of the Pd Membrane Tube Bundles

the upcoming year, we will perform WGS membrane reactor runs integrated with this post treatment to demonstrate the reduction of CO in the final product to <<10 ppm.

4. Cooled Pd Membranes in the Presence of Hydrogen

The application selected by our end-user requires the ability to cool the membrane in the presence of residual

CO Contaminant in the Hydrogen Stream Produced from WGS-MR

As shown in our previous membrane reactor study, our palladium membrane has been able to deliver a hydrogen product stream with ~50 ppm CO using our standard Pd membrane as a reactor.

Our Proposed Solution to Reduce CO Contaminant Level

A post treatment strategy has been developed and experimentally demonstrated on the technical feasibility in reducing CO contaminant to an extremely low level, such as <10-1 ppm as shown below

Concentration of CO in Feed [ppm]	Residual CO in Product [ppm]	W/F [g catalyst/(mol CO/hr)]
300	16	4,148
70	1.1	17,778
50	0.3	24,889

Activities Planned in 2011

- demonstrate this post treatment strategy in conjunction with our WGS-MR.
- further incorporate this post treatment into our WGS-MR as an integrated membrane reactor.

FIGURE 2. Post-Treatment for Reduction of CO Contaminant Level in Hydrogen Produced from our WGS-Membrane Reactor

hydrogen following shut-down of the hydrogen generator. Although this is a very desirable feature for the commercial use of the Pd membrane, very few literature studies have addressed this issue. The pure Pd membrane such as those we have produced thus far failed to maintain their membrane materials stability through cooling from 350 to 25°C in the presence of hydrogen. This year we conducted

a laboratory evaluation study using commercially available Pd alloy flat discs to determine the alloy formula required to sustain the cooling cycle. The results of our evaluation for the Pd-Ag (23%) and Pd-Cu (40%) alloys are presented in Figures 3 and 4. No damage through the cooling test for both alloys was observed under visual and scanning electron microscope examination. However, the H₂/N₂ selectivity

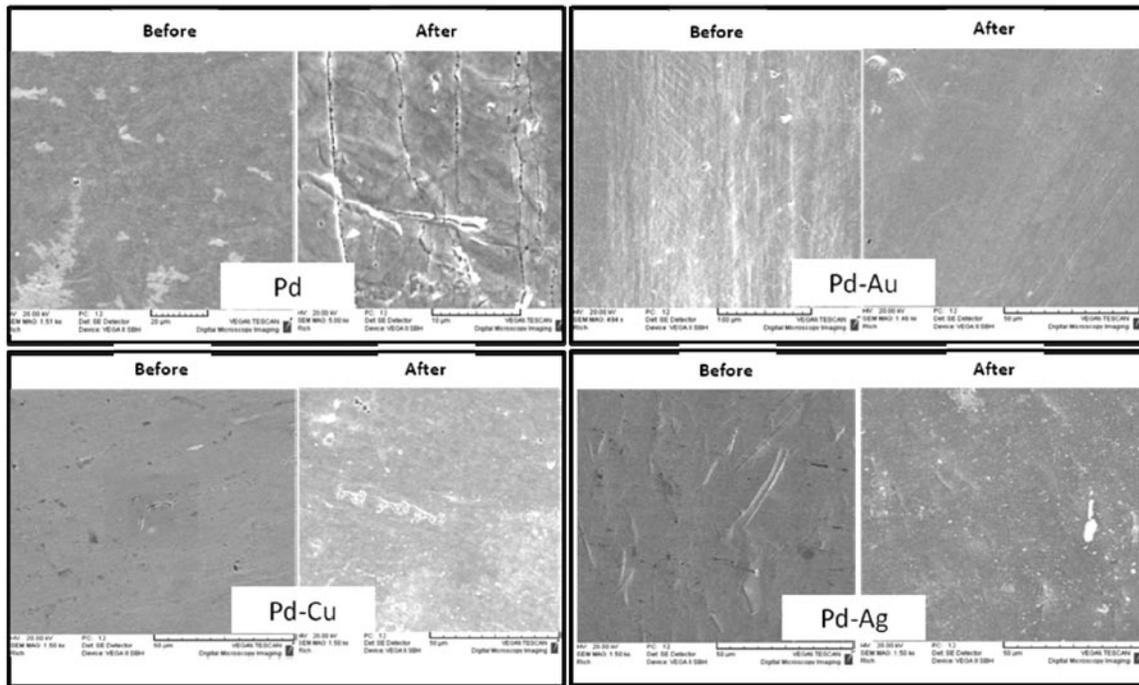

FIGURE 3. Evaluation of Pd Alloy Flat Discs for their Cooling Stability in the Presence of Hydrogen Required by Our Target Applications

H₂ and N₂ permeances of the Pd-Ag(23%) alloy (left) and Pd-Cu(40%) alloy (right) flat disc membranes following thermal cycling between RT and 350°C with cooling in hydrogen.

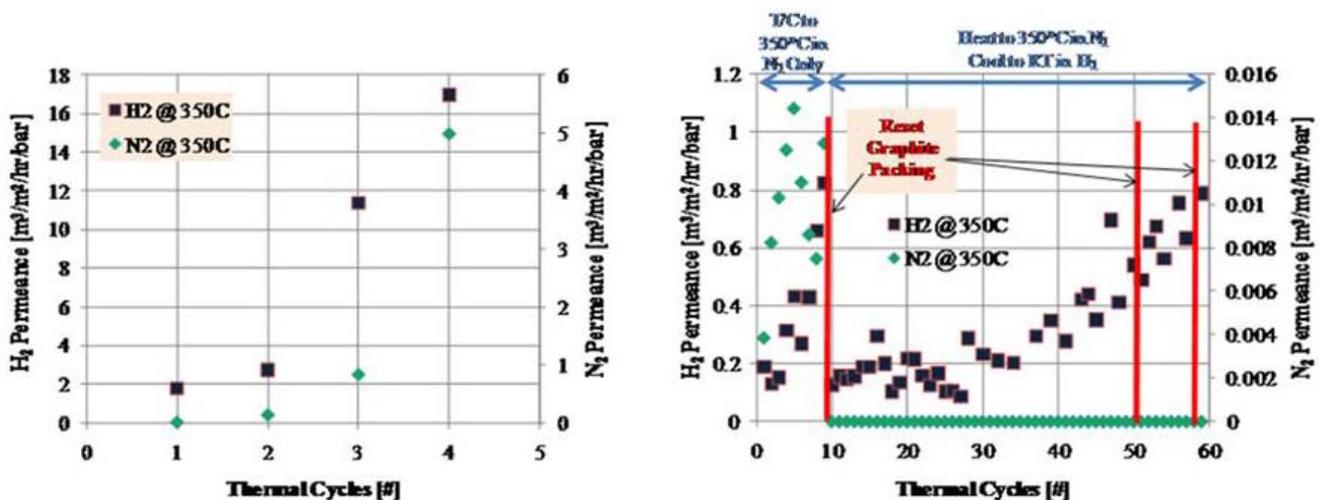

FIGURE 4. Evaluation of Pd-Ag vs. Pd-Cu for the Cooling Stability in the Presence of Hydrogen

for the Pd-Ag alloy deteriorates severely after 3-4 cycles while the Pd-Cu remains intact (i.e., N_2 permeance $\leq 0.01 \text{ m}^3/\text{m}^2/\text{hr}/\text{bar}$) for up to 60 cycles. In addition when the Pd-Au alloy was used in the Pd membrane considerable damage was exhibited throughout the test. In summary, we believe the Pd-Cu (40%) offers a fundamental basis for us to prepare a supported Pd membrane which can sustain the cooling in the presence of hydrogen. We will pursue fabrication of the Pd-Cu alloy membrane on our ceramic support in FY 2012.

Conclusions and Future Direction

- A newly developed potting technique has enabled packaging low-cost Pd membrane tubes into commercially viable bundles.
- Both pilot and field tests confirmed the separation efficiency of the Pd membrane bundles is similar to the performance of single membrane tubes.
- Bench-top feasibility tests indicate that the new post treatment strategy should reduce CO contamination to well below 10 ppm.
- A full-scale membrane reactor packed with our Pd membrane bundles and equipped with internal cooling coils has been designed and is currently under fabrication for the field test to be conducted in 2011.
- Commercially available Pd alloy foils of Pd-Ag (23%) and Pd-Cu (40%) remain intact through multiple cooling cycles, suggesting that Pd-Cu alloy could produce cooling stability for the reactor in the presence of hydrogen. This cooling stability is a desirable feature for our target application.

Our FY 2012 activities will be focused on the following areas:

- Complete fabrication and field test the full-scale membrane reactor packed with the Pd membrane bundles and equipped with cooling coils.
- Integrate the post-treatment strategy into the membrane reactor to deliver hydrogen product with $\ll 10 \text{ ppm CO}$.
- Conduct a field test with the use of the membrane reactor at the participating end-user site.
- Develop the third generation Pd membrane with the cooling stability in the presence of hydrogen.

Contract Number: DE-FG36-05GO15093

Subcontractors:

- Colorado School of Mines, Golden, CO
- Oak Ridge National Laboratory, Oak Ridge, TN

Project Start Date: July 1, 2005
 Project End Date: September 30, 2011

Fiscal Year (FY) 2011 Objectives

The overall project objective is the development, demonstration and economic analysis of a Pd-alloy membrane that enables the production of 99.99% pure H₂ from reformed natural gas as well as reformed bio-derived liquid fuels such as ethanol at a cost of \$2-3/gasoline gallon equivalent by 2011. The specific objectives for the past year were:

- Conduct long-term durability testing of Pd-alloy membranes in syngas/water-gas shift (WGS) reaction environments meeting Phase III performance goals.
- Determine the optimal Pd-alloy membrane composition and thickness to assure stable performance with respect to product hydrogen flux and purity in WGS reaction environments.
- Scale up the substrate and membrane synthesis processes to 12" elements.
- Design and fabricate multi-tube modules minimizing concentration polarization effects at high hydrogen recoveries.
- Work with an end user to compare cost/performance of a membrane-based system to pressure swing adsorption (PSA) and solvent-based systems for large-scale hydrogen production with CO₂ capture.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan and the technical targets indicated in Table 1:

- (K) Durability
- (L) Impurities (Hydrogen Quality)
- (M) Membrane Defects
- (N) Hydrogen Selectivity
- (O) Operating Temperature
- (P) Flux
- (Q) Testing and Analysis
- (R) Cost

TABLE 1. Applicable Technical Targets for Dense Metallic Membranes and Current Project Status

Performance Criteria	2010 Target	2015 Target	Pall Status 2011
Flux SCFH/ft ² @20 psi ΔP H ₂ partial pressure and 15 psig permeate side pressure	250	300	270*
Membrane Cost, \$/ft ² (including all module costs)	\$1,000	<\$500	<\$1,000
ΔP Operating Capability, system pressure, psi	400	400-600	>600 PSI
Hydrogen Recovery (% of total gas)	>80	>90	>80**
Hydrogen Permeate Quality	99.99%	>99.99%	99.999%***
Stability/Durability	2 years	>5 years	To be determined

*Maximum observed. Averaged over more than 20 samples ~190 scfh/ft².
 ** Measured on a 50%H₂/21%H₂O/up to 3.5% CO/balance CO₂ mixed gas stream. Hydrogen flux and recovery measurements are planned with other impurities starting in mid-2009. The experimentally observed recovery is determined by chosen operating conditions and is not necessarily a limit of the membrane performance.
 *** Projected purity based on H₂/N₂ ideal selectivity.

FY 2011 Accomplishments To Date with Specific Barriers Addressed

- Determined optimal Pd-alloy membrane composition as Pd₉₀Au₁₀ to assure stable performance with respect to product hydrogen flux and purity in WGS reaction environments (K, L, N, P, Q).
- Increased membrane operating capabilities to 400 psi at 550°C through use of 310SC stainless steel tubular substrate.

- Optimized and scaled up the membrane and diffusion barrier coating process to 12-inch lengths. The substrate tube manufacturing capability is up to 1 m length (N, R).
- Developed a commercial welding process for non-porous fittings to porous tubes (N, R).
- Met Phase III performance goal demonstrating up to 500 hours of durability testing on Pd-alloy membranes in syngas/WGS reaction environments meeting Phase III performance goals (K, L, N, P, Q).
- Observed high mixed gas hydrogen flux rate ($145 \text{ scfh/ft}^2\text{-atm}^{0.5}$) and high hydrogen purity ($<99.95\%$) for up to 120 hours at an operating feed side pressure of $>200 \text{ psig}$ (K, L, N, P, Q).
- Observed a reversible H_2 flux decline with H_2S exposure during testing with low concentration H_2S exposure (K, L, N, P, Q).
- Demonstrated membrane performance stability with thermal cycling ($50\text{--}400^\circ\text{C}$) (K, Q).
- Showed an achievable end-user cost of less than $\$1,000$ per ft^2 of area for a stand-alone membrane separator device (R).
- Minimized concentration polarization effects while maintaining high hydrogen recoveries for a 12-tube, 12-inch long, multi-tube module (P, R).
- Directed Technologies, Inc. calculated that a membrane-based process can enable cost reduction through process intensification and that the hydrogen production cost target of $\$/\text{kg}$ is achievable. The capital equipment cost estimate is based on sale price to the end user for membrane in a module (R).

Introduction

This project is focused on optimizing the overall composition of the Pd alloy, intermediate layers and tubular support, as well as on the manufacturing methods required to produce a very thin, high-flux, cost-effective membrane for H_2 separation and purification on a robust, porous, inorganic substrate. The substrate¹ is readily scalable to high volume production as it is manufactured in long lengths. Robust high area modules can be made by welding multiple tubes into a pressure vessel, eliminating low temperature seal materials.

Approach

The approach is to further develop and optimize the performance of Pd alloy membranes that have been shown to have both high flux rate and high separation factor for H_2 from reformat. This is being accomplished by design of a composite membrane based on robust, tubular, porous metal media as a substrate. The substrate is modified by the addition of a uniform, fine pore size diffusion barrier

layer. The deposition methods are modified to produce a thin, uniform, functional gas separation Pd-alloy membrane layer. The project plan includes commercial scale up of the high quality porous metal substrate and diffusion barrier layer that enables the development of a technically and economically viable composite membrane. Membrane alloy composition and thickness is optimized for assuring high hydrogen flux and selectivity as well as long-term durability with tolerance to contaminants. The membrane performance is determined under typical operating conditions for a reformed natural gas or bio-derived liquid fuels stream. The H₂A model, modified to incorporate a membrane reactor design, is used to verify economic viability. Our plan is to confirm an increase in the overall energy efficiency of a H_2 reforming system through the use of membrane technology for process intensification. Economic modeling is conducted to determine the cost benefit of an integrated membrane reactor that results from fewer pressure vessels and reduced catalyst volumes. An end user is conducting system economic and energy analyses and comparing the results to PSA and amine-based systems.

Results

Membrane Development

The process for depositing ceramic on the porous metal tubes was modified to increase the diffusion barrier substrate surface roughness and eliminate potential film stresses and membrane film delaminations observed in some of the earlier composite Pd-alloy membrane samples. Synthesis of membrane with varying thickness in 3 to 9 micron range and Pd-Au alloy composition in 0-30% Au range were prepared for determining optimal membrane composition and thickness for long-term stable membrane performance.

The substrate as well as Pd-alloy composite membrane synthesis processes were successfully scaled up to prepare elements of 12" overall length with 10" active membrane length. The scaled up membranes were tested to confirm their hydrogen separation performance as observed in shorter (2" active length) membranes. Several 12" overall length ceramic porous metal AccuSep[®] substrates were prepared and composite Pd-alloy membranes are being prepared for assembling them in a multi-tube module and testing in WGS environment. For the 12-tube module assembly, eight Pd-alloy membranes are complete while five more are currently being fabricated.

Membrane Durability Testing in WGS Streams and Membrane Optimization

Extensive testing of Pd-alloy membranes in pure gas streams and in methanol/natural gas reformat environments was conducted for parametric evaluation of their performance. For example, effect of concentration polarization and CO concentration was observed in another test with a $\text{Pd}_{95}\text{Au}_5$ membrane of $8 \mu\text{m}$ thickness with three

¹ Pall's AccuSep[®] inorganic media

different feed gas mixtures consisting of H₂/Ar, H₂/Ar/steam and WGS mixture (50% H₂, 25%CO₂, 20% H₂O, 5%CO – WGS-5) at 400°C and 132 psi feed pressure with a feed flow rate of 2,000 mL/min. The permeate pressure was 17 psia. The results shown in Figure 1 indicated a H₂ flux reduction due to the concentration polarization effect of ~20%, with an additional flux reduction of 20% due to CO.

The standard WGS composition was determined to be insufficient to cause a decline in flux or H₂ purity of most of the membranes for determination of the optimum alloy composition or thickness. For example, a 2.2 micron thick Pd₈₇Au₁₃ alloy membrane on Pall Accusep® support was tested in WGS with high CO content and steam to CO ratio of 1:1 (50% H₂, 10% CO₂, 20% CO and 20% steam – WGS-20). Temperature was varied between 400°C and 450°C. This composition also was determined to be insufficient to cause a decline in flux or purity and stable permeance and purity performance over ~400 hours is shown in Figure 2.

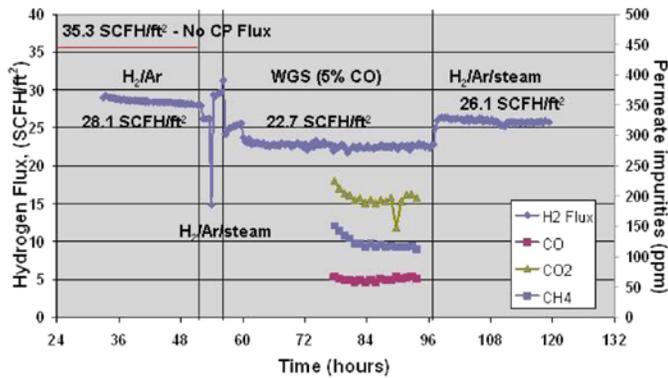

FIGURE 1. Hydrogen Flux Reduction due to Concentration Polarization and CO

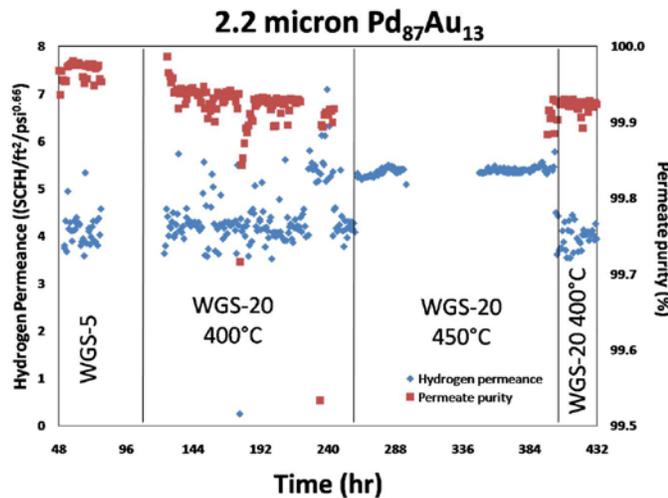

FIGURE 2. Stable Membrane Performance in WGS-5 and WGS-20 Syngas Conditions

To facilitate rapid durability evaluation of several alloy compositions an accelerated life test based on an aggressive variant of the WGS composition was tested and determined to be sufficient to cause a decline in the H₂ purity and H₂ recovery in the 100 hour range. The accelerated test conditions use a WGS gas mixture without any steam (50% H₂, 30% Ar, 20% CO – WGS-20D). As shown in Figure 3, a linear decrease in permeate purity was obtained in approx 100 hours for the same membrane referenced in Figure 2. Evaluation of two sets of three membranes with varying alloy composition were tested with results given in Table 2. One membrane of each composition was tested at each location. From the performance in WGS20D the Pd₉₀Au₁₀ alloy was selected for next durability tests.

TABLE 2. Performance evaluation of membranes of varying alloy compositions in accelerated test conditions for a minimum of 100 hours.

Thickness (micron)	Au content (wt%)	Purity Decline (ppm/day)
3.0	0	42
4.1	0	74
4.0	9	0
3.9	11	6
3.6	20	356
3.6	24	652

Module Development

A major advantage of using the porous metal AccuSep® is the ability to weld individual membrane elements in a metal tube sheet similar to the conventional shell and tube architecture. However, a multi-tube module must be designed to minimize the concentration polarization effect typically observed at high hydrogen recoveries. Different concepts of multi-tube membrane module design were

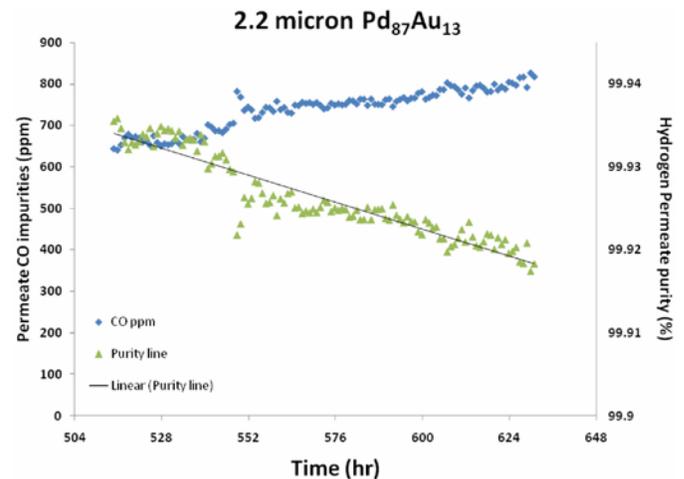

FIGURE 3. Membrane Degradation in WGS-20D Syngas Conditions

evaluated to overcome concentration polarization effects². Multi-tube modules were fabricated and tested to confirm hydrogen flux and recovery as predicted by the model shown in Figure 4. A test facility with a feed gas flow capacity of 200 liters/minutes needed for testing the performance of the 12-tube module is being assembled.

System Economic and Energy Analysis

The end user conducted a techno-economic study to compare Pd-membrane-based process to competing PSA and solvent scrubbing-based processes for large-scale hydrogen production (~36,000 kg/hr) from natural gas with CO₂ capture. This analysis assumed an autothermal oxygen-blown reforming of natural gas to provide hydrogen-rich reformat gas for further processing by the three option processes considered. A two-stage cascade of WGS reactor/membrane separator was found to be able to provide the desired 90% H₂ recovery with 90% H₂ purity. Utilization of an inert nitrogen sweep gas stream in the second stage was necessary to achieve the target 90% recovery from the reformat gas mixture generated by autothermal reforming of natural gas. The amount of sweep gas that could be used was dictated by the requirement of achieving the 90% target hydrogen purity. Pall Corporation provided estimates of total membrane area needed to produce 36,000 kg/hr of hydrogen. The total costs of the membrane system were estimated assuming utilization of 2,000-tube modules. This analysis included the costs of sequestration-ready CO₂ capture in addition to that would be needed for just the hydrogen production. As a result additional equipment was needed to be incorporated increasing the costs of processes based on hydrogen separation, i.e. PSA and membrane-based processes, significantly increasing the costs of those processes when compared to the amine scrubbing option. This report is being reviewed to modify the analysis to conform to the

²The resultant module designed to reduce concentration polarization was developed using Pall Corporation's internal funds in a separate project.

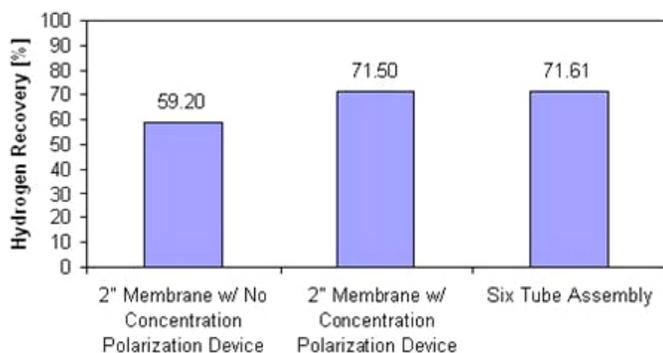

FIGURE 4. Multi-Tube Module Design with Minimization of Concentration Polarization

goals of hydrogen production in our DOE contract. A separate report is being prepared for DOE's review.

Conclusions

- Eliminated delaminations and improved membrane quality by optimizing the substrate/diffusion barrier substrate process.
- The PdAu alloy membranes were stable in a standard WGS stream environment.
- Developed more aggressive gas stream compositions to accelerate a decline in membrane performance in a reasonable time.
- Verified long-term durability of the optimal Pd₉₀Au₁₀ alloy composition.

Future Plans

- Complete membrane optimization tests to determine both the optimum membrane composition and thickness to assure long-term durability in WGS reaction environments.
- Demonstrate additional long-term durability to meet Phase III goals using membranes with optimum composition and thickness.
- Complete fabrication of 12-inch overall length PdAu membranes for the multi-tube module assembly and test a module with at least six tubes.
- Demonstrate multi-tube module performance is close to single-tube performance.
- Complete the techno-economic analysis of the membrane-based hydrogen production process.

Contract Number: DE-FE0004908

Subcontractors:

- Colorado School of Mines (CSM), Golden, CO
- T3 Scientific, Blaine, MN

Project Start Date: October 1, 2010
Project End Date: Project continuation and direction determined annually by DOE

Fiscal Year (FY) 2011 Objectives

- Demonstrate hydrogen transport membrane performance in syngas derived from coal or coal-biomass.
- Separate 800 scfh of hydrogen from syngas.
- Design a membrane reactor to separate at least 4 tons/day of hydrogen from a large-scale gasifier.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (K) Durability
- (L) Impurities
- (M) Membrane Defects
- (P) Flux
- (R) Cost

Technical Targets

TABLE 1. Progress towards Meeting Technical Targets for Dense Metallic Membranes for Hydrogen Separation and Purification^a

Performance Criteria	Units	Status	2010 Target	2015 Target
Flux Rate ^b	scfh/ft ²	>200	250	300
Module Cost (including membrane material) ^c	\$/ft ² of membrane	1,000	1,000	<500
Durability ^d	hr	<8,760	26,280	>43,800
Operating Capability ^e	psi	300	400	400-600

^aBased on membrane water-gas shift reactor with syngas.

^bFlux at 20 psi hydrogen partial pressure differential with a minimum permeate side total pressure of 15 psig, preferably >50 psi and 400°C.

^cAlthough the cost of Pd does not present a significant cost barrier due to the small amount used, the equipment and labor associated with depositing the material (Pd), welding the Pd support, rolling foils or drawing tubes account for the majority of membrane module costs. The \$1,500 cost status is based on emerging membrane manufacturing techniques achieved by our partners and is approximately \$500 below commercially available units used in the microelectronics industry.

^dIntervals between membrane replacements.

^eDelta P operating capability is application dependent. There are many applications that may only require 400 psi or less. For coal gasification 1,000 psi is the target.

^fIt is understood that the resultant hydrogen quality must meet the rigorous hydrogen quality requirements. These membranes are under development to achieve that quality. Membranes must also be tolerant to impurities. This will be application specific. Common impurities include sulfur and carbon monoxide.

Most tests have been conducted at higher pressure than 20 psi, but our current test unit is limited to 200 psi. A new reactor is under construction that will allow testing at 450 psi.

FY 2011 Accomplishments

- Demonstrated 90+% of original flux from membranes coated with MembraGuard[®] in pure gas and mixtures with no sulfur.
- Demonstrated high flux from Pd alloy membranes.
- Determined impact of ethylenediaminetetraacetic acid (EDTA) on membrane performance.
- Improved membrane seal.
- Designed and began construction of new test reactors to test larger membranes with H₂S and at higher pressure and flow rate.
- Coated membranes up to two feet in length.

Introduction

Hydrogen membranes can be used to separate hydrogen from syngas produced by coal gasification and facilitate CO₂ capture and sequestration. Currently, these membranes have not had widespread commercial success because of durability and performance issues, including susceptibility to sulfur contamination.

Approach

The project will examine different membrane alloys and determine the most appropriate alloys for different syngas compositions produced by gasification. The alloy(s) will be selected based on the expected contaminants in the syngas and their resistance to those contaminants. Other methods, such as sorption, will be used to remove contaminants, but employing a contaminant-resistant alloy will help ensure the success of the project. The alloy must be incorporated into a manufactured membrane. The project will examine different membrane architectures and manufacturing techniques to select the optimum membrane based on performance and manufacturing cost. The project will examine different manufacturing methods to select the most reliable low-cost production method that can produce large membranes on a commercial scale.

The membranes must be incorporated into a membrane unit that separates hydrogen from syngas. The project will examine different membrane reactor designs, including use of catalysts and sweep streams, to select the optimum membrane reactor configuration. Reactor modeling will evaluate different configurations and estimate the impact of reactor design on performance. In Phase I, a small proof-of-concept reactor will be built to separate at least 2 lbs/day (about 15 scfh) of hydrogen from coal-derived syngas. In Phase II, a pilot-scale reactor will be built and integrated with an operating gasifier to produce at least 100 lbs/day (about 800 scfh) of hydrogen. The reactors must be incorporated into a membrane process that produces hydrogen and power at a lower cost than competing processes. The project will examine different integrated process designs to select the most economical process based on the total cost of power and hydrogen produced. In Phase III, this process will be used as the basis for designing a commercial-scale hydrogen transport membrane unit capable of producing at least 4 tons per day of hydrogen.

Results

A Pd-Au membrane was tested for H₂ flux over a temperature range of 300-400°C and a pressure range of 20-200 psid as shown in Figure 1. The membrane showed H₂ fluxes of 96 and 511 scfh/ft² at 400°C and 20 and 200 psid, respectively. This is a very encouraging result because a high H₂ flux with a high Au content is expected to provide

acceptable performance and resistance to contamination due to impurities including sulfur. The best fit for the H₂ flux showed a pressure dependence of 0.56, indicating that the Pd-Au film is responsible for most of the resistance to hydrogen permeation.

The membrane was then tested in a mixed gas stream with CO (1%), CO₂ (30%), H₂ (50%), and H₂O (19%) and a feed flow rate of 6.2 slpm. As shown in Figure 2, the hydrogen recovery increased with pressure and reached 82% at a feed pressure of 200 psi. The composition of H₂ in the retentate decreased from 57 to 33% while the composition of CO₂ increased from 41 to 64% as the feed pressure increased from 50 to 200 psia.

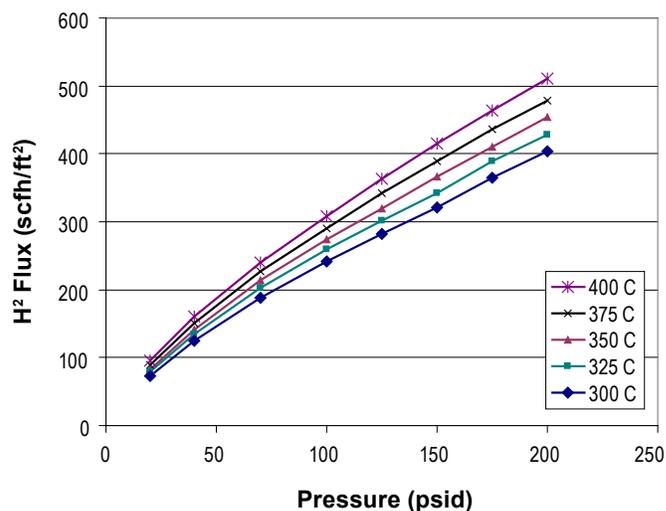

FIGURE 1. Flux Test Results for a Binary Pd-Au Membrane at 300-400°C

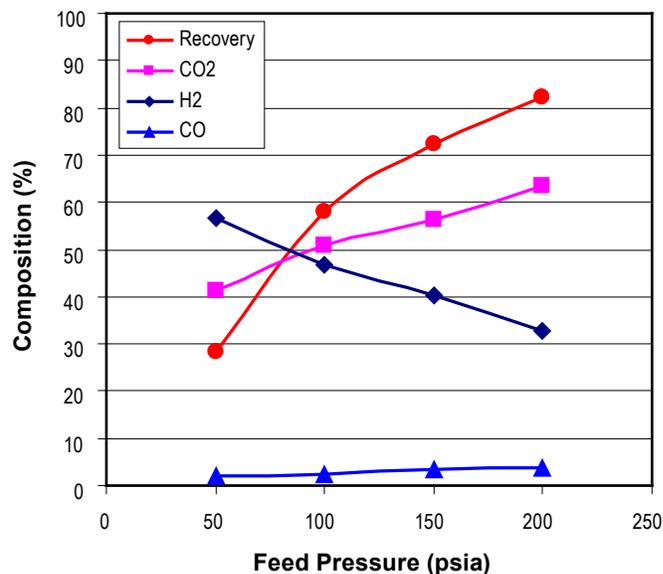

FIGURE 2. H₂ Recovery and Dry Gas Composition on the Retentate Side for a Pd-Au Membrane in a Mixed Gas Test

Other experimental work focused on understanding the effect of EDTA on hydrogen permeation in pure Pd films. EDTA is a bath stabilizer utilized to keep Pd ions in solution and to prevent formation of Pd particles during electroless plating of Pd. EDTA is added to the standard Pd electroless plating solution in amounts that bracket literature values. The plating temperature, hydrazine amount, and length of time in the plating bath were all held constant to understand the effect of EDTA on plating kinetics, which were shown to decrease as the amount of EDTA increased. Pure gas hydrogen permeation tests were completed and are discussed in detail in the following.

Effects of EDTA

The amount of EDTA added to the Pd electroless plating solution for the study was 0–80 g/l, spanning the amount used in the literature. The average amount of EDTA currently being used in the membrane literature is about 40 g/L EDTA. The single-gas permeation results are compared with Pd membranes made without EDTA as seen in Figure 3.

As the amount of EDTA used in the plating bath increases, the hydrogen permeability decreases. The percent differences from the estimated value of 0 g/L EDTA (linear fit trend line) are 2.6%, 5.7%, 14.3%, and 31.7% for the 20, 40, 60, and 80 g/L EDTA films, respectively. All of the films were exposed to air at 300°C for a minimum of five hours at 5 psi. Exposure to air provides a boost in hydrogen flux, more for membranes containing EDTA than for those that do not. As a result of air exposure, the flux for 0 g/L EDTA increased by a factor of 1.5, while it increased by factors of 1.8, 2.0, 2.42, and 3.1 for 20, 40, 60, and 80 g/L EDTA, respectively. This increase in flux did not allow EDTA membranes to be equivalent to those made without EDTA. A possible explanation is that although the carbon on the surface may have been cleared off with the air, there

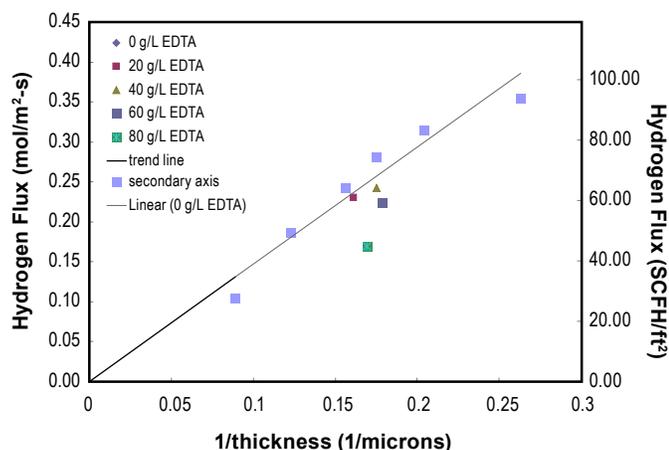

FIGURE 3. Hydrogen Flux of Pd Membranes Made With and Without EDTA at 400°C and 20 psi

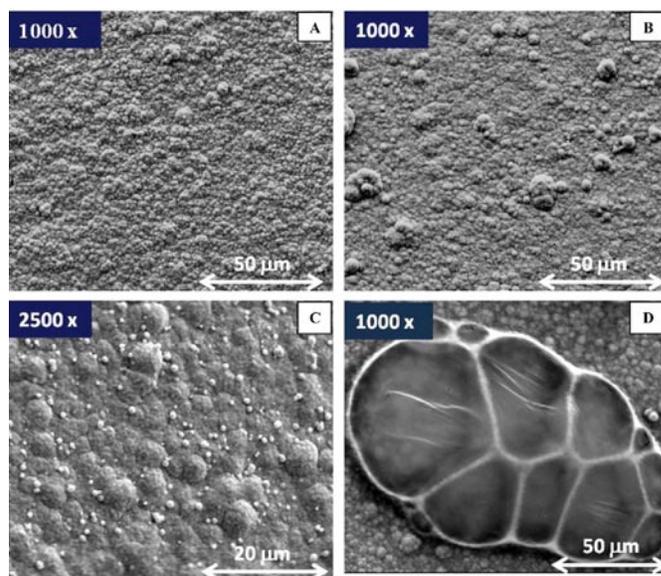

FIGURE 4. SEM micrographs of films made with EDTA. 20 g/L EDTA (A), 40 g/L EDTA (B), 60 g/L EDTA (C), and 80 g/L EDTA (D)

is still carbon left in the bulk and/or grain boundaries that is inhibiting the hydrogen transport.

All of the membranes were examined with scanning electron microscopy (SEM)/energy dispersive X-ray spectroscopy (EDS) after testing. Interestingly, as the amount of EDTA decreases, the films begin to resemble ones made without EDTA in that the surface is connected, bubbly, and “cauliflower” like. SEM micrographs of these films can be seen in Figure 4.

The 60 and 80 g/L EDTA films had noticeable carbon enrichment on the surface. In the case of 60 g/L, this can be seen in the small, white spheres (Figure 4C), which were identified by EDS in the peak magnitude of the carbon as compared to the larger, darker bubbles. In the case of 80 g/L EDTA, contamination could be seen with the naked eye and looked like black tar on the membrane surface. The micrograph in Figure 4D is a close up of one of the spots.

Future work with the EDTA membranes will have the objective to try to understand why the hydrogen permeation is suppressed. As hydrogen is transported through a palladium membrane using a solution-diffusion mechanism, permeability, P , is a function of solubility, S , and diffusivity, D , as seen in equation 1:

$$P = D \cdot S \quad (1)$$

Conclusions and Future Directions

- High flux has been demonstrated using Pd and Pd alloy membranes that are expected to have good resistance to contaminants, including H_2S .
- Future research will focus on demonstrating performance with H_2S contamination.

- Small-scale gasifier testing has begun at Colorado School of Mines.
- Future research will focus on integrating a membrane test unit with the gasifier to demonstrate performance in coal-derived syngas.

Contract Number: DE-FC26-05NT42469

Subcontractor:

Eastman Chemical Co., Kingsport, TN

Project Start Date: October 1, 2005
Project End Date: June 2012; American Recovery
and Reinvestment Act (ARRA) funded extension
through September 2015

- Module Cost: \$500/ft² of membrane
- Durability: >43,800 hours
- Hydrogen Recovery: 90%

FY 2011 Accomplishments

- Membrane manufacturing was scaled up to produce 5 ft-long tubular membranes. These tubular membranes are 1/2 inch outside diameter and have a wall thickness of 500 microns.
- Two foot-long membranes were tested at Eltron Research & Development and demonstrated 70% hydrogen recovery.
- A subscale engineering prototype pilot reactor was designed, constructed, and installed at Eastman Chemical Co.

Introduction

The overall objective of this project is to scale up the hydrogen transport membrane technology system for energy efficient carbon capture and hydrogen separation from industrial sources thereby enabling early technology commercialization by reducing time, technology risk, and cost. The goal of the project is to scale up Eltron's dense hydrogen transport membranes which can extract and purify hydrogen to very high levels from coal-derived water-gas shift mixtures, while minimizing the pressure drop of CO₂ in order to lower capital and compression costs for CO₂ sequestration. Dense hydrogen separation membranes are being developed to be compatible with high-temperature water-gas shift reactor conditions for water-gas shift reactors placed downstream from coal gasifiers in integrated gasification combined cycle (IGCC) type systems. Hydrogen separation membranes must be compatible with high-temperature water-gas shift reactor temperatures (approximately 320-440°C) and with mixtures of water-gas shift components containing hydrogen, steam, CO₂ and CO as well as residual impurities which escape upstream warm-gas clean up systems and the beds of water-gas shift catalyst. The hydrogen separation membranes must also function at pressures near that of the coal gasifiers, 450-1,000 psi.

Approach

Eltron is addressing all key issues to successfully scale up this technology. Bench scale testing is being conducted to demonstrate flux, hydrogen recovery, and durability. In addition, process modeling and techno-economic analyses are being developed. Eltron is scaling up this technology in three steps. Reactors nominally sized for 12 lbs/day

Fiscal Year (FY) 2011 Objectives

- Demonstrate a cost-effective H₂/CO₂ membrane separation system.
- Scale up membrane manufacturing.
- Construct, install, and operate subscale engineering prototype.
- Down-select engineering, procurement, and construction firm and conduct pre-front end engineering design for a 4-10 ton per day pre-commercial scale up.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (K) Durability
- (Q) Testing and Analysis
- (R) Cost

Technical Targets

Eltron's hydrogen membrane system has demonstrated high flux rates of >99.99% pure hydrogen at expected temperatures and differential operating pressures. This project is currently focused on scaling up these membranes while meeting the following 2015 DOE technical targets for dense metallic membranes:

and 250 lbs/day hydrogen separation will be designed, constructed, and operated. Eltron was awarded an ARRA project to further scale up this technology to a 4-10 ton per day pre-commercial module scale. The approach for the ARRA portion of the project is to continue membrane development, conduct pre-front end engineering design and front end engineering design engineering packages for the selected pre-commercial module site; and to design, construct, and operate the pre-commercial module and conduct appropriate engineering analyses.

Results

Figure 1 shows a general schematic of Eltron’s membrane system. The membrane is composed of three dense metal alloy layers. The center layer is 500 microns thick and is a low-cost metal alloy with high hydrogen permeability. A thin catalyst layer (<1 micron) is deposited on both the inside and outside surface of the membrane. High pressure shifted syngas is fed to the outside surface of the membrane. Pure hydrogen is collected on the inside of the tube. This membrane was designed to operate at water-gas shift conditions and retain CO₂ at high pressures to minimize compression costs for CO₂ capture and sequestration.

In FY 2011, Eltron scaled up the manufacturing of these tubular membranes to 5 ft-long tubes. These tubes are 1/2 inch outside diameter tubes with a wall thickness of 500 microns. Eltron deposits metal alloy catalysts on the inside and outside surface of the tubes. A scanning electron microscope image of a deposited catalyst layer is shown in Figure 2. The deposited catalyst is uniform, dense, and well-adhered to the bulk metal surface.

Two foot pieces of membrane were tested at Eltron at 340°C and a differential pressure of 400 psig in a simulated water-gas shift feed stream. Figure 3 shows the observed hydrogen flux as a function of time. A stable flux rate of

28 scfh/ft² was observed for 16 hours. This flux rate was lower than expected due to the effect of concentration polarization inherent in low-flow rate bench-scale reactors. In this particular test the membrane was able to recovery 70% of the hydrogen in the feed stream.

Finally, Eltron designed and constructed the first reactor in our three step scale up plan. Figure 4 shows the constructed sub-scale engineering prototype. This reactor was designed to separate up to 12 lbs/day of hydrogen from a gasified coal feed stream at Eastman Chemical Co. site in Kingsport, TN.

On the ARRA portion of the project Eltron has down-selected URS as the engineering, procurement, and construction firm for the pre-commercial module. URS and Eltron are evaluating three potential sites for operating the pre-commercial module.

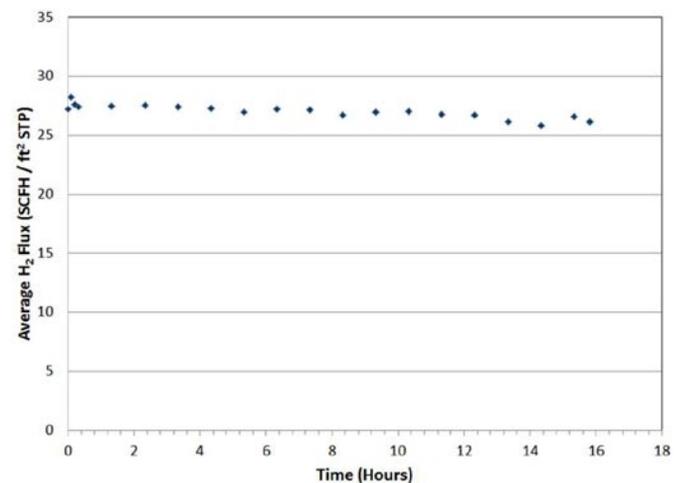

FIGURE 3. Hydrogen Flux vs. Time Recorded for a Two Foot-Long Membrane Tested at 340°C and 400 psig Differential Pressure

FIGURE 4. Completed Sub-Scale Engineering Prototype

Conclusions and Future Directions

In FY 2011 Eltron scaled up manufacturing of our tubular membrane and successfully tested membranes up to two feet long under expected operating conditions. In addition, Eltron designed, constructed, and installed the first scale-up reactor. During the next FY Eltron will operate the sub-scale engineering prototype, update our economic models with the results, and begin the design process for the next scale up step. Front end engineering design will be conducted on the down-selected site for the pre-commercial module.

Subcontractors:

- Power & Energy, Inc., Ivyland, PA
- Energy & Environmental Research Center, University of North Dakota, Grand Forks, ND

Project Start Date: October 1, 2010
 Project End Date: December 31, 2011

Fiscal Year (FY) 2011 Objectives

- Construct, test, and demonstrate a PdCu metallic tubular membrane micro-channel separator capable of producing 2 lb/day of H₂ at ≥95% recovery when operating downstream of an actual coal gasifier.
- Quantify the impact of simulated gas composition and temperature on separator performance.
- Compare the performance and durability of a surface-modified, higher H₂ flux PdCu membrane with the baseline PdCu tubular membrane.
- Evaluate various materials of construction for the separator's non-Pd structural parts to ensure durability under harsh gasifier conditions.
- Perform an engineering analysis using National Energy Technology Laboratory (NETL) guidelines of the separator design based on gasifier test performance for the co-production of electric power and clean fuels.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Separations section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan [1]:

- (K) Durability
- (L) Impurities

Technical Targets

The focus of this project is to construct, test, and demonstrate a PdCu separator capable of producing 2 lb/day H₂ operating downstream of a coal gasifier. As such, the emphasis is on achieving progress against the DOE technical targets pertaining to impurities (sulfur and CO tolerance) and durability. The current progress toward the DOE's 2015 technical targets for hydrogen separation is given in Table 1.

TABLE 1. Technical Progress for the Project as Measured Against the DOE's Technical Targets for Hydrogen Separation

Performance Criteria	Units	DOE 2015 Target	Current Status
H ₂ Flux	ft ³ h ⁻¹ ft ⁻²	300	125 (500°C, enhanced PdCu) (200 psia feed pressure, 185.3 psid)
Temperature	°C	250–500	250–600
Sulfur tolerance	ppmv	>100	618 h at 5–39 ppmv S (0.008 psia S) >24 h at 236–963 ppmv S (0.0104–0.0425 psia S) [8 h at 236 ppmv S (0.0104 psia S)] [5 h at 472 ppmv S (0.0208 psia S)] [4 h at 708 ppmv S (0.0312 psia S)] [7.5 h at 963 ppmv S (0.0425 psia S)] With reversible, low impact on permeability
Cost	\$/ft ²	<100	400–500 (metal cost, without recycle & leasing strategy)
ΔP operating capability	psi	800–1,000	400
CO tolerance	–	Yes	13.3% CO at 90 psia >9% CO at 204.7 psia
H ₂ purity	%	99.99	99.9999
Stability/Durability	Years	5	1,031 h

FY 2011 Accomplishments

- Demonstrated negligible impact of gas species for temperatures ≥400°C and pressures ≤200 psia. Sulfur partial pressures up to 0.008 psia and CO partial pressures up to 2 psia do not affect H₂ flux for temperatures ≥400°C.
- Identified potential non-membrane materials of construction superior to SS-316.
- Constructed four laboratory-scale separators and two pilot-scale separators capable of separating >2 lb/day H₂.
- Compared the performance and durability of a surface-modified, higher H₂ flux PdCu membrane with the baseline PdCu tubular membrane.

Introduction

Advancements in hydrogen (H_2) membrane separation are critical to allow the development of a viable H_2 economy based on coal/biomass processing with CO_2 capture. United Technologies Research Center (UTRC), in collaboration with Power+Energy, Inc. (P+E) and the Energy & Environmental Research Center at the University of North Dakota (EERC), therefore proposed to demonstrate palladium (Pd)-based membrane separation of H_2 from coal-derived syngas at the pre-engineering/pilot scale.

In Phase I, the objectives are to: (1) construct, test, and demonstrate a PdCu metallic tubular membrane micro-channel separator capable of producing 2 lb/day of H_2 at $\geq 95\%$ recovery when operating downstream of an actual coal gasifier; (2) quantify the impact of simulated gas composition and temperature on separator performance; (3) compare the performance and durability of a surface modified, higher H_2 flux PdCu membrane with the baseline PdCu tubular membrane; (4) evaluate various materials of construction for the non-Pd separator structural parts to ensure durability under harsh gasifier conditions; (5) perform an engineering analysis using NETL guidelines of the separator design based on gasifier test performance for the co-production of electric power and clean fuels; and (6) select a gasification facility partner for Phase III.

Approach

This project is a continuation of the UTRC-led team's approach to increase the technology readiness level of Pd-based metallic membranes for H_2 separation from coal-biomass gasifier exhaust or similar H_2 -containing gas streams. The current project is aimed at demonstrating at the pre-engineering/pilot scale the separation of H_2 from coal-derived syngas using a proprietary, surface-modified, palladium-copper (PdCu) tubular membrane separator. It will include testing of separators capable of producing 2 lb/day of H_2 and, in follow-on phases, separators capable of producing 100 lb/day of H_2 .

UTRC's subcontractor, P+E will manufacture the separators and EERC will test the separators downstream of a coal gasifier. The main objective of the first phase (Phase I) of the project is to construct, test, and demonstrate a PdCu dense metallic tubular membrane separator capable of producing 2 lb/day of H_2 at a minimum 95% recovery when operating downstream of an actual coal gasifier. The project will also acquire engineering data to reliably scale up PdCu membrane separators to a size of 4 tons per day (tpd) of H_2 and assess the combined effects of coal gas constituents and trace contaminants on membrane performance and durability. The data will be evaluated against the DOE's 2015 targets for H_2 membrane separation and used in an engineering analysis of the separation and production method using NETL guidelines.

Results

By the end of June 2011, P+E had delivered four out of six laboratory-scale ($\approx 0.1 \text{ ft}^2$) separators as well as two out of six pilot-scale ($\approx 1.5 \text{ ft}^2$) separators. Based on the information from preliminary corrosion tests, as well as the availability of alloys in the forms needed for fabrication, it was decided that all remaining separators to be delivered in Phase I of the project would be made out of C-22 and/or C-276. As a result, two of the laboratory-scale separators and both pilot-scale separators were made using these alloys. Due to manufacturing delays, the first two pilot-scale separators were made with non-surface enhanced PdCu alloys. All future pilot-scale separators will be made with the enhanced PdCu membranes.

Seven separators (identified as 5265, 5266, 5276, 5277, 5290, 5291, and 5297) have been evaluated for their hydrogen separation capability. An Arrhenius plot of the pure hydrogen permeability for each of the separators versus temperature is given in Figure 1. All but two separators (5266 & 5297) demonstrated similar performance, which was greater than that of conventional PdCu, although not as high as the original target for the enhanced PdCu.

Separator 5266 was a single-tube membrane separator from a previous DOE contract (DEFC2607NT43055) that was sent to EERC for gasifier testing and returned to UTRC. The data obtained at UTRC for separator 5266 indicated that the separator was leak tight and that performance of the membrane was equivalent to conventional PdCu after gasifier testing. Separator 5266 was used to establish reproducibility between EERC's and UTRC's testing hardware and will be characterized to determine the impact of gas contaminants on its materials of construction.

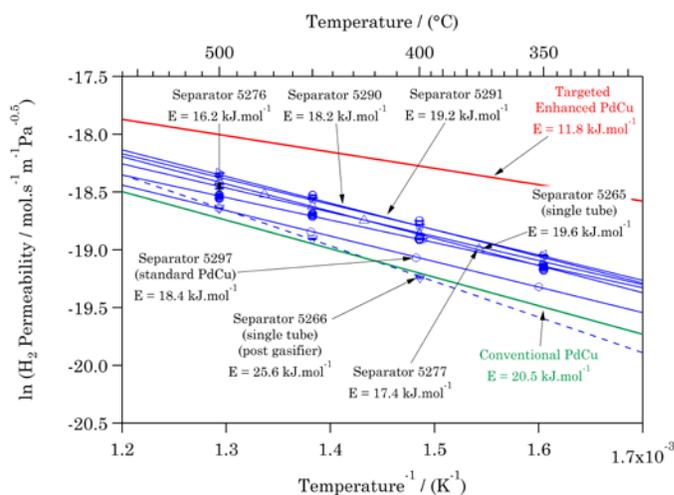

FIGURE 1. Arrhenius plot of the pure hydrogen permeability versus temperature for the PdCu separators tested so far on this project. Shown for reference are the hydrogen permeability curves for conventional PdCu membranes as well as the target performance for the surface modified, enhanced PdCu membranes.

Separator 5276 was tested for 1,031 hours, including 618 hours of hydrogen sulfide (H_2S) exposure with no signs of performance degradation. The impact of non-sulfur gas contaminants on hydrogen permeability for temperatures greater than or equal to $400^\circ C$ appeared to be negligible when compared to pure hydrogen experiments as shown in Figure 2. Furthermore, the addition of H_2S to the same gas mixtures also had a negligible effect on the hydrogen permeability as shown in Figure 3. One objective of the sulfur tests was to determine the length of time required for the membrane performance to come to a steady state upon exposure to H_2S . Preliminary durability data suggested that the separator needed to be equilibrated for at least 100 hours before stable gas contaminant testing could be measured.

Separator 5297 is a pilot-scale separator that was tested with pure H_2 and H_2/N_2 mixtures at feed pressures of 44.1 psia and 88.2 psia, respectively, to verify separator performance with UTRC's separator model. The separator was also tested with H_2S in H_2 to verify its ability to withstand gasifier poisons. The maximum H_2S concentration used was 963 ppmv at 44.1 psia, approximately five times the maximum sulfur partial pressure used for testing separator 5276. At $500^\circ C$, the reduction in H_2 permeation from the 0.043 psia H_2S was approximately 50% but the H_2 performance fully recovered after exposure to pure H_2 . Separator 5297 was also pressure checked at 400 psia and found to be leak free. The separator was exposed to four thermal cycles in H_2/N_2 from $200^\circ C$ to $500^\circ C$ with no performance degradation and no leaks. Separator 5297 was shipped to EERC after a total of 356 hours of testing at UTRC to serve as the test article for a coal gasifier test before the end of September.

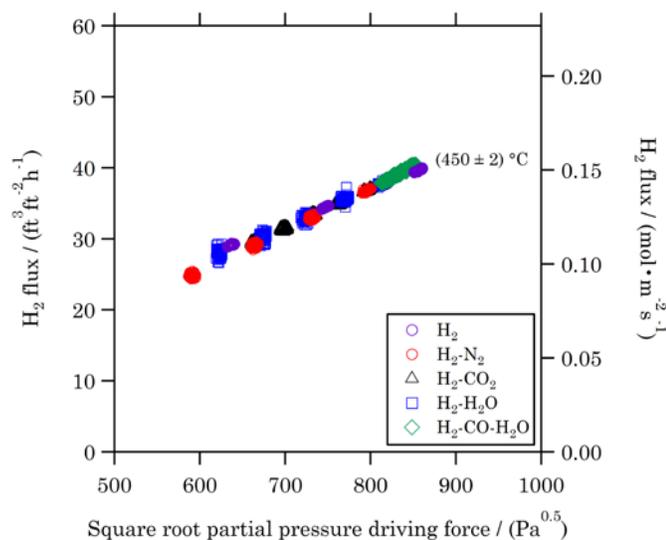

FIGURE 2. Hydrogen flux at $(450 \pm 2)^\circ C$ versus the square root hydrogen partial pressure driving force for separator 5276 for different gas mixtures, not including H_2S . The separator was tested at feed pressures varying from 29.4 psia to 200 psia with different binary and ternary gas mixtures.

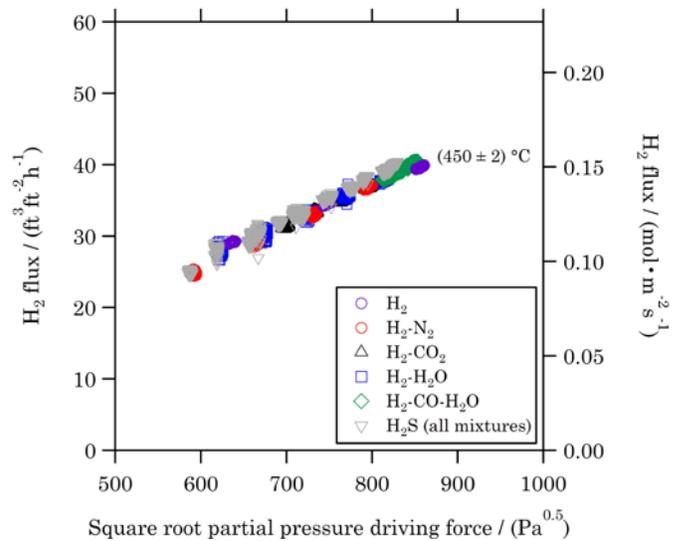

FIGURE 3. Hydrogen flux at $(450 \pm 2)^\circ C$ versus the square root hydrogen partial pressure driving force for separator 5276 for different gas mixtures, including H_2S . The separator was tested at feed pressures varying from 29.4 psia to 200 psia with different binary and ternary gas mixtures. The H_2S gas concentration was varied from 5 ppmv to 39 ppmv.

UTRC began preliminary corrosion testing under a slightly modified DOE test 2A condition at $500^\circ C$ in February. Initial Round 1 coupon tests were performed for 474 hours with samples of SS-316, SS-309, C-22 and C-276. After 474 hours of testing, it was observed that SS-309, C-22, and C-276 had weight gain constants that were two orders of magnitude lower than SS-316. This was likely due to their improved resistance to H_2S compared to SS-316. Some coupons exhibited crevice corrosion where the metal samples sat in a ceramic “dee-tube.” Thus, a new fixture was designed for Round 2 testing in which samples hang from an alumina rod to minimize this effect.

The Round 2 corrosion test included two Oak Ridge National Laboratory alloys (OC-10 and OC-11) as well as HR-120 and SS-310. Corrosion testing of these alloys is currently in progress, with more than 1,500 hours of accumulated run time. Round 2 corrosion testing will continue until approximately 2,000 hours of total run time has been achieved, after which the Round 1 coupon tests will be repeated for approximately 2,000 hours.

In addition to lab-scale tests performed at UTRC, a total of 24 samples were prepared for exposure testing under actual gasifier conditions at the National Carbon Capture Center (NCCC) in Alabama. The coupons were made of eight different alloys (SS-316, SS-309, SS-310, HR-120, C-22, C-276, OC-10, and OC-11) and were sent to NCCC in late March.

Conclusions and Future Directions

- Dense metallic, PdCu membranes can fully tolerate the DOE test protocol conditions for pressures up to 200 psia and temperatures between 400°C and 500°C.
- The impact of H₂S for partial pressures <0.008 psia on H₂ permeability was insignificant for temperatures between 400°C and 500°C, although exposure to partial pressures as high as 0.043 psia H₂S showed a reduction in permeability up to 50% which was completely reversible.
- The surface enhanced PdCu membranes show higher hydrogen permeability than the conventional PdCu, particularly at lower temperatures (<450°C).
- Several non-membrane materials of construction have been identified that have superior corrosion resistance to the DOE protocol conditions compared to SS-316.
- Samples of the non-membrane materials of construction were sent to the NCCC in Alabama for exposure testing under real gasifier conditions.
- A single-tube separator was exposed to coal gasifier exhaust and will be characterized to determine the impact of gas contaminants on the materials of construction.
- A pilot-scale separator will be tested at 400 psia downstream of a coal gasifier at EERC by September to evaluate the impact of real gasifier exhaust on membrane performance.

Contract Number: DE-FC26-07NT43058

Subcontractor:

Adsorption Research, Inc. (ARI), Dublin, OH

Project Start Date: May 7, 2007

Project End Date: November 6, 2011

Fiscal Year (FY) 2011 Objectives

- Synthesis of composite Pd and Pd/alloy porous metal (316L, Inconel, Hastelloy) membranes for water-gas shift (WGS) reactors with long-term thermal, chemical, and mechanical stability with special emphasis on the stability of H₂ flux and selectivity.
- Demonstration of the effectiveness and long-term stability of the WGS membrane shift reactor for the production of fuel cell quality H₂.
- Research and development of advanced gas clean-up technologies for sulfur removal to reduce the sulfur compounds to <2 ppm (ARI).
- Development of a systematic framework towards process intensification to achieve higher efficiencies and enhanced performance at a lower cost.
- Rigorous analysis and characterization of the behavior of the resulting overall process system, as well as the design of reliable control and supervision/monitoring systems.
- Assessment of the economic viability of the Pd-based membrane reactors integrated into integrated gasification combined cycle (IGCC) plants through a comprehensive calculation of the cost of energy output and its determinants (capital cost, operation cost, fuel cost, etc.), followed by comparative studies against existing pertinent energy technologies.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (K) Durability associated with the determination of optimum temperature for the WGS reaction.
- (L) Impurities associated with adsorbent selection and pressure swing adsorption (PSA) system build-up, testing completed with syngas + H₂O, H₂S and carbon oxysulfide (COS).
- (M) Membrane defects associated with the study of membrane surface upon WGS reaction.
- (N) Hydrogen selectivity, leak growth will be mitigated by working at 400-450°C.
- (P) Flux and reproducibility of high H₂ flux targets already achieved. Setting of Pd thickness and support characteristics to meet 2015 DOE targets.
- (R) Cost, two-dimensional (2D) model for catalytic membrane reactor (CMR) simulations, safety and economic analysis.

Technical Targets

A number of composite Pd and Pd/alloy porous metal (316L, Inconel, Hastelloy) membranes for WGS reactors have been synthesized and long-term thermal, chemical, and mechanical stability and hydrogen flux and selectivity have been determined. Technical targets and current membranes operational data are listed in Table 1. The typical microstructure of composite Pd membranes listed in Table 1 is shown in Figure 1.

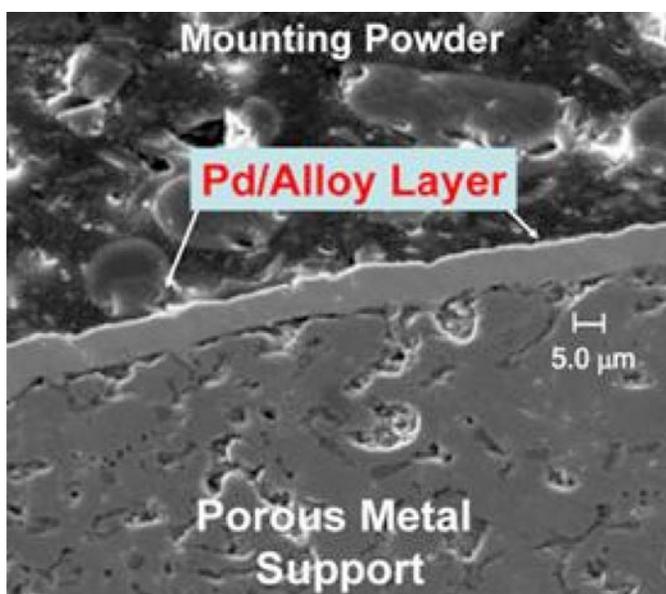

This project is conducting fundamental studies on composite Pd membranes permeance and selectivity stability in WGS reaction conditions. Insights gained from these studies will be applied toward the design and synthesis of hydrogen storage materials that meet the following DOE 2011 hydrogen storage targets:

- Durability (K): we are targeting a 1,000 hour WGS reaction long-term experiment with a stable H₂ permeance and H₂/He selectivity.
- Impurities (L): membranes were tested up to 20 ppm H₂S in pure H₂.
- Membrane defects (M): All membrane surfaces were studied after testing to investigate surface changes in syngas atmospheres.
- Hydrogen selectivity (N): a selectivity (H₂/N₂) of 10,000 at 180 psig was targeted.

**FIGURE 1.** Composite Pd/Porous Metal Support Microstructure

- Flux (P): H_2 permeances ranging from 29.2 to $43.8 \text{ scfh}/\text{ft}^2 \text{ psi}^{0.5}$ were targeted to achieve DOE 2010-2015 targets.
- Cost (R): 1,000 $\$/\text{ft}^2$ to meet DOE's target.

FY 2011 Accomplishments

- Shown and re-produced selectivity H_2/He stability at 400-450 $^{\circ}\text{C}$ over thousands of hours.

- Consistently achieved composite Pd membranes with thicknesses ranging between 4-12 μm porous metal supports indicating the reproducibility of our fabrication method.
- Pd/316L-PSS membranes have been synthesized and tested under WGS and $\text{H}_2/\text{H}_2\text{O}$ mixed gas conditions at 400 $^{\circ}\text{C}$ for 65 and 225 hours, respectively. The membrane leak growth was less than 11% over those testing periods.
- An integration option of the WGS-composite membrane reactor into IGCC plants was proposed and the performance of the industrial-scale WGS-composite membrane reactor's performance was assessed via a more accurate 2D model to achieve 98% CO conversion and 95% H_2 recovery.
- In the net present value (NPV)-based comparative assessment analysis, the positive NPV of \$40M for IGCC-membrane reactor (MR) with carbon capture with a net power output of 550 MW showed the advantage of the membrane reactor technology over more traditional options such as supercritical pulverized coal (SC-PC), IGCC baseline, IGCC-PBR (IGCC with traditional packed bed reactor) with CO_2 capture in the presence of CO_2 taxes.
- The uncertainty analysis performed with the Monte-Carlo techniques to assess the risk associated with the Pd-based membrane reactor technology indicated that regulatory action on CO_2 emissions would induce an appealing NPV profile for the IGCC-MR technology option.
- Accomplished PSA studies in collaboration with ARI.

Introduction

Combining the coal-derived syngas WGS reaction in a Pd-based membrane reactor leads to high purity hydrogen (>99.999%), high pressure CO₂ ready to be sequestered and energy and capital costs savings. The integration of the membrane technology into coal-fired power plants is an attractive option particularly due to benefits associated with both H₂ and CO₂ separation. MR technology should be economically competitive with the SC-PC, IGCC baseline and IGCC-PBR. Thus, the NPV-based economical analysis was performed on the basis of co-production of hydrogen and power from coal using Pd-based composite membrane reactors with sequestration. Moreover, the inherent uncertainty of the inputs of the NPV model has to be recognized and explicitly taken into account in investment decision-making.

However, coal gasification feedstocks raised challenges such as hydrogen permeance stability under H₂S, COS and heavy metal pollutants [1,2]. Selectivity stability was the second largest challenge since thin electrolessly deposited membranes developed leaks at temperatures ranging from 400 to 450°C [3]. The objective of this project was to develop a membrane module for the production of hydrogen using WGS reaction working at temperatures close to 450°C and under real gasification conditions.

Approach

Composite Pd membrane preparation consisted of the pretreatment of the porous stainless steel support i.e. deposition of an intermetallic diffusion barrier and a grading layer, surface activation and Pd deposition by the electroless plating method [4-5]. Pd thicknesses of 4-12 microns were targeted in order to reach DOE's flux target without compromising H₂/He leak stability at 450-500°C. WPI worked in collaboration with ARI to develop a PSA process to decrease contaminants level in syngas feed. In a parallel fashion Pd-Au alloy membranes and special protective coatings are being developed at WPI to mitigate H₂S and other coal contaminants. A complete WGS-CMR, seen in Figure 2, was also built at WPI to test 1-inch outer diameter, 10-inch long composite Pd membranes with synthetic syngas shown in Figure 3.

A comprehensive economic analysis was performed to identify the industrial-scale membrane reactor module cost, capital and operating and maintenance costs of the whole IGCC plant with the Pd-based membrane reactor technology. The NPV model was included into the economical analysis to compare the profitability of power plants with a net power output of 550 MWe both with and without future CO₂ taxes. In addition, the consequences and impact on project value of uncertain futures was calculated with the Monte Carlo simulation effectively. Detailed Monte Carlo simulations integrated into the detailed NPV model were performed in order to explicitly take into account the main uncertainty drivers associated with the NPV of

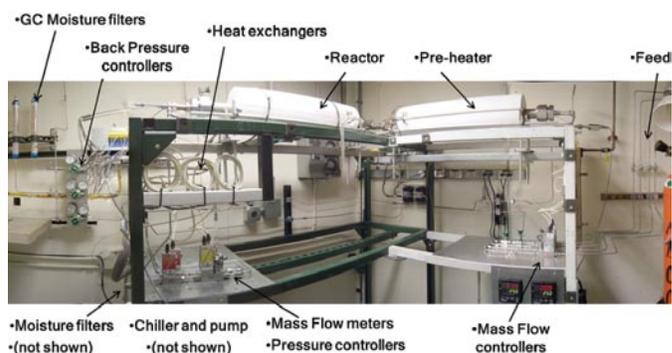

FIGURE 2. WGS-CMR for the Test of 1-Inch Outer Diameter, 10-Inch Long Composite Pd-Alloy/Porous Metal Membranes

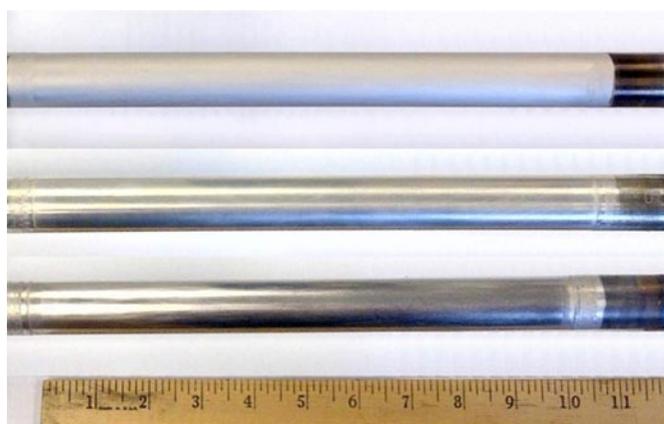

FIGURE 3. 1-Inch Outer Diameter, 10-Inch Long Pd/Porous 316L Composite Membranes

the whole IGCC-MR, namely, the plant capacity factor, initial CO₂ tax, CO₂ tax growth rate, nominal discount rate, inflation rate, electricity selling price, Pd price, support price and membrane life.

Results

- Achieved excellent long-term H₂/He selectivity stability, of essentially infinite value, over over a total testing period of ~3,550 hours (>147 days) at 300-450°C and at a ΔP of 15-100 psi (P_{Low}=15 psia).
- At 450°C, achieved re-producible, long-term H₂/He selectivity stability with several membranes with H₂ purity ≥99.99% over a testing period of 30 to 90 days.
- Achieved flux of ~359 scfh/ft², which exceeded DOE's 2010 and 2015 H₂ flux targets (T=442°C and ΔP of 100 psi [with P_{Low}=15 psia]). Such high fluxes were also achieved on high surface area composite Pd membranes 1-inch outer diameter, 10-inch long shown in Figure 3.
- Conducted an additional ~3,000 hours of mixed gas permeation experiments (61.7% H₂, 37.1% CO₂ & 1.2% carbon monoxide [CO] w/ and w/o 19% steam).

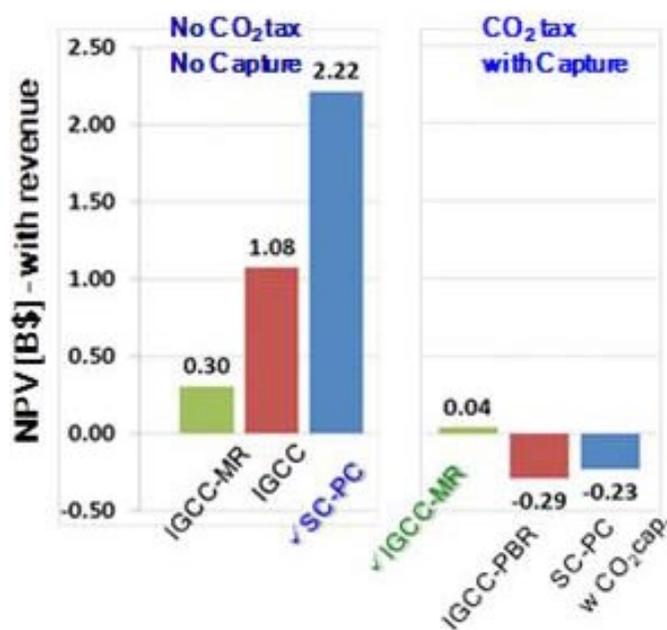

FIGURE 4. Single-Point NPV with Revenue Results of the Power Plants in Case of no CO₂ Tax (Without Capture) and with CO₂ Tax (With Capture)

- Reduced the number of synthesis steps for the large-scale membrane preparation for potential commercialization of WPI's composite Pd-based membrane production technologies.
- Achieved 99% total CO conversion and 89.9% H₂ recovery in a 12.5 μm-thick Pd-based CMR operated at ~350°C, ΔP=200 psi (P_{Low}=15 psia) H₂O/CO=1.44 and gas hourly space velocity (GHSV_{stp})=150 h⁻¹, exceeding equilibrium conversion of 93.4% and traditional packed bed conversion of 92.7% [5].
- Successfully completed steady-state methane steam reforming (MSR) and WGS reaction modeling studies and process intensification analysis.
- Successfully completed unsteady-state WGS reaction modeling studies and implemented process control strategies.
- Successfully completed a 2D model for WGS tube and shell membrane reactors.
- Successfully used the 2D model to calculate CO conversion and H₂ recovery for different configurations of MR integration into IGCC plants.
- Completed capital, operating and maintenance costs of a IGCC-MR plant.
- Completed NPV analysis of IGCC, IGCC-PBR, IGCC-MR and SC-PC plants.
- Completed isotherm measurements for the selected adsorbents (ARI).
- Completed the PSA system construction and PSA testing at 200°C and a feed pressure of 200 psia (with P_{low}=1 atm.), (ARI).

- A WGS experiment was conducted with a 10.3 μm Pd/316L-PSS membrane over 65 hours at 400°C, 200 psig, and with a feed rate of 2,100 h⁻¹ syngas feed (23% CO, 45% H₂O, 22% H₂, 10% CO₂). A stable CO conversion of 96% was achieved with an H₂ recovery in excess of 80%. The H₂ recovery declined by 10% over the course of the reaction due to coke formation on the membrane surface.
- The single estimate/projection NPV results showed that the IGCC-MR was an economically attractive technology option generating a positive NPV in a scenario with a \$25/ton CO₂ tax starting in 2015 as shown in Figure 4. The negative NPV values of IGCC-PBR and SC-PC with CO₂ capture plants would possibly preclude these options from investment consideration in the presence of regulatory action on carbon emissions.
- The expected total capital investment (average) for membrane reactor module consisting of 10 micron thick Pd-based membrane tubes was estimated at 1,285 \$/ft² which was slightly higher than the 2015 DOE target of 1,000 \$/ft² with a maximum and minimum of 2,267 and 310 \$/ft² (lower than the 2015 target), respectively.
- A comparatively more attractive NPV/cost distribution profile obtained in the IGCC-MR case assessed against the ones in the IGCC-PBR and SC-PC cases in the presence of regulatory action on CO₂ emissions made the Pd-based membrane reactor technology option integrated into an IGCC power plant a promising investment choice.

Conclusions and Future Directions

- Membrane preparation led consistently to thin 4-12 μm membranes. Some membranes experienced relatively low flux when considering their thicknesses indicating the presence of mass transfer resistance in the porous metal support.
- Consistent H₂/He selectivities over thousands of hours were obtained at 400-450°C.
- The membrane stability during long-term WGS reaction and H₂/H₂O mixed gas conditions has been demonstrated, and the synthesis methodology necessary for producing those membranes has been developed.
- Total capital investment for the membrane reactor module was calculated to be around 1,285 \$/ft² very close to the DOE target (1,000 \$/ft²).
- NPV analysis suggested that if CO₂ taxes were implemented, IGCC-MR with carbon capture would be a quite attractive technology option. The most significant risk source was technological (reflected on lower capacity factor values) due to the lack of IGCC-membrane reactor operating experience, adversely impacting project value.
- Monte-Carlo techniques were used to study the effect of uncertainties namely, capacity factor, initial CO₂ tax, CO₂ tax growth rate on project economic value,

suggesting that regulatory action on CO₂ emissions, would induce an appealing NPV-profile for the IGCC-MR technology option.

Future Work (to be conducted under new award #FE0004895)

- A long-term WGS experiment will be conducted with a Pd-316L/PSS membrane for up to 1,000 hours at 400°C, 200 psig, and with a feed rate of 2,700 h⁻¹ syngas feed (19% CO, 55% H₂O, 18% H₂, 8% CO₂).
- Pd-Au and Pd-Ru membranes will be synthesized for testing under WGS conditions for up to 200 hours with up to 20 ppm H₂S present in the feed.
- Flexibility analysis will be included into the NPV-based economical model for the integration of the membrane reactor technology into IGCC plants to increase the value of the project (increased NPV) and also to decrease the risk associated with the membrane reactor technology.
- Prepare thin and stable composite pure Pd membranes on 1-inch outer diameter PSS 316 and test them under real gasification conditions at National Center for Carbon Capture, Wilsonville, Alabama.
- Conduct DOE Test 2A (simulated effluent of WGS reactor) on MembraGuard[®]-coated Pd membrane to further confirm the stability of MembraGuard[®]-coated membrane under WGS reaction conditions.
- Composite Pd membranes will be prepared on new supports with higher initial He permeability in order to decrease mass transfer resistance within the support.

 Project End Date: April 30, 2012

Technical Targets

TABLE 1. GES Progress toward Meeting DOE Targets for Distributed Electrolysis Hydrogen Production

Characteristics	Units	2012/2017 Target	GES Status
Hydrogen Cost	\$/kg H ₂	3.70/<3.00	4.66*
Electrolyzer Capital Cost	\$/kg H ₂	0.70/0.30	0.60
Electrolyzer Energy Efficiency	% (LHV)	69/74	75**

*Using H2A model rev 2.1.1. A cost of \$1.80 is included for H₂ compression, storage, and delivery

** Stack efficiency; System efficiency ~68%

LHV – lower heating value

FY 2011 Accomplishments

Membrane

- Demonstrated enhanced dimensionally stable membrane (DSM™) performance (>Nafion® 1135 membrane).
- Completed 5,000-hour life-test with DSM™ (@80°C).
- DSM™ operating lifetime estimated at 55,000 hours.
- Reduced membrane support costs by one order of magnitude in the past year.

Cell-Separator

- Demonstrated reduced hydrogen embrittlement in titanium/carbon cell-separator.
- Projected longevity of the carbon/titanium cell-separators (>60,000 hours).

Electrolyzer Stack and System Design

- Completed fabrication of electrolyzer stack utilizing low-cost components.
- Reduced electrolyzer stack costs by 60% over a four year period.
- Completed fabrication of electrolyzer system incorporating a high-efficiency hydrogen dryer.
- Completed extensive safety review of electrolyzer system.
- Completed modeling of electrolyzer capital and operating costs; performed economic analysis using the DOE H2A model illustrating cost-reductions.

Fiscal Year (FY) 2011 Objectives

Develop and demonstrate advanced low-cost, moderate-pressure proton exchange membrane (PEM)-based water electrolyzer system to meet DOE targets for distributed electrolysis:

- Develop high-efficiency, low-cost membrane
- Develop long-life cell-separator
- Develop lower-cost prototype electrolyzer stack and system
- Demonstrate prototype at the National Renewable Energy Laboratory (NREL)

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (G) Cost - Capital Cost
- (H) System Efficiency

Introduction

The DOE has identified hydrogen production by electrolysis of water at forecourt stations as a critical technology for transition to the hydrogen economy, and as the hydrogen economy matures, for hydrogen production at centralized locations using renewable energy sources. However, state-of-the-art electrolyzers are not economically competitive for forecourt hydrogen production due to their high capital and operating costs. The cost of hydrogen produced by present commercially available electrolysis systems is estimated to be \$5.20/kg-H₂, considerably higher than the DOE target of \$3.70/kg-H₂ by 2012 [1]. Analysis of electrolyzer systems performed by GES and others using the DOE H2A model indicate that the major cost elements are the cost of electricity, the capital costs of electrolyzer stacks and systems, and the high cost of hydrogen compression, storage, and delivery.

GES has developed PEM-based electrolyzer technology that operates at differential pressure for producing hydrogen at moderate to high pressure directly in the electrolyzer stack, while oxygen is evolved at near-atmospheric pressure. In this system, liquid water, which is a reactant as well as coolant, is introduced into the oxygen side at near-atmospheric pressure. The goals of the project are to reduce the cost of the stack and system, improve electrolyzer efficiency, and to demonstrate electrolyzer operation at moderate pressure.

Approach

To reduce the cost of PEM-based electrolyzers, GES is improving electrolyzer stack efficiency and reducing stack cost through development of an advanced low-cost, high-strength, membrane using a perforated polyimide support imbibed with perfluorosulfonic acid (PFSA) ionomer. GES is also reducing stack capital cost and increasing stack life through development of a long-life bipolar stack cell-separator, decreasing stack costs by initiating scale-up to a larger active area, and reducing the system capital cost by applying commercial production methods to PEM-based electrolyzer systems. In each of the key development areas, GES and its team members are conducting focused development of advanced components in laboratory-scale hardware, followed by life-testing of the most promising candidate materials. The project will culminate in fabrication and testing of an electrolyzer system for production of 0.5 kg-H₂/hr and validation of the electrolyzer stack and system in testing at NREL.

Successful development of the advanced electrolyzer stack and system will result in a high-efficiency; low-capital-cost electrolyzer that will meet the DOE cost targets for hydrogen production, assuming high-volume production. This will provide competitively priced hydrogen for delivery at forecourt stations to enable transition to the hydrogen economy.

Results

DSM™ Membrane Performance: To improve electrolyzer efficiency, GES has developed an advanced supported membrane having an ionic resistance comparable to that of a 0.0020- to 0.0035-inch-thick Nafion® membrane, but having significantly improved mechanical properties. This advanced membrane is referred to as a dimensionally stable membrane (DSM™) due to the membrane support that minimizes changes in dimensions (swelling/contraction) under high-pressure operation and with changes in water content. The support structure utilized in the development of the DSM™ consists of a polyimide (Kapton®) base film with a definable open pattern. The support structure is then imbibed with 1100-equivalent-weight (EW) PFSA ionomer to a thickness of 2 to 3 mil (0.002-0.003"). Initially the membrane support structures were fabricated using a laser-drilling procedure. A more cost-effective technique of fabricating the support structures via chemical-etching has recently been implemented by GES, reducing the cost of the membrane by one order of magnitude.

Polarization scans of the DSM™ were conducted in scaled-up, full-size electrolyzer hardware through a current density range of 0-2,000 mA/cm², a differential pressure of 300 psid, and temperature of 80°C. Results are compared to Nafion® 1135 membrane with similar cathode and anode electrode structures, Figure 1. During testing, the DSM™ exceeded the criterion for performance: exhibiting lower cell voltages and thus higher cell efficiencies than that of a Nafion® 1135 membrane.

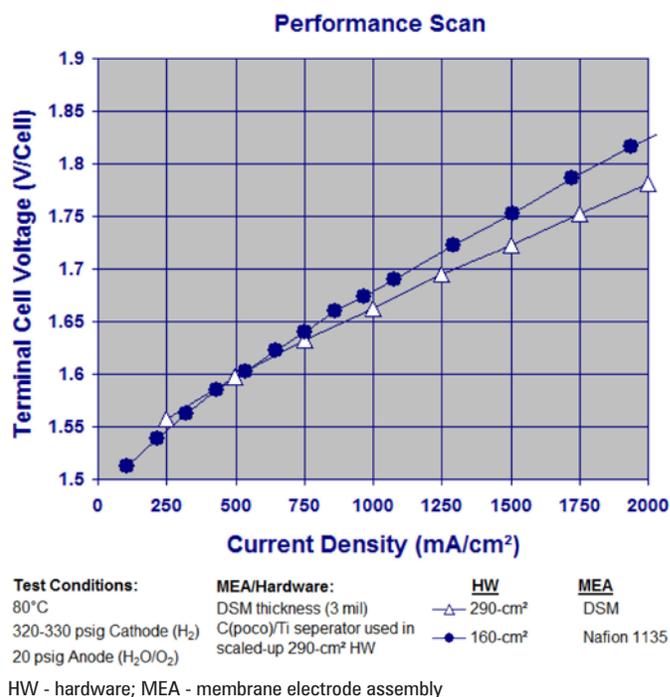

FIGURE 1. Performance Scans: DSM™ vs. Nafion® 1135

Durability of the DSM™ was also demonstrated in the scaled-up, hardware via fluoride release rate (FRR) measurements at constant-current operation. Since PFSA ionomer is used as the membrane material and in the binder for the catalyst layer, the loss of fluoride is used as a measurement of membrane degradation. An FRR rate of $3.7 \mu\text{g F}^- \text{ ion/hr}$ or less than 10 micrograms $\text{F}^- \text{ ion/liter}$ (<10 ppb) was present in the cathode effluent (electro-osmotically transported water) at the end of the 1,000-hour life test. Based on electrolysis FRR results, the lifetime of the DSM™ is projected to be between 45,000 and 55,000 hours, which exceeds the durability requirements of the electrolyzer system. In addition to its durability, the DSM™ exhibits high cell efficiencies in the range of 75% LHV (88.8% higher heating value) at an operating current density of $1,500 \text{ mA/cm}^2$.

Cell-Separator Development: The cell separator is a gas-impermeable conductive sheet that separates the hydrogen and oxygen compartments in the bipolar stack. The separator must be highly conductive, as well as resistant to hydrogen embrittlement and to corrosion in an oxidizing environment. GES's legacy high-pressure naval electrolyzers use a complex multi-layer cell-separator incorporating a conductive compliant member and sheets of niobium and zirconium metal. Zirconium is used due to its high resistance to hydrogen embrittlement. GES has previously evaluated a low-cost, dual-layer titanium cell-separator. Although performance was comparable to that of niobium/zirconium cell-separators, lifetimes were limited to 5,000 hours due to hydrogen embrittlement.

The most promising approach for long-term implementation has been achieved by coating titanium with a low-cost electrically conductive, embrittlement-resistant carbon coating. The challenge was the development of a pinhole-free, highly adherent coating with the required characteristics. Under the cell-separator development task, GES demonstrated performance of a carbon/titanium cell separator in scaled-up 290-cm² electrolyzer stack hardware. Performance is comparable to that of the niobium-zirconium separator. In addition, life expectancy of the carbon/titanium separator, determined via hydrogen-uptake analysis over a 1,000-hour period, indicates lifetimes exceeding the 50,000-hour system requirement.

Electrolyzer Stack and System Fabrication: The full-size (27-cell, 290-cm² active area) electrolyzer stack developed

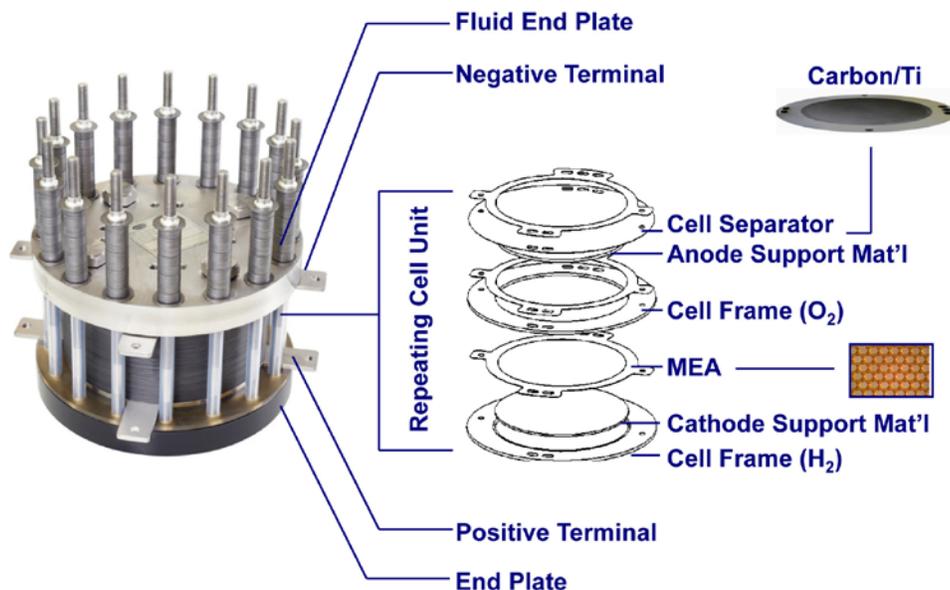

FIGURE 2. Low-Cost Electrolyzer Stack

during this project is shown in Figure 2. The electrolyzer stack, capable of producing $0.5 \text{ kg-H}_2/\text{hr}$ at an operating current density of $1,500 \text{ mA/cm}^2$, is designed with low-cost components. In addition to the use of chemically etched DSM™ and carbon/titanium cell-separators, the electrolyzer stack includes several modifications to GES's legacy hardware; (1) an increase in cell active area from 160 to 290 cm², effectively reducing the number of cells required to produce a given amount of hydrogen, thus reducing the stack manufacturing labor, (2) an overall decrease in the parts count per cell (from 41 to 10), (3) a 75% reduction in anode and cathode catalyst loadings, (4) molded thermoplastic cell frames, resulting in a cost reduction of 95% as compared to machining this component, (5) a 33% reduction in cell frame thickness, thus reducing the anode and cathode support materials and costs by 33%, and (6) a low-cost carbon-steel end plate. As a result of the component and membrane development during this project, the overall projected capital cost of the electrolyzer stack has decreased from greater than \$1,000/kW in 2007 to <\$400/kW in 2011 (Figure 3).

As shown in Figure 4, the system build, undertaken at the Parker facility, is in its advanced stages. The electrolyzer system required detailed planning with respect to system layout and fabrication sequence. Several factors, including specific codes and standards that are pertinent to hydrogen electrolyzer systems, were considered during the system layout. To meet these requirements, the system was designed with three separate compartments; the oxygen (O_2), the hydrogen (H_2), and the electrical (controller and power supply) compartments. The O_2 compartment contains the oxygen gas-phase separator, a circulating liquid pump, and the de-ionized water feed tank. The H_2 compartment encloses a novel high-efficiency (97%) hydrogen dryer assembly, high- and low-pressure hydrogen gas-phase separators, a

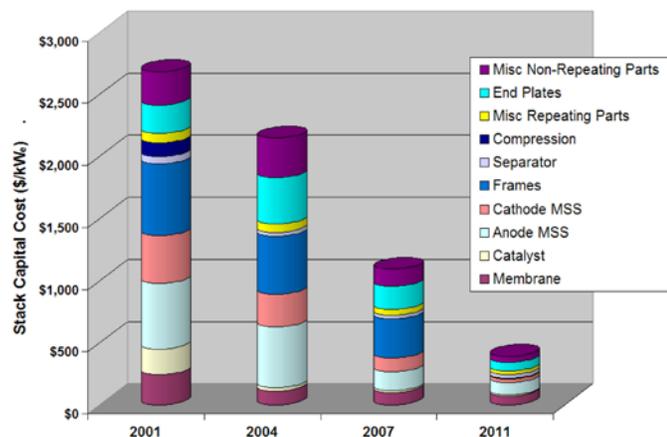

FIGURE 3. Electrolyzer Stack Capital Costs

FIGURE 4. Electrolyzer System

heat exchanger, cooling fans, and various flow valves. The electrolyzer stack is powered via a high-efficiency power supply rated at 94% located in the electrical compartment. The outside platform is also used as the staging area for the nitrogen (N₂) tanks that will provide N₂ gas for purging the electrolyzer stack during start-up and shutdown.

Conclusions and Future Directions

Significant progress has been made in DSM™ membrane development. GES has demonstrated membrane reproducibility and durability as well as a significant improvement in electrolyzer cell efficiency that exceeds the DOE's 2017 efficiency targets. In addition, development efforts conducted under this project have resulted in significant cost reductions in the PEM-based electrolyzer stacks and systems, an increase in the life of the low-cost cell-separators, and improved balance-of-plant components efficiency. The future objectives are to:

- Complete critical design review.
- Install electrolyzer stack into system.
- Assist in system start-up at Parker facilities and evaluate overall performance.
- Deliver and demonstrate the prototype electrolyzer system at NREL for validation.

Project Start Date: September 1, 2009

Project End Date: September 30, 2013

Fiscal Year (FY) 2011 Project Objectives

- Improve electrolyzer cell stack manufacturability through:
 - Consolidation of components.
 - Incorporation of alternative materials and manufacturing methods.
 - Improved electrical efficiency.
- Reduce cost in electrode fabrication through:
 - Reduction in precious metal content.
 - Alternative catalyst application methods.
- Design scale up for economy of scale including:
 - Scale up of the design to a large active area cell stack platform.
 - Development and demonstration of a robust manufacturing process for high volume plate production.
- Quantification of the impact of these design changes through utilization of the H2A model.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(G) Capital Cost

(H) System Efficiency

(J) Renewable Electricity Generation Integration

Technical Targets

TABLE 1. Proton Energy Systems Progress towards Meeting Technical Targets for Distributed Water Electrolysis Hydrogen Production

Characteristics	Units	2012 Target	2017 Target	Proton Status
Hydrogen Cost	\$/gge	<3.70	<3.00	3.46
Electrolyzer Capital Cost	\$/gge	0.70	0.30	0.64
Electrolyzer Energy Efficiency	% (LHV)	69	74	67

gge - gasoline gallon equivalent; LHV - lower heating value
Note: Estimates are based on H2A v2.1, for electrolysis only (compression-storage-delivery not included). Model assumes \$0.05/kWh.
Electrolyzer cost based on 1,500 kg/day capacity, 500 units/year. Efficiency based on system projections and demonstrated stack efficiency of 74% LHV efficiency.

FY 2011 Accomplishments

- Alternate electrode structures enabled 55% less precious metal on the anode (Proton process) and >90% less on the cathode (3M nano-structured thin-film [NSTF] structures).
- A new flow field design resulting in >20% part cost savings (12% stack cost savings) passed production validation and was commercially released.
- Composite bipolar plates from Entegris exhibited stability over >3,000 hours of operation.
- Alternative flow field manufacturing methods were surveyed and a path to additional 50% cost reduction in the subassembly was defined.
- Penn State comprehensive electrolyzer cell model was validated against physical test data and is being leveraged for cell characterization.
- Nitride coatings on flow fields and separators from Entegris, Proton, and Oak Ridge were characterized before and after cell operation and found to remain intact on surface after >500 hours.

Introduction

This project addresses the DOE Hydrogen Program objective for distributed production of hydrogen from proton exchange membrane (PEM) water electrolysis. The DOE Technical Targets for hydrogen cost as well as electrolyzer efficiency and capital cost will be directly addressed through the advancement of key components and design parameters.

Currently, a significant portion of the electrolyzer system capital cost comes from the cell stack(s). When added together, the flow fields and membrane electrode assemblies (MEAs) constitute over half of the total cell stack cost (Figure 1). Significant cost reductions of these components as demonstrated with this research are required in order to reach the targets. Further optimization of cell stack components results in efficiency gains at the system level and ultimately a reduction in the cost to produce hydrogen.

Approach

The scope of work for this project allowed for research and development in several key areas relating to cell stack cost reduction. Topics included: 1) catalyst formulation, 2) flow field design, 3) computational performance modeling, and 4) flow field coating development. Higher efficiency oxygen evolution catalysts are of interest because the oxygen evolution reaction is inefficient and therefore requires high catalyst loadings to achieve reasonable operational voltages at the desired current densities. Improving catalyst utilization can substantially reduce the cost of the MEA by reducing the noble metal content in the catalyst layers. Novel electrode structures have been constructed using alternate synthesis and processing techniques and are being characterized for performance and durability.

Advancements in flow field design are intended to be advantageous for low-cost, high-volume manufacturing. Alternatives to the current flow field design included either 1) composite bipolar plates or 2) unitized flow fields, which consolidate parts and reduce the amount of required precious metal plating. A parallel path is being followed, utilizing the top candidate from each category. Material testing samples for the composite materials are under test for compatibility with the corrosive environment known to exist within operating electrolyzer cells. Prototype flow fields will be fabricated and tested to determine dimensional capability. Computational modeling of an electrolyzer cell will allow for optimization studies to be performed around flow field material and architecture. Cell performance can be quantified in ways not typically possible with standard physical test experiments. Alternate coating strategies are also being investigated which eliminate metal plating entirely. Validation of all of the previously mentioned design

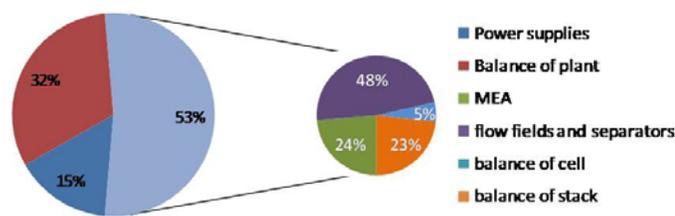

FIGURE 1. Relative Cost of Electrolyzer System Components

changes will be achieved through cost analysis based on the H2A model V2.1.

Results

Significant advancements have been made in the development of an optimized catalyst formulation and application technique. This work has demonstrated a 55% reduction in the amount of precious metal used in the anode catalyst layers of the MEA vs. current commercial production. Durability testing showed no degradation over the duration of the test. The application technique represents an improvement over existing production techniques in that it allows for improved accuracy and uniformity while also enabling higher speed throughput. Work with 3M has also shown feasibility of greater than 90% reduction in catalyst loading vs. current commercial production on the cathode side of the cell utilizing 3M’s NSTF electrodes. Even with 15% higher membrane thickness, the reduced loading cathodes demonstrated roughly equivalent performance to a Proton baseline (Figure 2), and durability was demonstrated to over 3,500 hours. A non-proprietary test cell was also qualified and shared with collaborators for increased throughput and cost sharing.

Near-term electrolyzer stack cost reductions of 12% vs. Proton’s 2010 commercial product were identified through the testing and validation of non-metal cathode flow field components. The new part was implemented in Proton’s commercial product, with thousands of cells manufactured to date.

Composite bipolar plates which enable substantial further reduction in metal content were procured and have been on test for over 3,000 hours without significant voltage decay (Figure 3). Samples were nitrided to protect the part from oxidative corrosion and hydrogen embrittlement. Selected samples will be examined after longer operating times to predict overall life based on any signs of corrosion

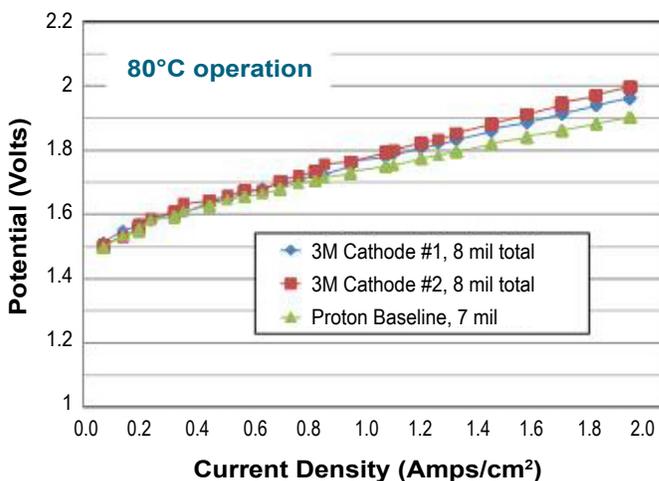

FIGURE 2. Performance of NSTF Electrodes as Electrolysis Cathodes

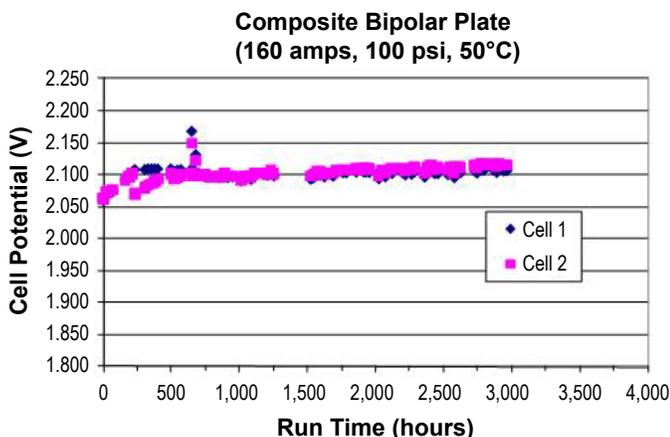

FIGURE 3. Voltage Trend for Composite Bipolar Assembly

or material degradation. A survey was also completed of over 30 bipolar assembly concepts, which showed opportunity for 50% cost savings in the subassembly over the production change already implemented. In addition to the composite plate, an alternate unitized part was selected for prototyping to verify cost and dimensional tolerancing.

The comprehensive computational model of an electrolyzer cell developed at Penn State was shown to be capable of predicting performance parameters based on the geometry of the flow fields and specified operating conditions. Calculated parameters included overall cell potential, distribution of potential and current density distribution, as well as volume fractions of water, oxygen and hydrogen in various regions of the cell. Predicted polarization curves were shown to be consistent with actual data. A parametric study was performed to flex the model variables. Learnings from this model will be used for refinement of cell component architecture for improved water distribution within the cell and better thermal management.

Nitriding was studied on both the composite parts as discussed above as well as metal parts. Characterization at Oak Ridge National Laboratory showed that both samples maintained similar thicknesses of the nitrided layer after electrolysis operation (Figure 4). Thermal nitriding was also explored at Oak Ridge and samples were tested for 500 hours in the electrolysis environment without evidence of corrosion. These results validate the potential for multiple options for plate fabrication and coating while eliminating noble metal coatings or plating.

Conclusions and Future Directions

- Cost reductions can be made by controlling the catalyst formulation process and through advanced application techniques. Further work is needed to integrate the anode and cathode benefits realized in this project into a single MEA configuration.
- Initial cost reductions on the cathode flow field were successfully implemented in production.
- Tests have shown that alternative conductive materials can remain stable in the corrosive environment of operational electrolyzer cells for tests over 3,000 hours. Further analysis is required to determine durability projections and progress towards the 30,000 hour minimum operational life of Proton cell stacks, but no obvious degradation has been observed.
- A unitized flow field plus frame assembly has been selected as the parallel path to the composite bipolar plate, with initial predictions of over 50% part cost reduction.
- Electrolyzer cell performance can be predicted with the use of a comprehensive computational model and flow distribution across the bipolar assembly can be modeled to provide valuable insights on design and flow requirements.

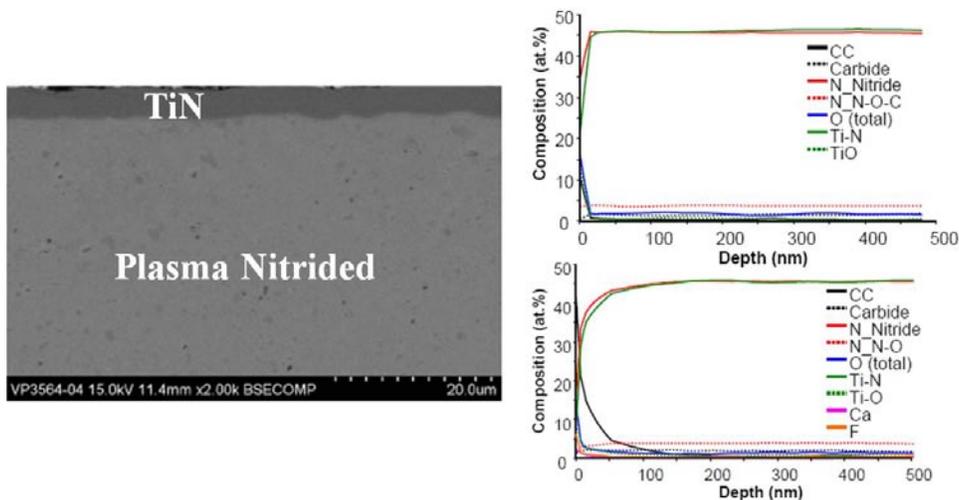

FIGURE 4. Image of Nitrided Part and Analysis of Composition vs. Layer Depth and Operation

- Nitride coatings fabricated by different methods appear to be very stable in electrolysis conditions and may enable reduction in metal coatings. Further process development will be performed to determine the best approach for manufacturability.

Contract Number: DE-FG36-08GO18066

Subcontractor:
 HyPerComp Engineering, Inc., Brigham City, UT

Start Date: June 1, 2008
 Estimated Project End Date: September 30, 2012

Fiscal Year (FY) 2011 Objectives

- Achieve at least a 15X increase in the gas production rate of a single high-pressure production cell.
- Demonstrate the high pressure cell composite wrap which enables significant weight reduction.
- Build and test a 1/10th-scale pilot plant.
- Have fabrication ready drawings for full-scale plant (300 kg/day, 750 kW).

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (G) Capital Costs of Hydrogen Generation by Electrolysis Systems
- (H) System Efficiency
- (J) Renewable Electricity Generation Integration

Technical Targets

TABLE 1. DOE Technical Targets: Distributed Water Electrolysis Hydrogen Production

Characteristics	Units	2012 Target	2017 Target
Hydrogen Cost	\$/gasoline gallon equivalent (gge)	3.70	<3.00
Electrolyzer Capital Cost	\$/gge \$/kW	0.70 400	0.30 125
Electrolyzer Energy Efficiency	% (lower heating value)	69	74

Distributed Water Electrolysis Hydrogen Production

In this project Avālenca is developing an enlarged version of its present electrolyzer design that will have 15X the capacity of the current single tubular cell. To achieve this, the diameter of the current Avālenca design individual tubular cell is being enlarged to enable an innovative cell core design: multiple coaxially arranged cylindrical electrodes, nested in a uni-polar configuration. This design is the core of a distributed water electrolysis hydrogen production system that will meet the following DOE 2017 targets:

- Hydrogen cost: \$3.00 gge
- Electrolyzer energy efficiency: 74 kWh/kg

FY 2011 Accomplishments

Detailed engineering and design and construction of the test cell continued during 2011. Significant engineering focus was directed toward a detailed design to seal the inner electrodes and membranes and the pressure flange and provide inlet and exit ports for the water and H₂ and O₂ gases. The cell prototype will be tested at 1,000 psi on an existing test stand at Avālenca that will provide electrical and pressure control and electrolyte level balancing. 2011 accomplishments include:

- Detailed design drawings for the prototype cell (Figure 1) to include the following elements:
 - A top gas exit manifold made of polyvinyl chloride (PVC) that will have gas collection channels machined into the manifold. Oxygen will be collected and sent to a center outlet port. The hydrogen manifold will be split into four quadrants with outlet ports in each of the four quadrants. The manifold, which will have an electrode sealing mechanism or clamp, is at the top end of the cell.

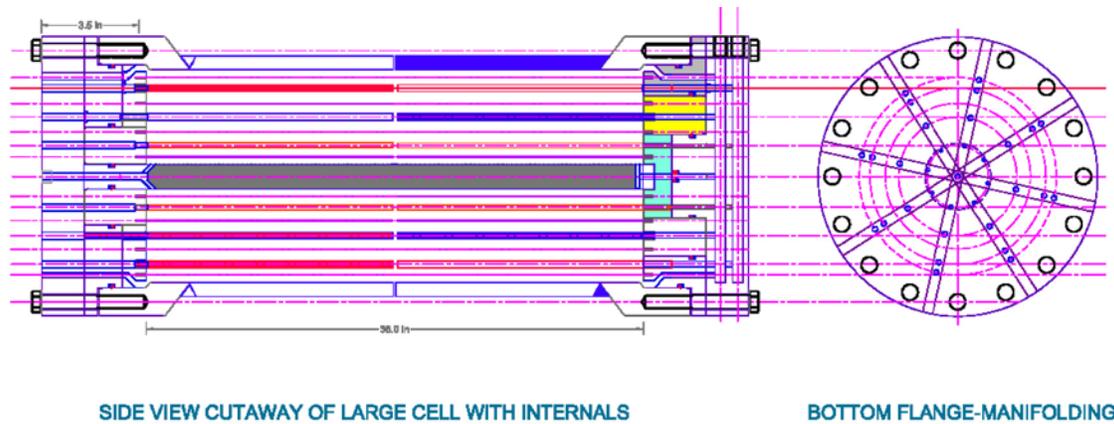

FIGURE 1. Cutaway View of Cell Nested Components

- An innovative method of joining and securing the electrode and membrane ends to the top and bottom of the cell via a mounting collar made of PVC.
- Detailed design of the exact geometry of the internal nested cylindrical components which consist of two inner anodes, two cathodes, and the four membranes that form the boundaries between the anolyte and catholyte chambers. The design utilizes 8-inch, 6-inch, 4-inch and 2-inch 316 stainless steel.
- Detailed engineering design of the inner and outer pressure flanges that will allow the assembly of inner electrodes and membranes in two modules:
 - One outermost piece of the outer flange assembly that holds an anode, inner cathode, and two membranes.
 - A second assembly that includes a flange which is sandwiched underneath the outermost flange. This assembly holds the second anode and the center cathode, plus two membranes in place.
 - Design of plastic mounting disks which are placed inside and are locked into position by the outer flange pieces to seal the electrodes and membranes in place.
 - The outermost piece of the outer flange is bolted through the second assembly (sandwich) flange into the inner flange of the cathode/pressure cylinder, pressure sealing the entire cell.
 - The design calls for a top outer flange/mounting disk assembly with gas exit paths, and a bottom outer flange/disk assembly with liquid distribution and recirculation.
 - In a departure from the current smaller scale Aváence product design [1], the cell membranes are sealed at both ends of the cell to prevent anolyte and catholyte from mixing. This will ensure high purity by preventing H_2 and O_2 gases dissolved in the electrolyte from crossing the cell boundaries formed by the membranes by eliminating an open circulation path below the membrane. Anolyte and catholyte entrained in the exiting gas bubbles (through gas paths in the top of the cell) will return to the appropriate cell chambers via external circulation and reinjection through the bottom outer flange/disk assembly.
 - The design makes extensive use of O-rings to seal leak paths through liquid inlets and gas outlets, as well as to seal the flanges at both ends of the cell.
- The outer cathode/pressure cylinder was cut from an 8-inch pipe and the inner flanges machined from a stainless steel solid bar stock at Aváence and welded together and dye penetrant-checked, see Figures 2 and 3.
- The cylinder was shipped to HyperComp in Brigham City, Utah, for wrapping with carbon fiber, see Figure 4.

Introduction

Aváence has existing technology that is globally unique in its ability to deliver hydrogen directly at storage-ready pressures of 2,500 and 6,500 psi without a separate compressor. Using an alkaline electrolyte process, the Aváence Hydrofiller systems integrate the production and compression processes by operating the electrolytic cells at the desired delivery pressure. The systems can interface directly with renewable electricity supplies and have been shown in previous work (DOE Small Business Innovation Research project completed in April 2005) that the electrolyzer operates through the full range of voltages output from the connected photovoltaic (PV) array without using any power conditioning equipment. These characteristics result in a renewable hydrogen production and delivery system that is significantly more efficient and reliable, and substantially less expensive than existing commercially available electrolyzer and compressor system sets. The smaller scale Hydrofillers are based on a single cathode/anode tubular cell design with production

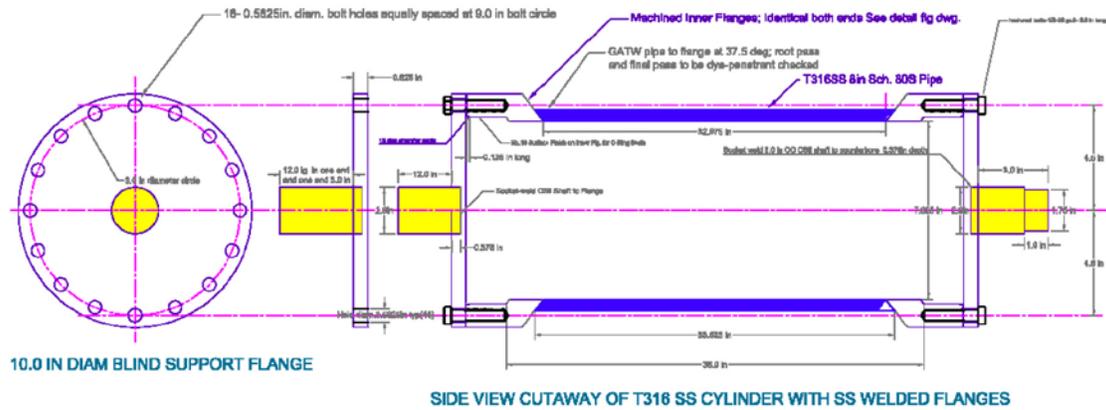

FIGURE 2. Cell with Flange Ends for Carbon Fiber Wrapping

FIGURE 3. Photograph of Cell Prior to Carbon Fiber Wrapping

capability of about 0.1 kg/day per cell. A revolutionary design approach to this high-pressure cell core is needed for an order-of-magnitude capacity scale up of the individual electrolyzer modules.

Approach

In this project, Avācence is developing an enlarged version of the current Avācence design that will have at least 15X the capacity of our present single tubular cell. The diameter of the large individual cell will be substantially increased in order to enable an innovative cell core design – multiple coaxially arranged cylindrical electrodes, nested in a uni-polar configuration – enabling up to 1½ kg/day of production per individual cell. In order to accomplish this cell diameter increase with a practical pressure boundary while operating at either 2,500 or 6,500 psi, Avācence has partnered with a composite cylinder manufacturer, HyPerComp Engineering Inc. They will develop a custom designed containment vessel/cathode using their composite technology expertise that will allow an increase in the diameter of the individual

electrolysis cell, enable operation at 2,500 psi and above, and reduce the cell weight and cost relative to conventional metal containment (similar to what is seen today with composite storage tanks used on vehicles). Ninety-six of these high-capacity cells will now produce a single unit (module) with a production capacity of 150 kg/day.

To complete this development process, Avācence is proposing to build a quarter-scale pilot plant to be composed of 20 cells that will replicate the full plant design and operation, but minimize the cost to DOE for this technology demonstration. The pilot plant will be sent to the National Renewable Energy Laboratory for verification testing. The final result of the project will be a commercially operating 30 kg/day pilot plant integrated with a wind turbine and/or PV array, and delivering H₂ gas at pressure directly to storage cylinders. Operation of this plant and extensive testing of this and earlier development versions throughout the course of the project will thoroughly document the performance and operation of the technology. This combination of an operating pilot plant and substantial performance and operating data will position the technology for commercialization.

Results

Initial test work on nested components, with passive circulation, was conducted during the first quarter of FY 2011. The test results from one nested set did demonstrate substantial recirculation (driven only passively at this point). The recirculation had a very positive effect in that purity of hydrogen (before the catalyst) increased from 98.5% typical at 2,200 psig to >99.5% at 2,200 psig. The recirculation resulted in less dwell time inside the cells for the gas bubbles and therefore less opportunity to diffuse or leak by whatever minute paths exist. This is an indication that Avācence should be able to return to high pressure operation (6,000 psig) with no compressor, and stay below the required safety limit of 2% impurity before the catalysts. The test cell, with five nested electrodes, will use active circulation, which should further reduce dwell time, so even better results

FIGURE 4. HyperComp Wrapping Sequence and Finished Cylinder

are anticipated. In support of the multi electrode testing, Avālenca has selected circulation pumps for testing of the five nested electrodes.

Based on the tests conducted during the first quarter of FY 2011 and additional analysis, there is a problem of excessive voltage drop associated with axial electrical conductivity in the nested set of 316 stainless steel electrodes. As a result, additional design work was undertaken to decrease electrical resistance within the cells and associated with pass through (sealed) conductors. This is focusing on the selection and construction of the anodes and cathodes that provide the axial conductivity and electrical pass through, and which are also of acceptable cost. The test cell design is limited to 3' height due to concern over voltage loss axially. This means that the pilot plant cells at 6' will require that electrical connections are made at both ends of the electrodes or another solution is devised in order to improve the conductivity. For example, it is possible to solve this problem with a change in material (to nickel for example), but this is costly. Avālenca is working on other concepts such as layering (cladding) the electrodes to deliver both the conductivity required and to manage the cost.

Lastly, design work focused on how to align the plurality of electrodes and membranes top and bottom for better manufacturability. This is being addressed by securing the membranes and inner electrodes to a top alignment mount

made of PVC that will be glued to the upper gas manifold (also made of PVC). The relatively thin membranes will be reinforced at the bottom with a PVC guide ring glued to the membranes. The membranes and electrodes are attached to a PVC bottom alignment guide, and the entire assembly can then be inserted into an outer anode and flange assembly. Avālenca is researching the manufacture and supply of stiff tubular membranes made by casting a membrane material onto a rigid ceramic, extruded PVC, or other support.

Conclusions and Future Directions

Conclusions

Through changes in conceptual design and detailed engineering design currently underway, Avālenca is addressing the design challenges of this unique high pressure concentric ringed electrolysis cell, all of which impact manufacturability, gas purity, and high pressure operation:

- Electrode and membrane sealing to cell ends
- Gas collection
- Axial conductivity
- Electrolyte balancing
- Cell cooling
- Etc.

Future Directions

- Demonstrate large diameter cell operation at 1,000 psi:
 - The cell will be tested on a test stand that Avãence has adapted from the balance of plant of a Hydrofiller 15.
 - Will circulate electrolyte on both sides using cat pumps.
 - No gas recirculation will be required until the design pressure goes above 2,500 psig.
- Test long-term 6,500 psi operation approaches:
 - Using existing small cell apparatus.
 - Purified gas “recirculation/dilution” approach as required to achieve lower explosive level requirements.
 - Neutral electrolyte chamber approach – membrane related effort.

Project End Date: Project continuation and
direction determined annually by DOE

demonstrated small-scale (16-kW) electrolyzer system energy efficiency of 55% (lower heating value, LHV). The current (2009) state-of-the-art cost for delivered hydrogen from electrolysis for a forecourt refueling station ranges from \$4.90/kg-H₂ to \$5.70/kg-H₂ dispensed at the pump, with a base-case estimate of \$5.20/kg-H₂. This base-case estimate of \$5.20/kg-H₂ includes an electrolysis production cost of \$3.32/kg-H₂ and compression, storage and dispensing costs of \$1.88/kg-H₂. These costs are evaluated using Energy Information Administration Annual Energy Outlook 2005 High A Case industrial electricity costs (\$0.053/kWh on average) [1]. In the coming year, this project will test the performance of two DOE-awarded systems to demonstrate their technical readiness for improved stack efficiency and higher pressure (>2,500 psig) hydrogen product directly from the electrolyzer stack. Based on information provided by electrolyzer suppliers for their state-of-the-art technologies, both alkaline and polymer electrolyte membrane (PEM) electrolyzers are now capable of producing hydrogen using less than 50 kWh/kg, representing a lower heating value efficiency of greater than 67% [1].

Fiscal Year (FY) 2011 Objective

- Optimize the coupling between wind and solar electric resources and the hydrogen-producing stacks of commercially available electrolyzer systems.
- Quantify performance differences between variable and constant current operation of electrolyzer stacks and systems.
- Collaborate with industry and utilities to advance the commercialization of integrated renewable electrolysis systems.
- Demonstrate the technical readiness of DOE-awarded advanced electrolysis systems.

Technical Barriers

This project addresses the following technical barriers from the Production section (3.1) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (G) Capital Cost
- (H) System Efficiency
- (J) Renewable Electricity Generation Integration

Technical Targets

Results from the project demonstrate improved system efficiency and offer opportunities to reduce capital costs by reducing redundant components in a renewable-coupled system. Previously, testing conducted under this project of a DOE-awarded system, from Giner Electrochemical Systems,

TABLE 1. Progress toward Meeting DOE Technical Targets for Distributed Water Electrolysis Hydrogen Production

gge – gasoline gallon equivalent

FY 2011 Accomplishments

- Completed Fuel Cell Technologies Program milestone for Hydrogen Fuel R&D for Quarter 1: “Complete testing (300 hours) of multiple commercial electrolysis stacks into a wind-to-hydrogen system to characterize the impacts of the power electronics interface and varying wind power input on electrolyzer performance and cost of renewable-based hydrogen production.”
 - Conducted varying current stack testing continuously for more than 3,800 hours by the end of July 2011.
 - The testing revealed that the duration of full-current steady-state operation embedded between long-duration, varying-current wind profile operation influences the anode catalyst oxidation state and may have a role in transient voltage behavior.
- Demonstrated 10% efficiency improvement by combining direct-coupled photovoltaic (PV) and power converter-to-stack operation based on solar irradiance.
- Installed new test facility and power switch gear at the Wind-to-Hydrogen (Wind2H2) project to support testing of DOE-awarded electrolyzer systems in FY 2012.

- Installed refurbished alkaline stack and balance-of-plant components enabling side-by-side comparison testing of similarly sized competing electrolyzer technologies.
- Completed initial hourly analysis of central wind electrolysis production facility (50,000 kg/day). See project II.E.6, “Hour-by-Hour Cost Modeling of Optimized Central Wind-Based Water Electrolysis Production”.

Introduction

Renewable electrolysis is inherently distributed, but large-scale wind and solar installations are becoming more common and will take advantage of economies of scale. Life cycle assessments of large-scale wind turbines, for example, show payback for the greenhouse gas emissions required to manufacture the equipment in about nine months [2]. Renewable electricity sources, such as wind and solar, can be closely (and in some cases directly) coupled to the hydrogen-producing stacks of electrolyzers to improve system efficiency and lower the capital costs of this near-zero carbon pathway.

Approach

The Xcel Energy/NREL Wind2H2 project is advancing the integration of renewable electricity sources with state-of-the-art electrolyzer technology. Real-world data from daily system operation are revealing opportunities for improved system design and unique hardware configurations to advance the commercialization of this technology. Lessons learned and data-driven results provide feedback to the analytical and modeling components of this project [3].

In hydrogen production facilities even small increases in system efficiency result in significant reductions in hydrogen cost. DOE is funding electrolyzer manufacturers to design and build improved stacks and system balance of plant to reduce the cost of electrolytically produced hydrogen. This project provides independent testing and verification of the technical readiness of these advanced electrolyzer systems by operating them from the grid and renewable electricity sources.

Results

We conducted side-by-side testing and comparison of stack voltage decay rates between constant and variable current operation. Two, 34-cell stacks of an H-Series PEM electrolyzer, from Proton On Site, were operated with a highly variable wind profile for more than 3,800 hours between November and July 2011. The third stack was operated over the same time with a constant stack current while having the same average current as the two variable stacks. Varying wind current profile was normally operated for hundreds of hours continuously and only interrupted to operate all three stacks at their full-current steady-state point for a few days at a time.

Table 2 summarizes these results, which are based on over 3,800 hours of combined varying wind and full-current steady-state operation through July 2011. Before delivery to NREL, the stacks under test faced severe abuse with no hydration for about a year in a warehouse without operation or attention. Furthermore, this testing is intended only to reveal relative stack decay rates between a variable wind profile and constant current operation if there is any difference. Stack decay rates of today’s PEM stacks are in the range of 2–5 $\mu\text{V}/\text{cell-h}$.

TABLE 2. Summary of Full-Current Steady-State Scans and Resulting Decay Rate

Mode	Stack Voltage (104°F)					Average Decay $\mu\text{V}/\text{cell-hr}$
	1/7/2011	2/9/2011	4/12/2011	6/10/2011	7/22/2011	
Variable	76.5	77.6	78.6	79.1	78.3	13.9
Variable	74.5	75.5	76.9	77.2	76.3	13.7
Constant	75.1	75.9	77.1	77.3	76.7	12.4
Cumulative Hours		594	1,853	3,143	3,803	

The cell membrane resistance supports the linear fitting and extrapolation to 104°F (40°C) to establish a common temperature to compare the full-current scans. The data indicate a narrow band of operation during the colder winter months and the wider temperature operating range from the April 12 full-current scan (Figure 1). We expect that hotter summer months will shift stack operating temperature to even higher temperatures, which is the reason 104°F was selected as the comparison temperature.

Original plans to operate the three stacks in full-current steady-state mode for tens of hours between the varying wind profile were quickly replaced when longer duration full-current scans revealed a change in the voltage behavior. The longer duration full-current scans suggested that the anode catalyst layer has a role in this transient voltage behavior. As a result, all future full-current steady-

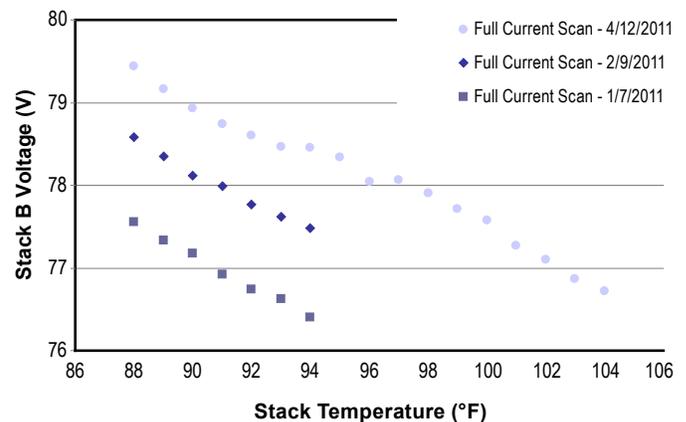

FIGURE 1. Stack B (Varying Stack) Voltage Responses During Full-Current Steady-State Operation

state scans will be run for several days. Proton On Site has suggested a brief electrolyzer shutdown between varying stack and full-current steady-state mode may provide further insight to stack voltage behavior.

The three stacks are periodically brought to their full-current steady-state operating point to enable comparison of their stack voltages at stable conditions. Input and output deionized (DI) water temperature, stack current, and voltage are monitored. DI input and output water temperatures are averaged and binned for every 1°F and the corresponding stack voltages are averaged for each bin. Stack B (varying stack) voltage responses are shown in Figure 1 for three of the full-current steady-state periods and are representative of each stack. Each stack responded similarly during these full-current steady-state operation periods.

In FY 2010, NREL conducted testing comparing the performance of direct coupling a PV array to a PEM electrolyzer stack with that of a power converter using maximum power point tracking. The electrolyzer stack operating point was intentionally aligned with that of PV array. In FY 2011, the power converter switching losses and diode reverse recovery were investigated. The direct coupling and power converter data were further analyzed to show a 10% system efficiency improvement if direct coupling were used in solar irradiances less than 500 W/m² and the power converter was used when higher irradiances were present (Figure 2).

Conclusions and Future Direction

Through the end of July 2011, NREL conducted more than 3,800 hours of varying wind profile stack current testing with two PEM electrolyzer stack while holding a third stack at constant current. As these results are preliminary, the testing continues.

NREL's comparison testing between direct coupling a PV array to a PEM electrolyzer stack versus a power converter using maximum power point tracking provides an opportunity to improve system efficiency. System efficiency can improve by 10% if direct coupling is used in solar irradiances less than 500 W/m² and the power converter is used when higher irradiances are present.

- To support the opportunity to use electrolyzers as dispatchable loads for grid support services, NREL plans to induce frequency disturbances on its 80 kW and 125 kW diesel generators using resistive step loads. Both the PEM and alkaline electrolyzers will be triggered to shed or add load to the microgrid to mitigate these frequency changes.
- Similarly, the 5 kW PEM fuel cell will be direct current coupled with the PV array to quantify its response time as clouds passing by the PV array induce load changes.
- NREL plans to test the performance of two DOE-awarded electrolyzer systems in the coming year. These advanced systems were designed and built to improve stack efficiency and high-pressure electrochemical operation of the stack.

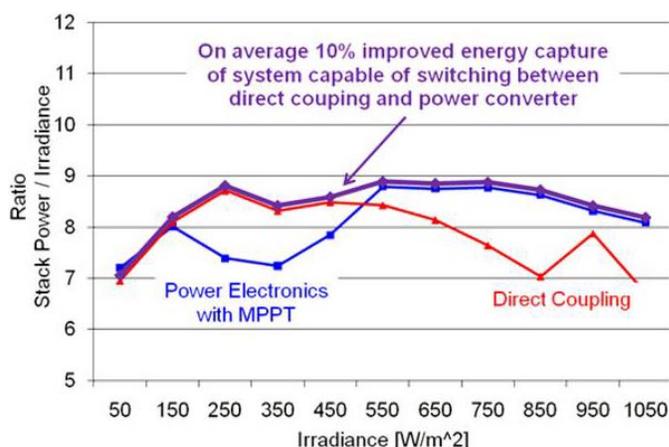

FIGURE 2. 10% Improved Energy Capture by Taking Advantage of Direct Coupling at Solar Irradiances Less Than 500 W/m² and Power Conversion when Irradiances are Greater

- Equipment downtime, reliability, and maintenance data will be tracked to help quantify the performance of this integrated renewable hydrogen production system.
- Multiple stack electrical isolation tests will highlight the challenges of electrical floating and bipolar stack operation. If successful, multiple stacks could be configured to take advantage of the direct current bus of large-scale variable-speed wind turbines.

Contract Number: DE-SC0002185

Subcontractors:

- PBI Performance Products, Inc., Rock Hill, SC
- Plug Power, Inc., Latham, NY

Project Start Date: Phase II: August 15, 2010
Project End Date: August 15, 2012

Fiscal Year (FY) 2011 Objective

Develop and demonstrate a multi-functional hydrogen production technology based on a polybenzimidazole (PBI) membrane which exhibits:

- High efficiency (70%)
- 100 scfh pumping capability
- CO₂ and CO tolerance
- 300 psig (differential) pressurization capability
- \$3/kg operating costs

Technical Barriers

This project addresses the following technical barriers addressed in the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan.

- (K) Durability
- (L) Impurities
- (N) Hydrogen selectivity
- (O) Operating temperature
- (P) Flux
- (R) Cost

Technical Target

This project is focused on fundamental chemical and mechanical engineering studies on PBI proton exchange membranes and electrochemical cell hardware, respectively. Learnings gained from these studies will be applied to the membrane fabrication process as well as toward the electrochemical cell architecture to meet the following key targets:

- 300 psid differential pressure operation at 160°C
- CO₂ tolerance
- High efficiency

FY 2011 Accomplishments

- 300 psig compression demonstrated at 160°C for over 600 hours on a PBI-based electrochemical pump.
- A process to increase the membrane durability and performance was developed.
- Advancements in the pump support and seal design (50 cm² format).
- Characterization of the gas diffusion layer (mechanical properties), enhanced pump architecture, and a 1st generation large format pump design completed to achieve the program target of 100 scfh.

Introduction

One of the barriers to fuel cell acceptance is the lack of a simple, reliable, cost-effective and robust process to purify, pump, and pressurize hydrogen. This challenge is magnified by impurities and hydrogen generation occurring at near ambient pressure. Technical means of pressurizing the hydrogen is especially daunting for low to moderate flow rates. If the pressurization, purification, and recovery of the hydrogen can be developed into a single unit operation, the key goals relating to cost and reliability via process simplification could be an attractive and enabling option. Application of electrochemical methods is a potential solution. H2Pump has leveraged its extensive experience in electrochemical separation and pressurization systems to meet the project objectives with a high temperature membrane-based electrochemical hydrogen pump. The solutions have been based on developing a chemically and mechanically robust membrane in conjunction with advancements in cell hardware.

The significance of the success of the project to date is that multiple unit operations have been combined into a

single device and demonstrated to be capable of generating the targeted pressures and impurity tolerances.

Approach

H2Pump has shown that electrochemical methods to recover, purify, and pressurize hydrogen is a viable option for low to moderate volumes of hydrogen containing gases. The main challenge for this specific application is the lack of a proton conducting membrane which exhibits carbon dioxide and carbon monoxide tolerance and at the same time pressurize the hydrogen from atmospheric pressure to 300 psig. The approach has been to work closely with its partner, PBI Performance Products, to enhance the membrane properties relevant to this application while at the same time address cell hardware architecture so as to support the high temperature, CO₂ and CO tolerant membrane. The results (properties) of the membrane modifications were then used to guide the cell hardware program in which cell components have been assessed and characterized for the desired operating conditions. The combined efforts have led to the successful operation of 50 cm² cells which meet or exceed the program targets. Design guidelines developed with lab-scale pumps are then applied to a larger format to meet the volume requirements of the effort.

Results

The most significant result during this period is having achieved the targeted 300 psig compression using the high-temperature CO₂, CO tolerant membrane. Other accomplishments include membrane enhancement and characterization, gas diffusion layer characterization and selection, enhanced pump architecture, and completion of a 1st generation large format pump design. High pressure electrochemical hydrogen compression was achieved through rigorous material characterization and selection processes in conjunction with advancements in the pump support and seal design. Presented in Figure 1 are the data for a 300 psig 50 cm² pump operated at 160°C on humidified hydrogen for 300 hours. Membrane enhancement was accomplished via various treatments with the intent to improve material durability and performance over long lifetimes. Acid absorption, mechanical strength and electrochemical performance were studied after membrane treatments were performed. Polarization data for the pump operating with a 300 psig differential pressure are presented in Figure 2. Hardware design and material preparation methods were studied and improved to boost the maximum differential pressures within the hydrogen pump. This work was essential to address the failure modes which are unique to the high temperature and high pressure operation.

Tests are currently underway to assess lifetime of the multi-functional device at the targeted operating conditions. Additional cells have been tested with various sealing designs at pressures between ambient and 300 psig to assess the impact of the sealing method on high differential

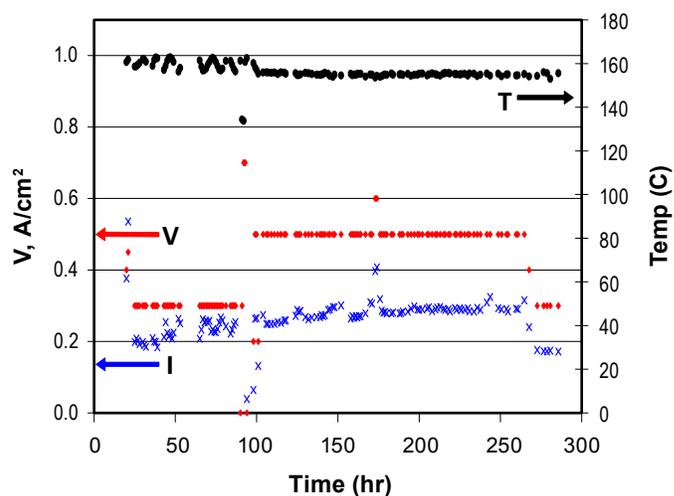

FIGURE 1. Cumulative Run Time: voltage, current, and temperature vs. time. 50 cm² PBI Performance Products enhanced membrane operating at 300 psi differential pressure in the H2Pump advanced cell hardware.

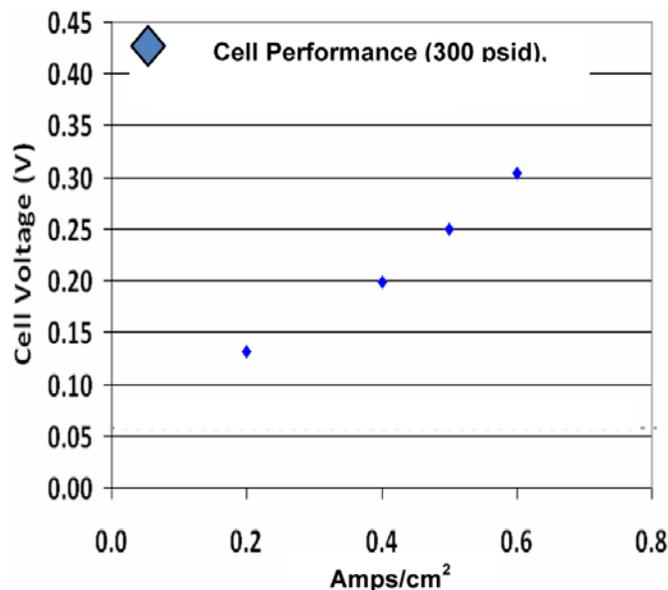

FIGURE 2. Voltage vs. current density: 50 cm² cell operating at 300 psi differential pressure with the PBI Performance Products enhanced membrane.

pressure operation. There are currently two approaches which have proven viable for the 300 psig pressurized operation, both relating a novel sealing and support design. In future activities one will be down-selected. Single cells operating at 300 psid have now exceeded 600 hours and remain on test.

Additional work is being carried out on enhancing the membrane properties via two approaches, thermal and chemical cross-linking of the polymer in the PBI membranes. Results of both methods (impact on stability and mechanical properties) have guided the effort to date.

Conclusions and Future Directions

- In collaboration with our partner, PBI Performance Products, PBI membrane has been successfully modified and is now stable in the targeted operating environment.
- Enhancement of the membrane – electrode interface successfully completed.
- Cell hardware has been modified and sub-components evaluated and down-selected.
- 300 psig differential pressure operation has been demonstrated for hundreds of hours.
- Life testing, impact of operating conditions, and durability will continue to be evaluated.
- Scale up of the membrane and electrode assemblies as well as the hardware is underway so as to achieve the 100 scfh target.
- Gas quality and analytical tests will be performed to further assess the performance of the 300 psig pump cells.
- Plans and preparation for an on-site demonstration of the technology will commence in the forthcoming months.

Project Start Date: October 1, 2010
Project End Date: Project continuation and direction determined annually by DOE

Fiscal Year (FY) 2011 Objectives

- Corroborate recent wind electrolysis cost studies using a more detailed hour-by-hour analysis.
- Examine consequences of different system configuration and operation for four scenarios.
- Initiate understanding of sizing implications between electrolyzers and wind farms.
- Identify areas for further analysis and cost reduction.
- Determine the sensitivity of the cost of hydrogen to various inputs, such as turbine cost, electrolyzer efficiency, electrolyzer capital cost, capacity factors, and availability.

Technical Barriers

This project addresses the following technical barriers from the Production section (3.1) of the Hydrogen, Fuel Cells and Infrastructure Technologies Program's Multi-Year Research, Development and Demonstration Plan:

- (G) Capital Cost
- (H) System Efficiency
- (J) Renewable Electricity Generation Integration

Technical Targets

This analysis shows that using current prices for electricity from Class 4-6 wind resources, the hydrogen cost can approach the DOE 2012 cost per gallon of gasoline equivalent (\$/gge) target. (See Table 1 for more details.) Using wind electricity prices collected in the 2000 to 2002 time frame, which are lower than now (2011), a Class 6 wind

resource could produce hydrogen at the production plant gate for \$3.06/gge. This analysis focused on the production components of hydrogen cost, including, electrolyzer capital, electricity cost, depreciation, and operation and maintenance. Table 1 includes an additional \$1.88/kg for compression, storage, and dispensing, the value assumed by an independent review panel on low-temperature electrolysis from which the electrolyzer performance and costs were derived for this analysis [1].

TABLE 1. Progress towards Meeting Technical Targets for Distributed Water Electrolysis Production

Characteristics	Units	2012 Target ¹	2017 Target ¹	Status	Analysis
Hydrogen Cost at Production Gate	\$/gge	3.70	<3.00	4.90-5.70 ²	5.70-7.49 ³

¹ 2012 and 2017 target for forecourt hydrogen station includes production and CSD (compression, storage, and delivery)

² The current (2009) state-of-the-art cost for delivered hydrogen from electrolysis for a forecourt refueling station ranges from \$4.90/kg-H₂ to \$5.70/kg-H₂ dispensed at the pump, with a base-case estimate of \$5.20/kg-H₂. This base-case estimate of \$5.20/kg-H₂ includes an electrolysis production cost of \$3.32/kg-H₂ and compression, storage and dispensing costs of \$1.88/kg-H₂. These costs are evaluated using Energy Information Administration Annual Energy Outlook (AEO) 2005 High A Case industrial electricity costs (\$0.053/kWh on average)[1].

³ The analysis found production gate values between \$3.82-5.61/kg. Additional CSD of \$1.88 CSD is included in agreement with the independent review panel [1].

FY 2011 Accomplishments

- Completed initial hourly analysis of central wind electrolysis production facility (50,000 kg/day).
- Determined that Class 4-6 wind sites can produce green hydrogen for between \$3.82-\$5.61/gge at the production plant gate without additional compression, storage, or dispensing.
- Presented results at the Fuel Cell Hydrogen Energy Association (FCHEA) conference, Feb. 14-16, 2011, Washington, D.C.
- Technical paper.

Introduction

This project is a analytical component of the "Renewable Electrolysis Integrated System Development and Testing" and is aimed at understanding the barriers and costs associated with large-scale (50,000 kg/day) wind-based hydrogen generation plants. Such plants can

take electrical energy from the wind or from the grid and use it to split water molecules into hydrogen and oxygen molecules. The hydrogen can then be used for a variety of purposes, including vehicle fuel, fertilizer feedstocks, petroleum upgrading, metal processing, and other industrial processes. The hydrogen can also be stored, converted back to electricity, and sold to an electric utility for the grid.

Approach

The approach used in this analysis was to review a range of wind sites from Class 1 to 6 for their ability to produce hydrogen economically by electrolysis. An hourly model was created by modifying the DOE H2A Production model version 2.1 to work in conjunction with an hourly analysis. The wind sites were modeled using 8,760 hr/yr data calculated from profiles in Western Wind Data Sets [2] and 3 MW turbine performance profiles adapted from the WindPACT Turbine Rotor Design Study [3]. Wind farms were created as a number of 3 MW wind turbines. Wind turbine costs came from the 2008 Wind Market Report [4]. The electrolyzer performance and cost was modeled consistently with an independent review panel on high volume production costs of the current state-of-the-art low-temperature electrolyzers [1]. Further, each site was analyzed under four different scenarios run hourly over a year.

- A. Cost balanced: \$ grid purchased electricity = \$ wind electricity sold.
- B. Power balanced: kilowatt-hour (kWh) grid purchased electricity = kWh wind electricity sold.
- C. Same as A, but no purchase of summer peak electricity.
- D. Same as B, but no purchase of summer peak electricity.

In addition to these scenarios, sensitivities to various inputs were analyzed, including wind turbine capital cost, wind electricity costs, electrolyzer efficiency, electrolyzer capital cost, capacity factor, and availability.

Results

This analysis found that in power balanced scenarios, the cost of hydrogen at the production plant gate can range from nearly \$12/gge down to \$3/gge, depending on the class of the wind site. It is only in wind sites of Class 4 or better that such a plant begins to approach DOE technical targets. This analysis looked at electricity prices in the California market. Electricity process will have an influence on the quality of the wind resource required.

An example of the range of costs for all the wind sites analyzed can be seen in Figure 1 which shows a power-balanced scenario where no summer peak electricity was bought from the grid. In this scenario the wind electricity sold to the grid was balanced with the grid electricity bought on a per megawatt basis per year. The electrolyzer was run at peak capacity except during summer peak hours in which it was run separate from any wind electricity

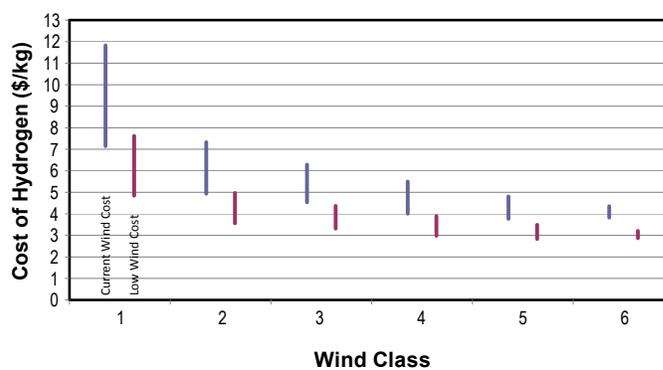

FIGURE 1. Power Balanced Scenario – Range of Costs at the Production Plant Gate

available. A ramification of this scenario was that slightly less than 50,000 kg/day of hydrogen was produced during the summer, but the cost of hydrogen at the production plant gate was also slightly less (~\$0.10/kg) than it would be if expensive summer peak grid electricity was purchased. Figure 1 shows the range of costs for the power-balanced, no-summer-peak scenario across the different wind class sites analyzed.

In places with low-cost electricity (no production tax credit included), <\$0.10/kWh, hydrogen can be produced for approximately \$3.79-\$5.90/gge at the production plant gate with no additional compression, storage, or dispensing. This was true of both power and cost-balanced scenarios. Scenarios with no-summer-peak electricity buy resulted in lower hydrogen costs but could also result in unmet hydrogen demand. The difference in the cost of hydrogen at the production plant gate between buying summer peak electricity and not buying was more pronounced in the cost-balanced scenarios, but resulted in <\$0.10/kg for all of the power-balanced and between about \$0.50-\$0.10/kg for the cost-balanced scenarios depending on the quality of the wind profile. See Figure 2 for more details.

In order to produce 50,000 kg of hydrogen per day, the required installed wind capacity varies greatly with the wind class, and thus with the cost of wind electricity. It can be as low as 200 megawatt (MW) (Class 6), and as much as 850 MW (Class 1) (see Figure 3).

In the sensitivity analysis, the largest component changes in hydrogen cost were caused by wind turbine capital cost, followed by electrolyzer efficiency (see Figure 4).

In summary, at the production plant gate the largest hurdles to hydrogen cost from water electrolysis remain wind turbine capital cost and electrolyzer efficiency. Figure 4 shows the sensitivity of costs for a particular Class 5 wind site using the power-balanced, no-summer-peak scenario described previously. Table 2 shows the base case assumptions for the different variables with the high and low values used to calculate the cost of hydrogen at the production plant gate. As seen in Figure 4, a 20% reduction in wind turbine capital will reduce hydrogen costs by

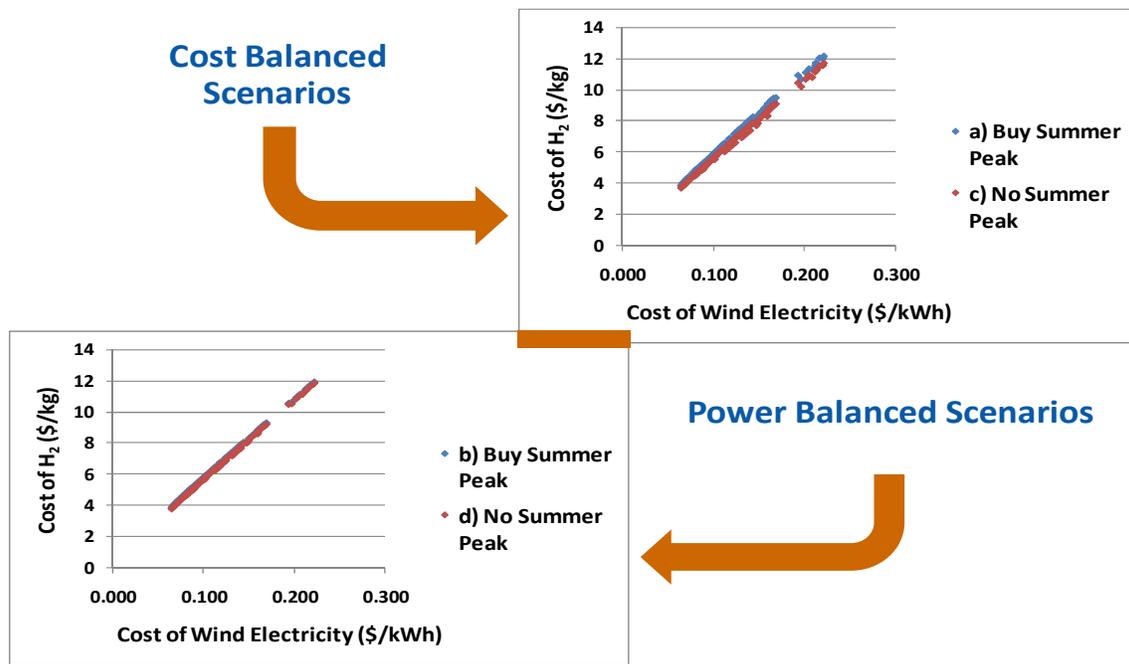

FIGURE 2. The Effect of Wind Electricity on the Cost of Hydrogen at the Production Plant Gate for Two Scenarios

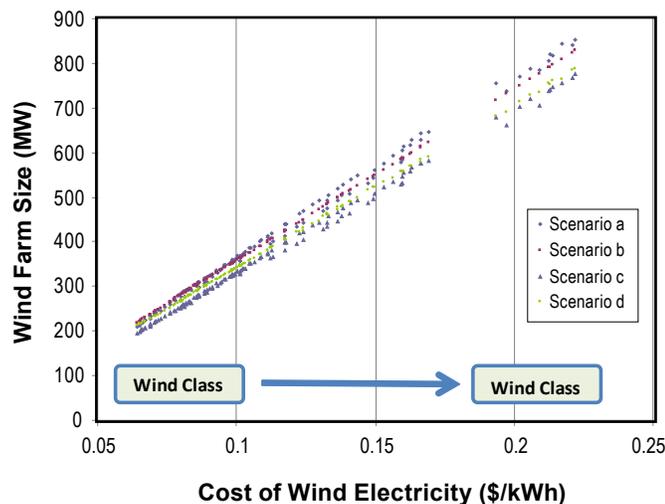

FIGURE 3. The Effect of Wind Electricity on the Installed Capacity of a Wind Farm Capable of Producing 50,000 kg/day of Hydrogen

\$0.58/gge, or 15%. Similarly, dropping electrolyzer-specific energy use from 50 to 47.5 kWh/kg can remove another \$0.13/gge from the hydrogen cost. Other sites and scenarios exhibited very similar ranges in the cost of hydrogen at the production plant gate for these sensitivity values.

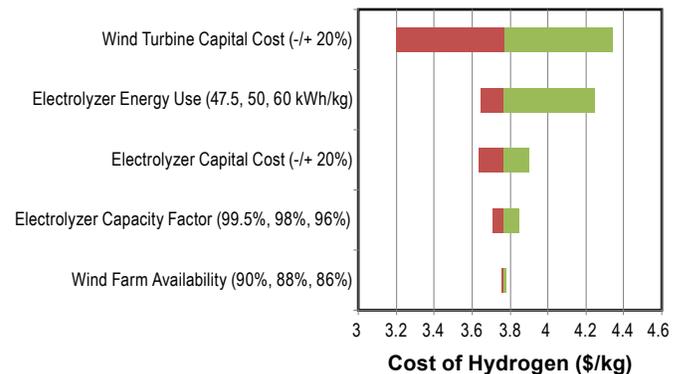

FIGURE 4. EHydrogen Cost at the Production Plant Gate - Example Sensitivity for a Power-Balanced Case, No-Summer-Peak Scenario, Wind Class 5

TABLE 2. Base Case and Sensitivities for a Power-Balanced, No-Summer-Peak Class 5 Wind Site, Cost of Hydrogen at the Production Plant Gate

Variable Name	Base Case Value	Low Value	High Value
Wind Turbine Capital Cost (\$/kW)	1,964	1,571	2,356
Electrolyzer Energy Use (kWh/kg)	50	47.5	60
Electrolyzer Capital Cost (\$/kW)	384	307	461
Wind Farm Availability (%)	88	90	86
Electrolyzer Capacity Factor (%)	98	99.5	96

Conclusions and Future Direction

Given the large influence of electricity pricing on this type of system, future work will analyze areas of the country with high electricity prices and good wind resources (Hawai'i and New England, for instance).

In addition to different geographical regions, the analysis will be deepened to look at solar integration and possibly smaller generation stations supporting the emerging vehicle and material handling fleet vehicle markets. Future analysis will include:

- More sensitivities to various inputs possibly including grid pricing, wind farm size, and production tax credit.
- Use of curtailed wind.
- Regionally expanded grid pricing structures.
- Examination of solar integration.
- Other optimal electricity/hydrogen production balance scenarios.

Fiscal Year (FY) 2011 Objectives

- Demonstrate a cost-effective high-temperature water splitting cycle for hydrogen production using concentrated solar energy.
- Evaluate photocatalytic and electrolytic options for generating hydrogen that meet DOE's solar high temperature H₂ production efficiency and cost goals.
- Confirm the feasibility of the selected cycle via bench-scale experiments.
- Determine the economic prospects of the selected cycle using the Aspen Plus chemical process model and H2A economic analysis program.
- Demonstrate a fully-integrated pilot-scale solar H₂ production unit.

Technical Barriers

This project addresses the following technical barriers from the Production section (3.1.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (U) High-Temperature Thermochemical Technology
- (V) High-Temperature Robust Materials

FY 2011 Accomplishments

- An independent thermodynamic and chemical plant analysis reaffirmed that the cycle can be closed and indicated cycle viability.
- A high pressure reactor was developed to allow high temperature operation of the electrolytic cell. Various catalysts, cell configurations and membranes were tested.
- Steady progress was made and a total cell voltage of 0.8 V @ 160 mA/cm² and 1.02 V @ 300 mA/cm² (in short term runs) was attained while achieving near quantitative hydrogen production and sulfite conversion.
- Initial lab results prove the feasibility of the all-(liquid/gas) K₂SO₄/K₂S₂O₇ chemistry for the high-temperature oxygen evolution sub-cycle using potassium sulfate. Residual gas analysis equipment was added to the thermogravimetric analysis (TGA) unit at UCSD and the combined system is producing results.

- An improved Aspen Plus model of the sulfur-ammonia system was developed by UCSD and is being refined based on lab results and additional data.
- H2A economic model results were updated and aligned with DOE program assumptions showing the 2015 estimated hydrogen cost of \$7.74/kg and the 2025 cost of \$4.65/kg. The results assume no credit for excess electrical production. The process is being optimized to eliminate excess electrical production, improve efficiency and thus reduce cost.

Introduction

Thermo-chemical production of hydrogen by splitting water with solar energy is a sustainable and renewable method of producing hydrogen. However, the process must be proven to be efficient and cost effective if it is to compete with conventional energy sources.

Approach

To achieve the project objectives, the Bowman-Westinghouse “sulfur-family” hybrid thermo-chemical water splitting cycle (aka “Hybrid Sulfur, HyS” cycle) was modified by introducing ammonia as the working reagent, thus producing the sulfur-ammonia, or “SA,” cycle. The purpose of the modification is to attain a more efficient solar interface and less problematic chemical separation steps. Several versions of the SA cycle were developed and evaluated experimentally as well as analytically using the Aspen Plus chemical process simulator.

Two approaches were considered for the hydrogen production step of the SA cycle, namely: photocatalytic and electrolytic oxidation of ammonium sulfite to ammonium sulfate in an aqueous solution. Also, two sub-cycles have been considered for the oxygen evolution side of the SA cycle, namely: zinc sulfate/zinc oxide and potassium sulfate/potassium pyrosulfate sub-cycles. The laboratory testing and optimization of all the process steps for each version of the SA cycle were then carried out. Once the optimum configuration of the SA cycle has been identified and the cycle has been validated in closed loop operation in the lab, it will be scaled up and tested on-sun.

Results

Cycle Evaluation and Analysis

In previous years, significant work was performed on the photo-catalytic SA cycle. During the past year, work focused on the electrolytic SA cycle, which is summarized in the following equations:

$\text{SO}_{2(g)} + 2\text{NH}_{3(g)} + \text{H}_2\text{O}_{(l)} \rightarrow (\text{NH}_4)_2\text{SO}_{3(aq)}$	(1 – chem. absorption)	25°C
$(\text{NH}_4)_2\text{SO}_{3(aq)} + \text{H}_2\text{O}_{(l)} \rightarrow (\text{NH}_4)_2\text{SO}_{4(aq)} + \text{H}_2$	(2 - electrolytic)	80-150°C
$(\text{NH}_4)_2\text{SO}_{4(aq)} + \text{K}_2\text{SO}_{4(l)} \rightarrow \text{K}_2\text{S}_2\text{O}_7(l) + 2\text{NH}_{3(g)} + \text{H}_2\text{O}_{(g)}$	(3 – solar thermal)	400°C
$\text{K}_2\text{S}_2\text{O}_7(l) \rightarrow \text{K}_2\text{SO}_{4(l)} + \text{SO}_{3(g)}$	(4 – solar thermal)	550°C
$\text{SO}_{3(g)} \rightarrow \text{SO}_{2(g)} + \frac{1}{2} \text{O}_{2(g)}$	(5 – solar thermal)	850°C

The electrolytic oxidation of the ammonium sulfite solution occurs more efficiently at higher temperatures requiring the development of a system capable of running at higher pressures. Reactions (3) and (4) form a sub-cycle by which potassium sulfate is reacted with ammonium sulfate in the low temperature reactor, to form potassium pyrosulfate. That substance is then fed to the medium temperature reactor where it is decomposed to SO_3 and K_2SO_4 again, closing the sub-cycle. The potassium sulfate and pyrosulfate form a miscible liquid melt that facilitates the separations and the movement of the chemicals in reactions (3) and (4). The oxygen production step (5) occurs at high temperature over a catalyst. Separation of the oxygen from SO_2 occurs when they are mixed with water in reaction (1). The net cycle reaction represented by reactions 1-5 is decomposition of water to form hydrogen and oxygen. All of the reaction steps described above have been demonstrated in the laboratory and shown to occur without undesirable side reactions. Figure 1 shows a schematic of the electrolytic SA cycle.

Independent Thermodynamic and Chemical Plant Analyses

An independent thermodynamic analysis of the feasibility of the SA Cycle was performed. The first step was to perform a preliminary thermodynamic analysis of the SA cycle. Subsequently a detailed analysis of the potassium pyrosulfate/electrolytic version of the SA cycle was performed. The analysis reaffirmed that the cycle can be closed and indicated cycle viability. The thermodynamic analysis was based on ideal solutions using HSC Chemistry 7.0 (Outotec Oyj, Espoo, Finland) augmented with SO_3 vapor pressure over $\text{K}_2\text{SO}_4/\text{K}_2\text{S}_2\text{O}_7$ solutions from reference [1]. The analysis was performed with Excel using add-in links to the HSC database enthalpy, and Gibbs energy functions. Vapor pressure data was fit using non-linear least squares analysis to generate functions for use in an Excel spreadsheet.

The major concerns to be addressed were in the oxygenation subsystem: the decomposition of ammonium sulfate, the formation of potassium pyrosulfate and the liberation of SO_3 from potassium pyrosulfate. Figure 2 shows details of the high temperature portions of the oxygen generation subsystem. The analysis assumed that the oxygen generation system would be operated at one bar and that the

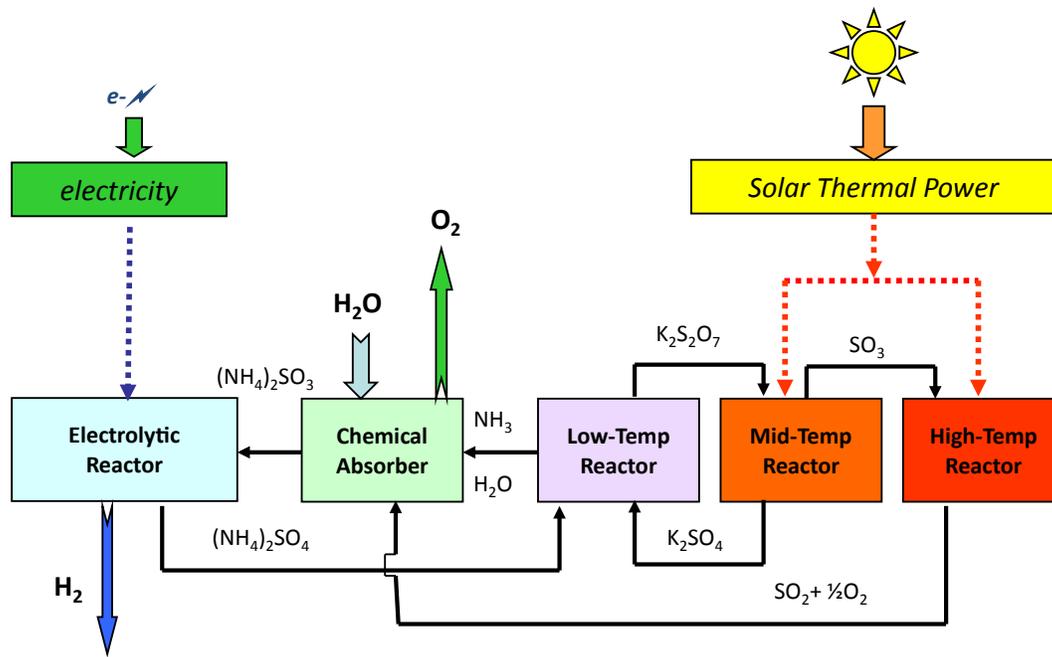

FIGURE 1. Schematic of the Electrolytic SA Cycle

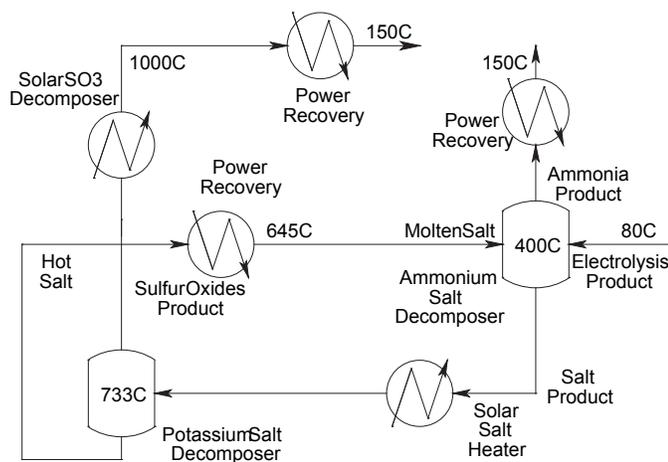

FIGURE 2. High-Temperature Portion of the SA Oxygen Generation Subsystem

ammonium sulfate decomposition step (low-temp reactor of Figure 1) would be accomplished at 400°C. For this analysis, the SO₃ decomposition temperature (high-temp reactor of Figure 1) was assumed to be 1,000°C. The composition of the electrolyte fed to the oxygen generation, obtained from ESC was H₂O:(NH₄)₂SO₄:(NH₄)₂SO₃ = 7.2:1:0.05. The minimum melting point of a K₂SO₄/K₂S₂O₇ mixture occurs at about 8.3 mole percent K₂SO₄ at about 400°C. The ratio K₂SO₄:K₂S₂O₇ = 2:10 in the molten salt fed to the ammonium salt decomposer was chosen such that, after absorbing one mole of SO₃ from the (NH₄)₂SO₄, the composition would be K₂SO₄:K₂S₂O₇ = 1:11, or 8.33 mole percent K₂SO₄.

The exact temperature of the NH₃/SO₃ separation is not of major importance, but it must be at least 400°C so that the K₂SO₄/K₂S₂O₇ product is molten. If slightly higher temperatures are required, there may be some recycle of SO₃ back to the electrolysis section with the NH₃ but this will have a minimal effect on the efficiency. What must be minimized is ammonium species accompanying the potassium salts into the high temperature section where the NH₃ will react in the catalytic SO₃ decomposer according to the reaction 2NH₃ + 3SO₃ → 3SO₂ + 3H₂O + N₂. If this occurs, not only will ammonia reduce the oxygen yield, and thus indirectly the amount of hydrogen generated, ammonia will have to be purchased continually or manufactured on site to make up the lost material.

The temperature of the potassium salt decomposer (the mid-temp reactor of Figure 1), 733°C is the temperature required to vaporize one mole of SO₃ from the salt product to return it to the required composition for feed to the ammonium salt decomposer. The stream must be cooled to 645°C such that when mixed with the electrolysis feed the resultant temperature of the ammonium salt decomposer is the specified 400°C. The only use of the heat from 733°C to 645°C is the production of electricity. This amount of heat is sufficient to power the electrolysis system at a voltage of 1.5 volts if the electricity is generated at 25% efficiency. If the hydrogen is produced at a reasonable voltage (0.5 to 0.8 volts) and the electricity is generated at normal efficiencies (30-40%) there will be a large excess production of electricity available for export. Since we intend to operate the hydrogen production system on a continuous 24/7 basis and the SO₃ decomposition system only during insolation, the hot molten salt will be available to generate electricity continuously.

Electro-Oxidation of Aqueous Ammonium Sulfite Solutions

Optimization of the electrolytic process continued at ESC. New catalysts and electrode materials have been screened at 80°C, with the most promising materials including spinels ($M_xN_{3-x}O_4$ where M,N=Fe/Ni/Co), platinum/cobalt mixtures and alternate felts. These materials were further screened in a new high pressure reactor which was built for this project and is shown in Figure 3. The high pressure reactor is capable of operation at 150 psi and 260°C. Cell performance with the Pt/Co catalyst at 130°C gave 0.8 V @ 160 mA/cm² and 1.02 V @ 300 mA/cm² as shown in Figure 4 with further improvements at higher temperature. Work also showed that the use of an undivided cell is most likely not possible at temperatures above 60°C, as the present cathode structure becomes inefficient with reduction of sulfite competing with hydrogen production.

High-Temperature Cycle Step Evaluation

Evaluation of the all-liquid/gas high-temperature cycle steps continued. As shown in Figure 5, TGA experiments were conducted to show the evolution of ammonia and water vapor at ~365°C, followed by evolution of sulfur trioxide at 496°C. A residual gas analyzer was used to detect the gases from the reaction. However, as tiny amounts (~10 mg) of reactants are used for the TGA with an argon

FIGURE 3. Pressure Vessels Required for Electrochemical Cell Operation at High Temperature

purge stream, the product concentrations are very diluted, and often not detectable. A large reactor system is being built to use ~10 g of reactants to study the reaction kinetics and evolution of gases products under more realistic operating conditions. The reactant ratios will be optimized to increase the temperature difference between the evolution of ammonia and SO₃.

Aspen Plus Process Analysis

The Florida Solar Energy Center (FSEC) supplied a copy of their model of the SA plant in Aspen Plus. Unfortunately, the data supplied was not sufficient to run the

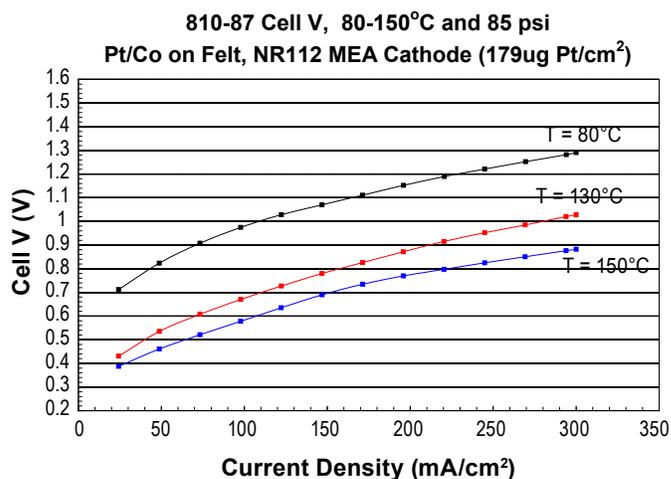

FIGURE 4. Cell Performance as a Function of Current Density and Temperature

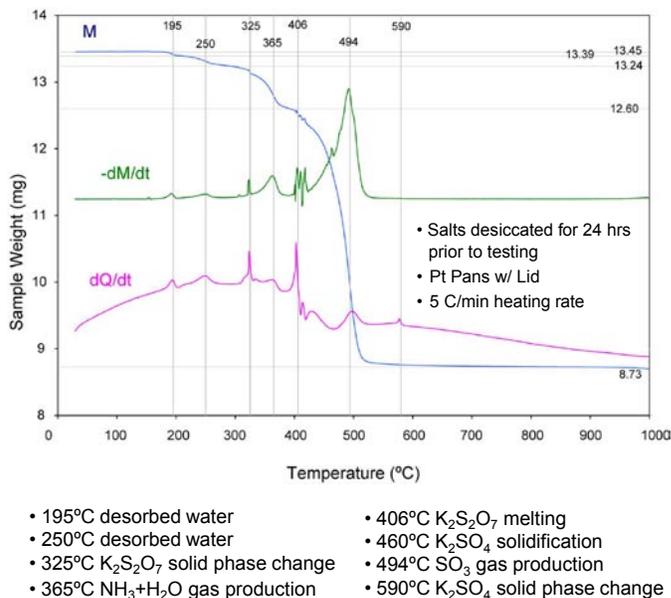

FIGURE 5. TGA/Differential Thermal Analysis of:
 $(NH_4)_2SO_4 + 2 K_2SO_4 + 8 K_2S_2O_7 \rightarrow 2 NH_3 + H_2O + 9 SO_3 + 10 K_2SO_4$

model with revised input values. UCSD supplied additional specifications for recycle streams within the plant so that the model could be run with new input values.

Using the FSEC model as a guide, UCSD is developing its own Aspen Plus model of the plant. This is being performed for several reasons. The first is to better understand all the characteristics of the plant model. Another reason is to include better thermodynamic data for some of the less common materials in the plant such as the molten sulfate/pyrosulfate mix in the oxygen section of the plant. To date, all units have been incorporated into the UCSD model and the material balance has been closed. Current work involves performing a process heat integration analysis, or pinch analysis, of the plant in order to place heat exchangers and optimize the thermal energy efficiency of the plant. UCSD is also developing rate/kinetic models of the individual unit operations in the plant.

Solar Field Optimization

The solar field configuration has continued to be updated as the thermo-chemical system evolves.

Evaluations were performed to determine the optimum way that the system could operate continuously on a 24/7 basis. The all-liquid $K_2SO_4/K_2S_2O_7$ system provides the opportunity to absorb and store heat directly in the reactants of the system. The molten salt solubility curves are such that a large excess of $K_2S_2O_7$ is needed to keep the mixture liquid, so much more heat capacity is present than is needed to operate the reactions. The sensible energy contained in the salts in the medium-temperature reactor is therefore also sufficient to provide the heat needed for the low-temperature reactor, and the excess energy is used to produce electricity that runs the electrolysis process. The highest-temperature oxygen evolution process can be operated in a solar-only mode using a separate high-temperature receiver, or electricity produced from the excess heat of the molten salt mixture can be used to operate that reaction 24/7 as well.

Economic Analysis

The H2A economic model for the electrolytic SA process was updated. Discrepancies between the inputs for the SA model and those of other groups were removed by using scaled values from the Sandia heliostat field analysis to update the solar field model. Updated results for the electrolytic process efficiency were also included in the calculation. The resulting estimated production costs for hydrogen were found to be \$7.74/kg in 2015, and \$4.65 in 2025.

The H2A cost analysis program was also used to examine the optimization of the electrolytic portion of the system. The electrolytic system design is a balance between capital costs for electrolytic cells and operating costs for electricity. Recent test data for the polarization curve of the electrolytic cell (i.e., voltage vs. current density) were combined with estimated costs from H2A for the electrolysis

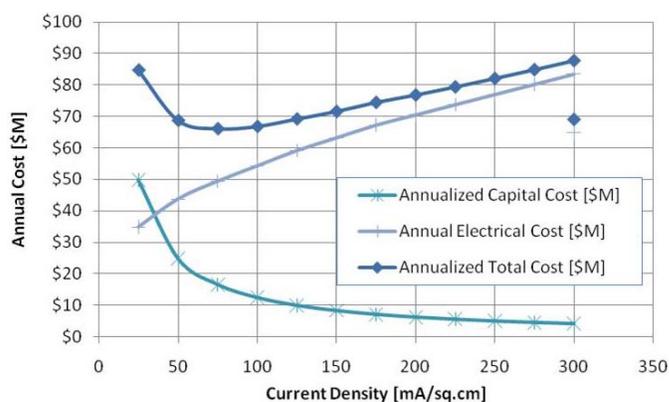

FIGURE 6. Economic Optimization Study Results

cells ($\$/m^2$) and for electricity. The capital costs were annualized using the capital recovery factor from H2A and combined with the annual electricity costs to obtain a levelized annual cost for the electrolytic system, and the calculation was repeated over a range of current densities from 25 mA/cm² to 300 mA/cm². The results are shown in Figure 6. At low current densities, the cost is high because of the large area of electrolysis cells needed to pass the required electrolysis current. At very high current density, the increase in cell overpotential leads to high electricity so the cost again increases. The lowest cost point is at 75 mA/cm². This is a much lower value than had been expected. For comparison, the target value of 0.8 V at 300 mA/cm² is plotted on the figure as the separate point to the far right – note that the minimum cost point predicted using our current data is actually lower than the cost for that set of conditions.

The conclusion from this study is that it is more important to focus our efforts on reducing cell voltage to reduce electrical costs rather than focusing on increasing current density to reduce capital costs. Sensitivity studies of the results confirm this conclusion. Increasing electricity costs drive the minimum cost to lower current densities, but not strongly. Doubling the cost of electricity reduces the minimum cost point from 75 to about 50 mA/cm². Likewise, doubling the capital cost of the electrolysis system components only moves the minimum cost point to about 100 mA/cm².

Conclusions and Future Directions

In summary:

- An independent thermodynamic and chemical plant analyses reaffirmed that the cycle can be closed and indicated cycle viability.
- Significant progress was made in reducing the cell voltage and increasing the current density of the electrolytic cell by operating at higher temperatures and with improved cell design. Improvements made over

the last year have enabled us to increase the current density by a factor of 2.5 times to 160 mA/cm² at a total cell voltage of 0.8 V.

- Additional evaluations of the all-liquid/gas high-temperature oxygen generation cycle steps continued to prove the subcycle feasibility.
- A new Aspen Plus chemical plant model has been developed that is more robust and more accurately models the thermodynamic characteristics of the model.
- Evaluations were performed that show the SA system with solar energy storage can operate continuously on a 24/7 basis.
- The H2A economic model for the electrolytic SA process was updated and aligned with the assumptions for other hydrogen production cycles. H2A analyses show that the lowest total annualized cost of hydrogen achieved to date at 0.6 V and 75 mA/cm² is actually lower than our target performance of 0.8 V and 300 mA/cm².

Activities planned for the upcoming year include:

- Further optimization of the electrolytic process and cell. This will include identification of catalysts that will reduce the over-potential at the anode and allow operation at high current densities. The best catalyst will be evaluated in longer term operation by performing a 500 hour durability test.
- Complete evaluation of the K₂SO₄ oxygen subcycle reactions. A large reactor system will be constructed to use ~10 g of reactants to study the reaction kinetics and evolution of gases products under more realistic operating conditions.
- Using Aspen Plus, optimize the thermal energy efficiency of the plant.
- Development of the thermal reactor/receiver designs including materials specification and testing.

- Development of the solar field configuration and design to match the final chemical plant requirements.
- Continue to update H2A economic analyses to document the potential cost of hydrogen from the SA cycle.

After completion of phase 1, the next phase of the project will involve laboratory validation of the closed-loop SA cycle leading to on-sun hydrogen production demonstration.

Start Date: October 2010

Projected End Date: September 2012

FY 2011 Accomplishments

- Identified several membranes with low copper permeability at 80°C.
- Conducted electrolysis tests that showed no visible copper crossover with two membranes—double layer Nafion® and CG2, a porous separator. The hydrogen production efficiency exceeded >80-90% when the cell potential was 0.7 V and the current density was 100-150 mA/cm².
- Scaled up the electrolyzer from 5 to 31 cm² and obtained a stable current for almost 800 hours with CG2 and a cell potential of 0.7 V and a current density exceeding 100 mA/cm².
- Developed a speciation model of the electrolyzer's anolyte to calculate any thermodynamic property such as decomposition potential, solubility of CuCl(s) in HCl(aq) anolyte, concentration of HCl(aq) to dissolve Cu(s) in catholyte, etc. over a wide temperature range from 25 to 100°C.
- Continued collaborations with Atomic Energy of Canada Limited and a group of Canadian universities.

Fiscal Year (FY) 2011 Objectives

The strategic objective is to develop a robust process for producing hydrogen that meets DOE's targets for cost and energy usage; the tactical objectives are the following:

- Identify methods that prevent copper deposition at the cathode of the electrolyzer while meeting targets for cell potential (0.7 V) and current density (500 mA/cm² to be met in three years).
 - Identify membranes with low copper permeability and sufficient proton conductivity.
 - Optimize operating conditions and electrolyzer design to further minimize copper crossover.
- Continue collaborative work on the thermal reactions with Canada.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (U) High-temperature Thermochemical Technology
- (V) High-Temperature Robust Materials
- (W) Concentrated Solar Energy Capital Cost

Technical Targets

The technical targets are the cost of hydrogen production and the process energy efficiency.

- For 2017, these are \$3.00 per gasoline gallon equivalent (gge) H₂ and >35% (lower heating value, LHV), respectively.

Introduction

The U.S. Department of Energy's Office of Energy Efficiency and Renewable Energy (DOE-EERE) is supporting the development of H₂ production technologies that use solar heat. One approach involves thermochemical cycles whose heat source is the solar power tower, which is near commercialization and provides heat near 550°C now and up to 650°C in the future. The CuCl cycle is unique because its maximum temperature is 550°C.

The three major reactions in the Cu-Cl cycle are shown in Table 1. All reactions have been verified at the temperatures shown. Note that the maximum temperature is less than 550°C.

TABLE 1. Three Major Reactions in the Cu-Cl Cycle

$\text{CuCl}_2 + \text{H}_2\text{O} \leftrightarrow \text{Cu}_2\text{OCl}_2 + 2\text{HCl}(\text{g})$	Hydrolysis, ~375°C
$\text{Cu}_2\text{OCl}_2 \leftrightarrow 2\text{CuCl} + \frac{1}{2}\text{O}_2$	Decomposition, 450-525°C
$2\text{CuCl} + 2\text{HCl} \leftrightarrow \text{CuCl}_2 + \text{H}_2$	Electrolysis, ~80 -100°C

No separations or phase changes are specified in this high level representation. There is a significant challenge in the electrolysis reaction because of copper crossover, which has been observed at the Atomic Energy of Canada Limited and at laboratories in the U.S. Copper crossover can lead to catastrophic failure of the cell. Work in the past year has therefore been focused on reducing copper crossover.

Approach

A collaboration involving several laboratories with expertise in different types of membranes was established. Pennsylvania State University investigated s-Radel (polysulfone-type) membranes, some of which were crosslinked, as well as double layered Nafion[®]. Argonne National Laboratory modified Nafion[®] by copolymerizing it with intertwining various aliphatic and aromatic polymers to reduce the pore size and also developed a cross-linked polybenzimidazole. Seven commercial separator-type membranes, which were available to Gas Technology Institute (GTI) for use in another study and were characterized by their manufacturers as having low metal ion transport and good chemical and thermal stability, were also examined. Screening evaluations were conducted with permeability and conductivity measurements. Electrolysis tests were conducted with the most promising membranes at 80°C.

Results

Permeability Measurements: The various membranes were screened by measuring copper permeability at 80°C and through-plane conductivity at room temperature. An initial target permeability of 10% of Nafion[®]'s was used. The permeability was measured in a diffusion cell, which consisted of two compartments, clamped together but separated by a membrane. The solute side contained a solution of CuCl₂ in 10.2 M HCl. The solvent side contained 10.2 M HCl. The permeability was calculated from the equation,

$$k = \left(\frac{IV_{\text{sample}}}{At_{\text{exp}}} \right) \ln \left(\frac{C_1}{C_1 - C_2} \right)$$

where l is the thickness of the wet membrane (cm), V_{sample} is the volume of the sample solution in our cell (cm³), A is the surface area of membrane (cm²), t_{exp} is the time of the exposure (sec), C_1 is initial concentration of Cu²⁺ in the first compartment (1 M), and C_2 is concentration of Cu²⁺ measured in the sample in the second compartment

at $t = t_{\text{exp}}$. Ideally k values should not be dependent on time as long as the properties of the membrane are stable and osmotic pressure does not result in significant solvent diffusion. The test period was 24 hours in most cases. However, large volume changes in the solute side due to osmotic pressure caused some permeability tests to be terminated after only several hours.

The membranes with the lowest copper(II) permeabilities are shown in Figure 1. Only one of the seven separator-type membranes examined, CG2, had very low copper permeability and further work, e.g., supports and pretreatments, was justified on this basis. The CG2 membrane is significantly thinner than Nafion[®] as shown in Table 2. Mechanical supports are therefore being developed to facilitate fabrication of membrane electrode assemblies (MEAs). CG2's proton conductivity is also relatively small (see Table 2) and various pretreatments are being investigated to increase this property. In addition, this membrane has the highest osmotic pressure and the diffusion tests can be run for very limited time periods. The membrane consisting of a double layer of Nafion[®] exceeded the permeability target by almost a factor of 6

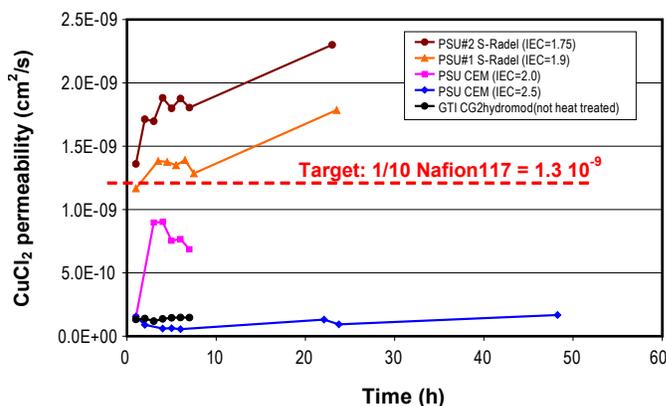

FIGURE 1. Permeability measurements at 80°C vs. time. HCl concentrations are 10.2 M in both compartments of the diffusion cell.

TABLE 2. Properties of Membranes for Possible Use in the Cu-Cl Electrolyzer

Membrane	Pretreatment	Thickness, / (mm)	Conductivity, σ (S/cm)	Permeability $k * 10^{-9}$ (cm ² /s)	Selectivity $\sigma / k * 10^5$
Nafion [®] 117	20 h in 2 M HCl, 25°C	0.180	0.086	0.18	48
Double-layer Nafion	20 h in 2 M HCl, 25°C	0.350	0.083	5.80	143
Mit-1 (from GTI)	None	0.003	Inconclusive		
CG2 (from GTI)	None	0.030	0.0054	94	57
s-Radel, IEC 2.0	None	0.054	0.038	3.68	102
s-Radel, IEC 2.0, crosslinked	None	0.107	0.053	4.77	111
s-Radel, IEC 2.5, crosslinked	None	0.100	0.045	83.5	535
s-Radel, IEC 2.5, crosslinked	66 h in 3.3 M HCl + 1 M CuCl ₂ , 25°C	0.109	0.045	1.48	300
s-Radel, IEC 2.5, crosslinked	2 h in 10 M HCl, 80°C	0.107	0.072	0.112	64

but this membrane had the highest proton conductivity and therefore the highest selectivity see Table 2. Two of the s-Radel membranes were very close to the target. After cross-linking, their permeabilities were below the target. Co-polymerized Nafion®-type membranes had low permeability at room temperature but exceeded the target at 80°C and further effort on this type of membrane was terminated. Studies are still ongoing with the crosslinked polybenzimidazole.

Conductivity Measurements: Conductivity was measured using the two-electrode through-plane method in 2 mol/L HCl(aq) solution at ambient temperature and pressure. Conductivity values were calculated using measured membrane resistance (R), thickness of wet membrane (δ), and exposed membrane surface area ($A=0.74 \text{ cm}^2$), as follows: $k = \delta / (R \times A)$. The equipment and method are described in detail elsewhere [1]. No target was set for proton conductivity except that it had to be measurable. Those membranes which met the targets were tested in electrolyzers at GTI and Pennsylvania State University for a more realistic evaluation.

The results of the through-plane conductivity measurements are given in Table 2. Nafion® 117 membrane was used as a bench mark. Table 2 also summarizes permeability and selectivity data. The latter are calculated by dividing the conductivity by the permeability. Some of the samples were pretreated. The data in Table 2 for the cross-linked s-Radel membranes show that pretreatment affects selectivity. Pretreatment processes are still under development for CG2.

Electrolyzer Results: Electrolyzers were built at both Pennsylvania State University and GTI. Details of the electrolyzer at Pennsylvania State University are published elsewhere [1]. The performance of the electrolysis process was monitored by taking polarization data and comparing experimental and theoretical hydrogen production. Targets for the cell potential and the current density in the model are 0.7 V and 500 mA/cm², respectively. However, short term targets specify lower current densities for cell potentials of 0.7 V.

Several MEAs were tested in the electrolyzers. The MEA fabricated from the double-layer Nafion® gave promising results in a 24-hour test at 80°C with 10.2 M HCl as the catholyte and 1 M CuCl in 10.2 M HCl as the anolyte. Hydrogen production followed Faraday's Law, as shown in Figure 2. There was, however, some degradation with time as shown by the polarization curve in Figure 3, which may be due to the consumption of CuCl. At the conclusion of the test, no copper deposition was observed on the cathode, membrane or gas diffusion layers. Photographs of the latter are shown in Figure 4. Similar results were obtained with CG2 using the same conditions but with deionized water as the catholyte. Lifetime tests at GTI were run intermittently for almost 800 hours with the intermittent addition of CuCl. The cell voltage was 0.7 V and the current density was stable near 150 mA/cm². Hydrogen production followed Faraday's

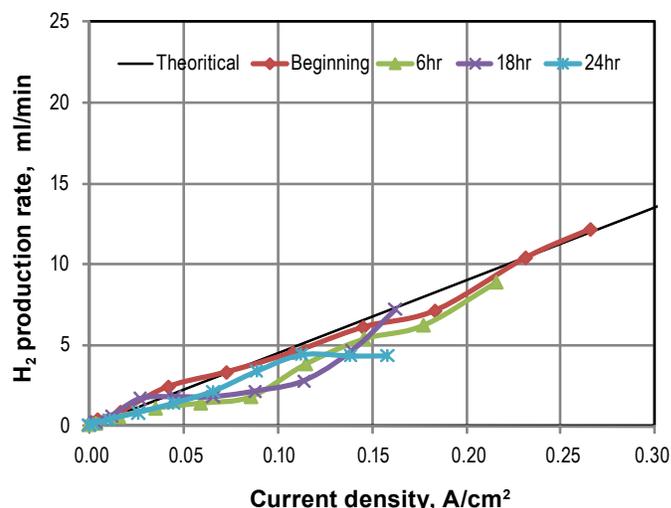

FIGURE 2. Hydrogen production as a function of cell voltage over 24 hours with the double layer Nafion® membrane.

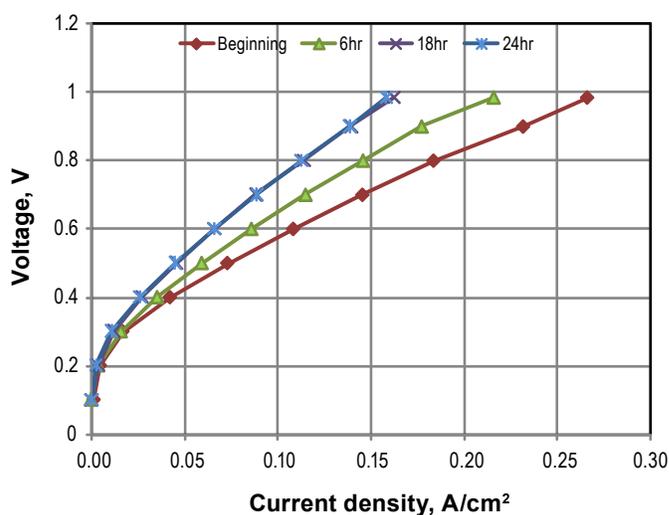

FIGURE 3. Current vs. voltage as a function of time with the double layer Nafion® membrane.

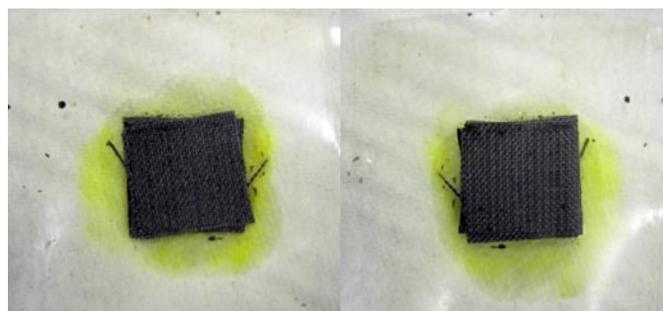

FIGURE 4. Photographs of the MEA diffusion layers facing the cathode (left) and anode (right) of the electrolysis cell used in the 24-hour electrolysis test with double layer Nafion® that show no visible copper deposits.

Law. No copper deposition was visible on the components of the cell after the test was terminated. Comparison of peak hydrogen production in the two electrolyzers showed essentially identical results. Electrolyzer tests with the cross-linked s-Radel membranes are planned.

Collaborations: Collaborations between the U.S. team members and their Canadian colleagues are focused on the study of the hydrolysis and oxychloride decomposition reactions using X-ray absorption near edge structure at the Advanced Photon Source. It is hoped that these measurements will result in kinetic measurements and mechanistic understanding of these two thermal reactions. Information is exchanged periodically, e.g., Ontario Workshop Foundation workshops (see presentation #2) and in discussions between the researchers, especially in modeling activities.

Conclusions

- Identified two membranes that had low copper diffusion in permeability tests and had sufficient proton conductivity.
- Conducted electrolyzer tests that showed no visible copper deposition in/on the cell components.

Future Directions

- Develop methods to improve the mechanical stability of CG2.
- Optimize the electrolyzer's performance by investigating other compositions for the anolyte and catholyte, flow rates, flow field design, electrode surface, mass transport media, etc. to obtain higher current densities at 0.7 V.
- Investigate the degradation mechanisms in the electrolyzer and develop methods to mitigate these.
- Continue collaboration with staff at Atomic Energy of Canada Limited and six Canadian universities.

Project End Date: Project continuation and
direction determined annually by DOE

been estimated to be 37% using commercially available cerium oxide reactant powder. This material is not the ideal from a thermodynamic perspective and will likely be improved upon as the project progresses. The reactor itself can be configured for any particulate reactant.

TABLE 1. Progress towards Meeting Technical Targets for Solar Drive High Temperature Thermochemical Hydrogen Production

Characteristic	Units	2012 Target	2017 Target	SNL 2011 Status
Hydrogen Cost	\$/gasoline gallon equivalent H ₂	6	3	N/A
Heliostat Cost	\$/m ²	140	80	N/A
Process Efficiency	%	30	>35	30% estimated ¹

¹ This number is the product of receiver efficiency (solar in to heat available, ~82%) and thermochemical efficiency (heat available to lower heating value H₂ ~37%).
N/A - not available

Additional project targets outside of those listed in Table 1 are given as follows:

- Thermochemical Cycle (reactive materials): Oxidation and reduction reactions must reach 90% completion within two minutes.
- Reactor: Demonstrated conversion efficiency for the prototype reactor (5 kW_{th}) must be in excess of 20% at a pressure greater than 10 Pa.
- System: Estimated system level efficiency including collection and conversion losses must be in excess of 19% annual average for a dish system and 14% for a tower system.

Fiscal Year (FY) 2011 Objectives

- Characterize reactive materials suitable for thermochemical hydrogen production under realistic operating conditions (e.g. temperature, atmosphere, heating rate).
- Develop a particle-based thermochemical reactor suitable for deployment on a central receiver platform and embodying several key design features.
- Evaluate the likely system level performance of the reactor concept and identify energy losses and opportunities for performance improvement.

Technical Barriers

This project addresses the following technical barriers from the production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (U) High-Temperature Thermochemical Technology
- (V) High-Temperature Robust Materials
- (X) Coupling Concentrated Solar Energy and Thermochemical Cycles

Progress toward the technical targets is shown in Table 1. Hydrogen cost from the particle reactor system has not yet been evaluated because the system level design is not complete and this is needed as the basis for an economic analysis. Heliostat cost reduction is not actively funded by this project, but is an element of the DOE Solar Program. The thermochemical efficiency for the particle reactor has

Accomplishments

- Reactor
 - A detailed reactor performance model was developed and indicates that heat to hydrogen conversion efficiency in excess of 37% is possible using a cerium oxide-based thermochemical cycle.
 - Evaluated the compatibility of cerium oxide reactant with reactor construction materials including Al₂O₃, SiC, and Haynes 214 at nearoperational temperatures. SiC and Haynes 214 showed minimal or no interaction to 1,400°C, Al₂O₃ showed no interaction to 1,450°C.
 - Designed a particle conveyor system (subcontract with Jenike and Johanson) suitable for moving a powder reactant vertically in a packed bed arrangement. This configuration is required to achieve the best-case efficiency in the particle reactor. Prototype construction of the conveyor is currently in progress.

- Materials
 - A laser-based heating method was incorporated into our stagnation flow reactor that enables rapid thermal processing of sample materials. Heating rates in excess of 100°C/s are achievable at 500 W/cm² (5,000 suns).
 - The thermal reduction of various CeO₂ reactive structures, comprised of powders, felts, and fully dense forms, was characterized at operating pressures and heating rates relevant to solar thermochemical applications. It was determined that for CeO₂ reactive structures with characteristic dimensions less than 1 mm, oxygen evolution kinetics would likely not limit use of this material in the proposed reactor configurations.
 - Experiments to characterize the thermal reduction and water splitting kinetics for the following material structures and chemistries have been conducted: CeO₂ felt, CeO₂ and Mn-doped CeO₂ powder, atomic layer deposition (ALD) thin film Fe₂O₃/CeO₂, ALD thin film Fe₂O₃/m-ZrO₂, ALD thin film Fe₂O₃/Al₂O₃ (hercynite). We are in the process of analyzing the complete data set.
- System
 - A general system level model was developed to estimate the annual average hydrogen production efficiency of the particle reactor system. Results show that an annual average solar-to-hydrogen conversion efficiency of 24% is possible in a dish based system with a cerium oxide reactant.
 - A separate system model that includes a more detailed description of the reactor (temperature dependent properties, rigorous treatment of chemical reactions) was developed in ASPEN.

Introduction

Solar-powered thermochemical water splitting produces hydrogen using only water, heat from the sun, and chemicals that are completely re-cycled so that only hydrogen and oxygen are produced and only water and solar thermal energy are consumed in the cycle. All known thermochemical cycles face obstacles that could include extremely high temperature, highly corrosive chemicals, difficult separations of chemicals during sequential cycle steps, multiple reaction steps necessary to close the cycle, or side reactions with stable products that poison the process upon recycling. Many of these barriers can be overcome, but generally at the expense of energy efficiency, consumption of feedstocks other than water, and possibly much higher temperature to drive reactions to completion. All of these measures add cost to the product, inhibit acceptable production rates, or prevent the realization of plant designs with acceptable lifetimes. Overcoming these barriers is

made even more difficult by turning to solar radiation for the driving energy source, primarily because of its transient nature and relatively low power density. The low power density characteristic of solar power requires large collector areas and efficient concentrators to drive energy-intensive processes like water splitting.

The ultimate success of solar thermochemical hydrogen production is contingent on developing suitable reactive materials and on incorporating these materials into an efficient solar thermochemical reactor. Currently, SNL and the University of Colorado are working together to identify and characterize prospective thermochemical cycles and associated reactive materials. Recent efforts have focused on ferrites, cerium oxide, and hercynite as potential candidate material “families”. Additional research and development efforts are directed at reactor and system level challenges related to collecting and applying solar thermal energy to the water splitting function within each of these cycles. Solar thermochemical reactors for ultra-high temperature processes ($T > 1,300^\circ\text{C}$) are being developed and tested by SNL.

Approach

Metal oxide-based materials, such as those containing cerium oxide or iron oxide (ferrites), have demonstrated the capability of splitting water in a two-step cycle consisting of a high temperature, oxygen-liberating thermal reduction reaction (up to 1,500°C) and a lower temperature, hydrogen-producing water oxidation reaction (<1,000°C). In order to achieve large hydrogen production volumes in a practical device these two reactions should be run in a continuous manner. In addition, in order to achieve high efficiency it is desirable to maximize the extent of reaction and essential to recover sensible heat between the high and low temperature reactions (recuperation). Also, any practical solar-driven reactor will operate continuously for thousands of hours without requiring service. Any reactive materials used in such a reactor must demonstrate an acceptable level of chemical and mechanical durability.

We are developing a particle-based reactor concept suitable for continuous hydrogen production on-sun in either a central receiver or parabolic dish configuration. Our technical efforts are organized into three tasks:

- **Reactor Development:** This task focuses on the reactor design, performance estimation and eventual validation at the prototype level (5-10 kW_{th}). Specific areas of effort include the design of high temperature solar reactor components along with material compatibility studies to evaluate interactions between the thermochemical reactant and products and materials used in reactor construction.
- **Materials Characterization:** Although materials are available today that can achieve performance levels near the DOE targets, there is considerable room for improvement. In this task we use a unique experimental capability to evaluate the performance of prospective

materials under controlled conditions similar to what might be found during on-sun operation. This system, based on a laser heated reaction chamber, allows for the evaluation of reaction thermodynamics and kinetics of prospective thermochemical cycles.

- **System Level Analysis:** The ultimate goal of this project is to produce hydrogen efficiently from solar energy. In this task we estimate the performance of thermochemical technologies at the system level, identifying energy losses and calculating annual average hydrogen production efficiency based on the collection platform and facility location.

Results

The results from FY 2011 show that the combination of our particle reactor concept and cerium oxide-based reactive materials has the potential to achieve performance near the 2012 and 2017 DOE targets. Meeting these targets with actual hardware during on-sun operation will require additional effort in FY 2012 and beyond.

Reactor Development – The particle reactor being developed in this project uses cerium oxide powder in a two-step redox cycle to continuously produce hydrogen from solar energy and water. A schematic of the reactor concept is shown in Figure 1. Key attributes of the reactor are recuperation of sensible heat between the reaction steps, continuous flow, direct absorption of solar energy by the reactant, and the spatial separation of pressure, temperature, and reaction products within the device.

Our preliminary work in FY 2011 focused on estimating the likely level of reactor performance achievable in a mature technology. For this study we assumed that the

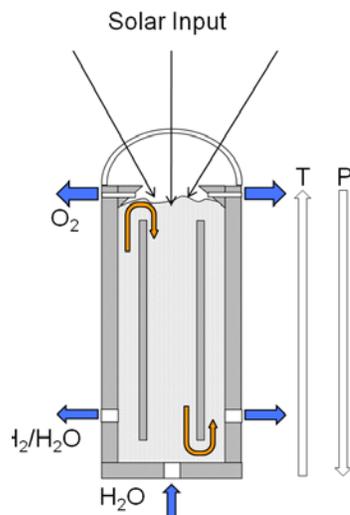

FIGURE 1. A schematic of the particle reactor concept. Particles must be conveyed vertically as a packed bed within the reactor. Concentrated solar energy enters from the top.

reactant would be CeO_2 , which has been shown to be suitable for two-step thermochemical hydrogen production, but is not considered to be ideal due to the relatively small amount of oxygen exchanged per mole of reactant. Even so, with recuperation the performance of the reactor in terms of the conversion of thermal energy to chemical energy in the form of a hydrogen product can exceed 40% at a thermal reduction pressure in excess of 100 Pa (Figure 2). With improved materials this level of performance can be even higher.

Efforts to design a reactor prototype at the 5-10 kW_{th} level have focused on identifying a suitable means of conveying a packed powder vertically within the reactor. To this end a contract was placed with Jenike and Johanson, specialists in the field of powder conveyance. They identified a conveyor based on the “Old’s Elevator” approach in which particles are moved by friction up a stationary central screw by contact with a rotating cylindrical housing. A conceptual design of the conveyor system, included rotary airlocks and cyclone separators, is shown in Figure 3. This system will be modified during the final solar prototype design stage.

Our reactor design efforts also included a study of the compatibility of various construction materials with cerium oxide powder. We have shown that several materials including Haynes 214 and Al_2O_3 are compatible with cerium oxide up to 1,400°C. Our hope is that it will eventually be possible to use a metal like Haynes 214 for the main components of the screw conveyor as this would minimize difficulties with fabrication. This may not be possible at a temperature much in excess of 1,200°C due to material strength issues. We are therefore continuing to investigate options for fabricating the conveyor components from suitable ceramic materials.

Materials Characterization – A number of experiments were conducted that focused on the characterization of pure cerium oxide reactive materials. In this work, a

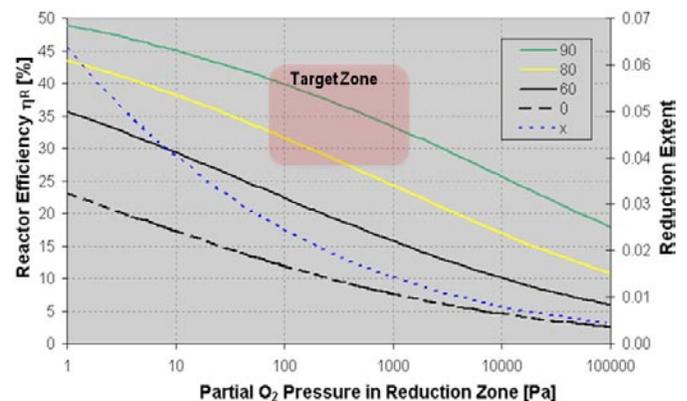

FIGURE 2. Predicted performance of the particle reactor using pure CeO_2 reactant. Reactor efficiency is analogous to the DOE “process efficiency” number.

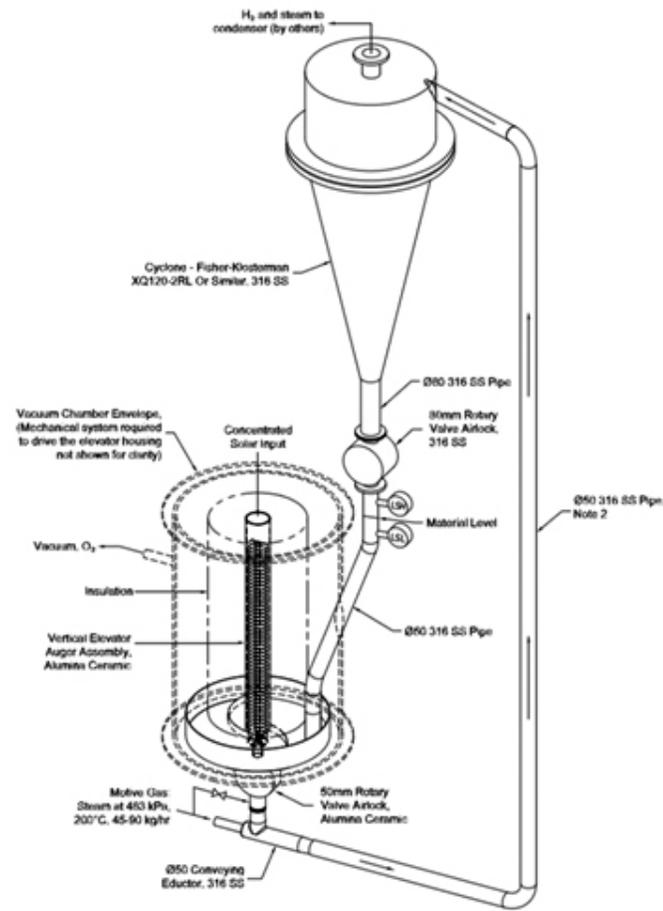

FIGURE 3. Conveyor system preliminary design.

laser-based heating method was used in conjunction with a stagnation flow reactor equipped with a mass spectrometer to investigate both the thermal reduction and oxidation reactions for cerium oxide powders, dense pellets, and felts. The rate of oxygen evolution during thermal reduction was measured for: (1) a powder having a ~5 μm particle diameter, (2) a 1,000 μm thick fully dense pellet, and (3) a felt with ~10 μm fiber diameter. Tests were conducted at a peak temperature slightly above 1,500°C and a heating rate in excess of 100°C/s. The results are illustrated in Figure 4 and show that the reaction rate and ultimate extent of thermal reduction was independent of the length scale over the range evaluated. The rate of the hydrogen-producing water splitting reaction using cerium oxide felt was measured over a range of temperatures in an attempt to characterize the optimal operating point for this type of reactive structure. These tests showed that the peak hydrogen production reaction rate varies with temperature, reaching a maximum near 1,000°C, but the overall amount of hydrogen production per unit mass of reactant was independent of reaction temperature (Figure 5). In the case of reaction at 1,000°C, the amount of time required for 90% completion is less than 90 seconds, which is consistent with

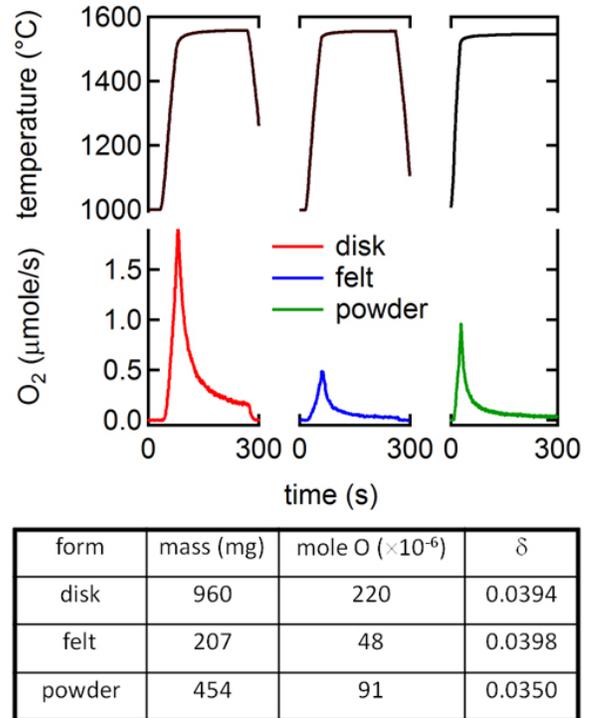

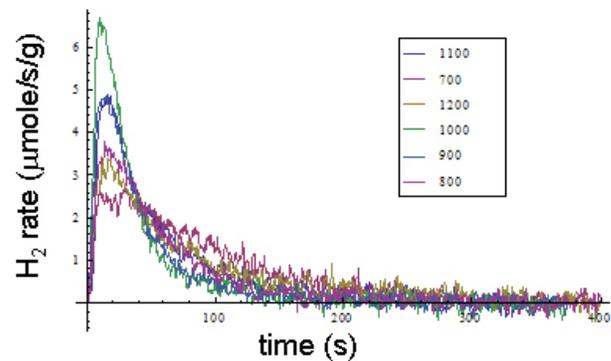

FIGURE 4. Thermal reduction behavior observed for various forms of CeO_2 .

temperature (°C)	total H ₂ (μmole/g)	peak H ₂ (μmole/s/g)
1200	274	3.27
1100	273	4.76
1000	249	6.51
900	229	4.75
800	235	3.60
700	285	2.64

FIGURE 5. Rate of H₂ production for thermally reduced CeO_2 felt.

the operational requirements of a solar thermochemical reactor. Thirty cycles were run over which the production characteristics remained constant, which indicates that there was no degradation of the reactive material or its physical structure. A number of other chemistries for solar thermochemical water splitting were also evaluated this FY, including modified cerium oxide and ALD-ferrite-coated reactive structures. Analysis of the data is ongoing and will be completed before the end of FY 2011.

System Level Analysis – The focus of the system level analysis was to identify all energy losses within the solar collection and reactor sub-systems and then estimate the annual average conversion efficiency of sunlight to hydrogen. The analysis was based on hourly meteorological data for a design location in Daggett, CA. System performance was calculated for each hour of an entire year and the energy inputs and hydrogen outputs summed over the year to determine the efficiency. Figure 6 is a summarized output showing principal energy losses within the system. It is important to note that 42% of the solar energy available to the parabolic dish collector is lost during collection and not available to power the thermochemical reaction. Although this may be improved slightly, the parabolic dish is a very efficient optical platform and large gains in collection efficiency are not likely. This fact is a compelling argument in support of dedicating significant effort to reactor design in order to maximize its efficiency.

The current system model, which was constructed in Excel, was provided to researchers at Pacific Northwest National Laboratory for inclusion in their ASPEN-based studies. We have also begun developing our own reactor models in ASPEN with the intent of eventually simulating the entire system (annual performance) with this code.

Conclusions and Future Directions

The progress made in FY 2011 will provide a strong foundation for continued work in FY 2012 that will hopefully culminate in the on-sun demonstration of a particle reactor prototype. Specific conclusions and future directions for each of the three main project elements are given as follows:

Reactor Development – In FY 2011 we have shown that the particle reactor concept can meet the DOE performance targets and are well on our way to completing the design of a 5-10 kW_{th} prototype system. In FY 2012 and beyond we will focus our efforts on completing the design and performing on-sun testing of the reactor. Past experience has shown that when dealing with thermochemical fuel production hardware it is essential to test systems under realistic condition to identify technical challenges that are not apparent when performing more idealized preliminary analysis and simulation activities.

Materials Characterization – In FY 2011 we experimentally characterized several promising reactive materials under operating conditions similar to what would be expected in a solar thermochemical reactor. In FY 2012 and beyond we will define a standard performance evaluation process and metrics that can be used to more easily compare various candidate materials. We will also continue to characterize promising new redox chemistries for non-volatile metal oxide cycles using the laser-based heating method incorporated into the stagnation flow reactor, subject to the material characterization protocols developed in FY 2012.

System Level Analysis – In FY 2011 we developed an annual system performance model that shows all major

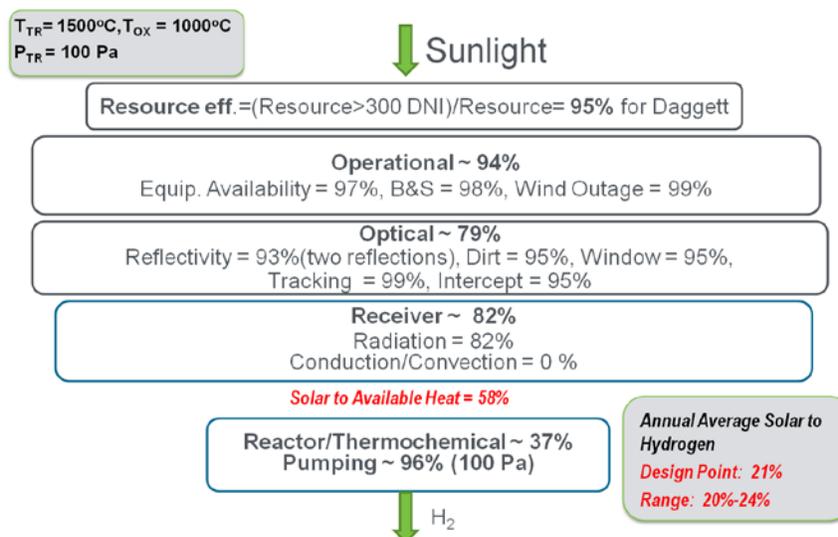

FIGURE 6. System level energy flow and annual average efficiency calculation.

energy losses in the system and enables the calculation of an annual average hydrogen production efficiency, a much more valuable number than a design point efficiency. In FY 2012 and beyond we will extend this model to a central receiver-based system configuration that will show the potential, and challenges, associated with scaling the particle reactor concept to larger sizes.

Definition of Terms

- Thermochemical Efficiency: This is the efficiency of the conversion of heat within the reactor to chemical fuel based on the lower heating value (LHV) of hydrogen. It does not include solar losses or energy losses from the receiver that are accounted for separately.
- Receiver Efficiency: The fraction of solar energy entering the reactor that is converted into useable heat available to the reactor. This term essentially accounts for radiation and convection losses from the receiver.
- Process Efficiency: The fraction of solar energy entering the reactor that is converted into chemical energy in the form of hydrogen on an LHV basis. This number is the product of receiver efficiency and thermochemical efficiency.
- Annual Average Efficiency: The total energy contained in hydrogen (LHV basis) produced over an entire year divided by the solar energy striking the collection system (mirrors) over the same period of time.
- Resource Efficiency: This quantity is the total solar energy that could be collected divided by the amount available over a year. Accounts for periods when the system is not operated by design.
- Operational Efficiency: The fraction of the total energy actually collected divided by the amount that could be collected over a year. This accounts for “wasted” energy when the collectors are not operating during the daytime due to weather outages or system maintenance.
- Optical Efficiency: The fraction of energy reaching the aperture of the reactor divided by the amount actually collected by the concentrator. Accounts for all reflection and transmission losses.

FY 2011 Publications/Presentations

1. Two abstracts submitted and accepted for presentation at SolarPaces 2011. Full papers are to be completed by July 31st, 2011.
2. A project summary was presented at the Annual Merit Review in Washington, D.C.
3. An invited talk entitled “*High temperature splitting of water and carbon dioxide using complex oxides as a route to solar fuels*” will be presented at the 242nd ACS National Meeting, Division of Fuel Chemistry, in August of 2011.
4. An abstract has been accepted for presentation at the 5th International Conference on Energy Sustainability hosted by the ASME in August of 2011.
5. “*Hydrogen Production via Chemical Looping Redox Cycles Using Atomic Layer Deposition-Synthesized Iron Oxide and Cobalt Ferrites*”, Jonathan R. Scheffe, Mark D. Allendorf, Eric N. Coker, Benjamin W. Jacobs, Anthony H. McDaniel, Alan W. Weimer in *Chemistry of Materials* 2011 23 (8), 2030-2038.

annually by DOE.

Fiscal Year (FY) 2011 Objectives

- Finalize the ferrite process flow diagram and H2A economic analysis.
- Determine the most cost effect design and construction materials for the FY 2010 conceptualized scalable central solar reactor/receiver per H2A guidance on economics.
- Demonstrate suitable materials for robust redox/thermochemical cycling.

Technical Barriers

This project addresses the following technical barriers from page 3.1-26 of the Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (U) High-Temperature Thermochemical Technology
- (V) High-Temperature Robust Materials
- (W) Concentrated Solar Energy Capital Cost
- (X) Coupling Concentrated Solar Energy and Thermochemical Cycles

Technical Targets

The technical targets are the cost of hydrogen and the process energy efficiency.

- For 2017, these are \$3.00 per gasoline gallon equivalent (gge) H₂ and >35% (lower heating value, LHV), respectively.

A recent report on H2A cost analyses for solar-driven thermochemical conversion [1] included an analysis of the developed ferrite cycle. The key figures of merit used for this study are summarized in Table 1. The projected thermal efficiency for the developed process is 55.5% LHV, thus exceeding the >35% figure of merit for the 2025 case. For a solar-to-receiver annual average efficiency of 40.2%, the overall solar to H₂ efficiency is estimated at 22.3% (LHV). Furthermore, the \$6/kg H₂ plant gate cost for the central 100,000 kg H₂/day facility 2015 case should be easily achieved for the \$126.50/m² installed heliostat cost. The \$3/kg H₂ plant gate cost for 2025 for a \$90/m² installed heliostat field may be achievable.

TABLE 1. Key Figures of Merit Used for Cost Analyses for 2015 and 2025 for Solar-Driven High-Temperature Thermochemical Hydrogen Production [1]

Characteristics	Units	2015	2025
Plant Gate H ₂ Cost Projections	\$/kg H ₂	\$6	\$3
Installed Heliostat Capital Cost	\$/m ²	\$126.50	\$90
Process Energy Efficiency (thermal)	%	30	> 35

FY 2011 Accomplishments

- Previously demonstrated that <5 nm thin ferrite films can be synthesized by atomic layer deposition (ALD) and provide for significant opportunities to reduce diffusional resistances and promote radiation-driven heat transfer; both potentially providing for rapid redox cycling. Since this material is not currently commercially available, determine the most reasonable market value (i.e. suggested retail price per kilogram of material) in order to finalize the H2A process economic analysis.
- Improved the design and materials of construction of a multi-tube absorbing fixed-bed cavity reactor/receiver that provides for efficient internal heat recuperation and the potential for rapid cycling; mitigates erosion and complications associated with transporting solids.
- Finalized the process design/H2A economic evaluation indicating that ALD of ferrite materials on 100 m²/g supports cycling every 5 to 1 minutes will have H2A projected costs of less than \$6/kg and \$3/kg in 2015 and 2025, respectively [1].
- Cycling studies in a thermogravimetric analyzer as well as on-sun cycling studies are currently in progress to demonstrate the thin film's robustness and lack of deactivation over time.

Introduction

The direct thermolysis to split water by reaction 1 requires materials operating at $T > 3,500^\circ\text{C}$ as well as methods to separate the H_2 and O_2 gases at high temperature [2]. This seemingly impossible task can be overcome by implementing a two-step thermochemical water splitting cycle in which a ferrite spinel material (MFe_2O_4 ; $\text{M}=\text{Co}, \text{Ni}$) can be thermally reduced using concentrated sunlight to release O_2 as shown in reaction 2. The reduced ferrite is then subsequently oxidized (reaction 3) with steam producing H_2 [3-5] recovering the original spinel structure in the process. Reactions 2 and 3 combine to form a complete redox cycle with reactants and products equal to reaction 1.

- $\text{H}_2\text{O} \rightarrow \text{H}_2 + \frac{1}{2} \text{O}_2$
- $\text{MFe}_2\text{O}_4 \rightarrow \text{MeO} (\text{Fe}^{2+} + \text{Fe}^{3+} + \text{M}^{2+}) + \frac{1}{2} \text{O}_2$
- $\text{MeO} (\text{Fe}^{2+} + \text{Fe}^{3+} + \text{M}^{2+}) + \text{H}_2\text{O} \rightarrow \text{MFe}_2\text{O}_4 + \text{H}_2$

The reduction step of this cycle occurs at $1,450^\circ\text{C}$ while the oxidation step occurs at $1,000^\circ\text{C}$; with significantly lower operating temperatures this cycle is much more efficient and desirable than direct thermolysis.

Approach

The primary scientific barrier to successful implementation of a solar-thermal water splitting process

is access to a robust active material for efficiently and rapidly carrying out redox cycles producing H_2 . Further, the key engineering barrier to successful implementation is demonstration of a large scale solar reactor concept that allows for rapid redox cycling taking advantage of highly active thin film materials while providing for highly efficient usage of delivered solar energy. The key scientific challenges to successfully overcoming the primary scientific barrier are:

- Identify/synthesize high surface area active materials with favorable transport properties.
- Identify/demonstrate suitable interfacial substrate materials to facilitate rapid redox cycling.
- Combine the active/substrate materials into a characteristic volume sample and demonstrate robust cycling to split water, particularly if able to operate the reduction in air.

High surface area active ferrite materials ($\text{M}_x\text{Fe}_{3-x}\text{O}_4$; $\text{M}=\text{Co}, \text{Ni}$) were synthesized using ALD to deposit nanometer thick films onto nanosized particles [6-9]. Nanoparticle substrates were placed in fluidized bed reactors and coated (Figure 1) with Fe_2O_3 , CoO , and NiO thin films using self-limiting surface chemistry via metallocene $[(\text{C}_5\text{H}_5)_2\text{M}]$; $\text{M}=\text{Fe}, \text{Co}, \text{Ni}$ and O_2 precursors. The approach recommended is to design the nanometer thick ferrite films and to deposit them on high surface area support materials.

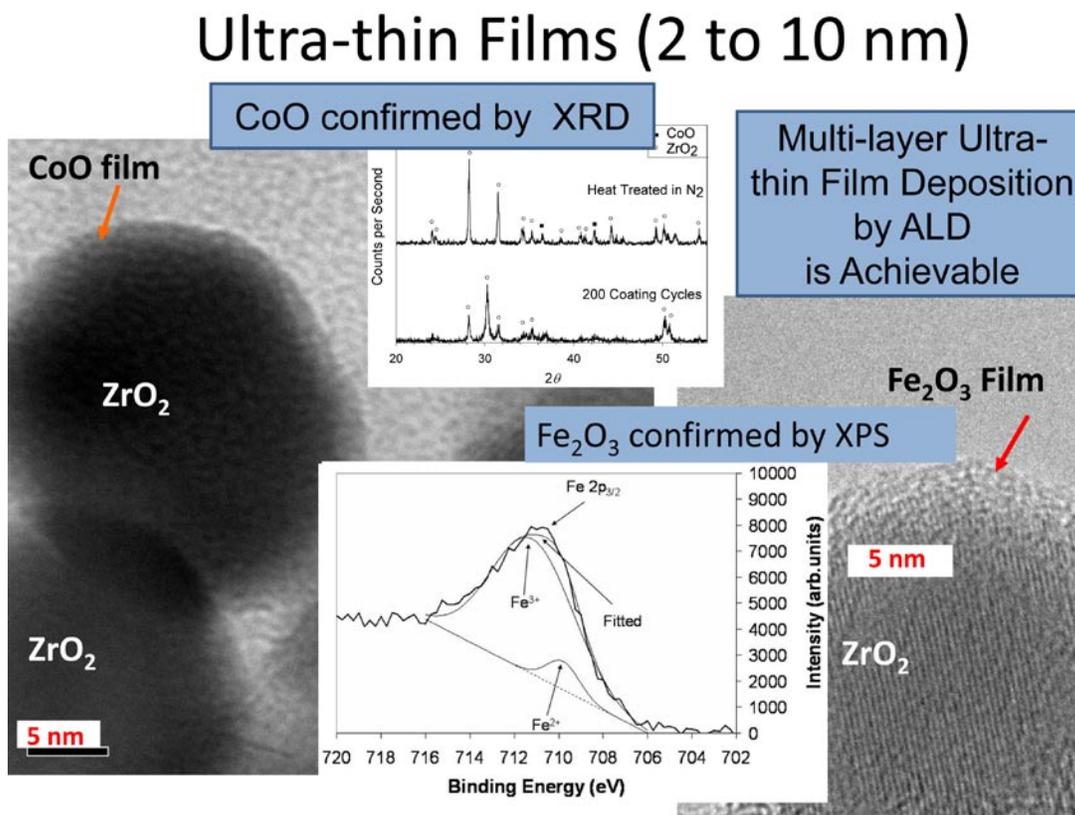

FIGURE 1. Thin Film Deposition of Ferrite Materials

Results

For this study, a 5-nm thick nickel ferrite film coated onto a 100 m²/g high surface area ZrO₂ support was considered; resulting in 0.67 moles ZrO₂ for every mole of NiFe₂O₄. Using the FACTSage™ thermodynamic database, it was determined that the amount of solar heat input required for this process is minimized when the solar reduction reaction occurs at 1,450°C and the oxidation reaction occurs at 1,000°C.

The conceptualized thermochemical redox receiver/solar reactor is shown in Figure 2. The reactor consists of a cavity-receiver, i.e. a well-insulated enclosure with a small opening – the aperture – for the access of concentrated solar radiation. The receiver will contain an even number of closed-end SiC tubes. Each tube will contain a 2nd open end SiC tube with a porous SiC plug at the base. Active high surface area and porous nickel ferrite material will be packed in the annular region between the two tubes allowing for efficient heat and mass transfer and, consequently, fast overall kinetics. The inner tube will be packed with media providing surface area for improved heat transfer to drive the vaporization of water to steam. At a given instant, half of the tubes will be operated in the reduction mode at T_R while the remaining half will be operated in the oxidation mode at T_O. When the reactions reach completion, the operational modes will be switched.

The process flow diagram is shown in Figure 3; 32°C water is pumped into the reduction tubes of the solar reactor at 12 psig. The water pumps are centrifugal cast iron and require a total of 135 kWhr/day electricity. The reduction tubes operate at a reduced pressure of 380 torr reached via vacuum pumps. The vacuum pumps remove oxygen being produced to prevent recombination with reduced ferrites. The flowrate of oxygen through each of three single-stage large cast iron pumps is 52,160 ft³/min requiring a total

of 55,310 kWhr/yr electricity. The oxidation tubes of the solar reactor operate near atmospheric pressure producing hydrogen that must be compressed to 300 psig before entering the plant gate. The three stage compression system with intercoolers has a compression factor of 2.85 and the intercoolers have a 2 psig pressure drop. This system requires a total of 52,848 kWhr/yr electricity and is designed for four compressors with only three operating at any time. Six 223 meter tall towers are required to produce 100,000 kg H₂/day. With one solar reactor per tower the total solar input is 2,332 GWhr/yr. Each receiver has three heliostat fields with 65 acres of land per field and 2.09E6 m² of heliostats. The heliostat field requires 1.22 GWhr/yr of parasitic electricity. This field and process design results in a thermal efficiency of 55.5% and a solar to thermal efficiency of 22.3%.

An H2A analysis was completed using varying redox cycle times of 1, 5, and 15 minutes [1]. Reducing cycle times reduces the amount of ferrite required to produce 100,000 kg H₂/day, which also reduces the number of SiC reaction tubes required thus decreasing the size and cost of each solar reactor. Ferrites can be produced for the cost of materials plus a reasonable retail markup. The cost of NiFe₂O₄ precursors are approximately \$225/kg of ferrite produced. Three retail markups were considered in this study: 20, 35, and 50%. The capital cost breakdown can be seen in Figure 4 and the resulting H₂ selling prices in Figure 5. With projected costs of \$6/kg in 2015 and \$3/kg in 2025, Figure 5 shows that with 10 minute cycles or less in 2015 the projection is achievable. However, in 2025 the projection is only achievable with cycles times of 1 minute or less. To date we have achieved cycles less than 15 minutes experimentally. With process improvements to not only the ferrite materials, but also the reactor and solar field 1 minute cycles can be reached by 2025. Lastly, Figure 5 shows that the resulting H₂ selling price is not sensitive to the purchase price of nickel ferrites.

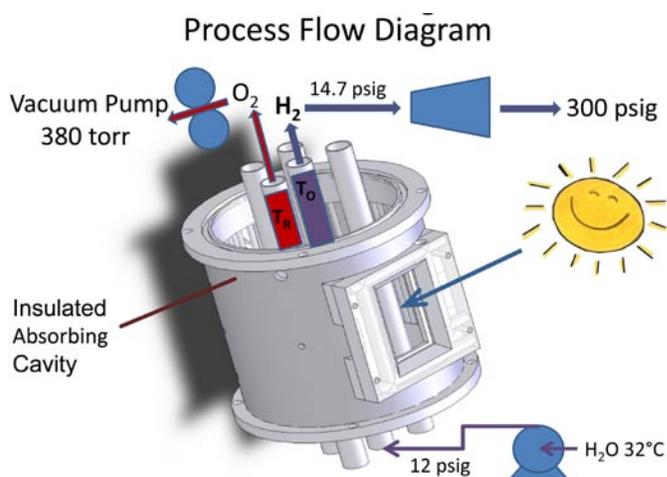

FIGURE 3. Process Flow Diagram

Capital Cost Breakdown

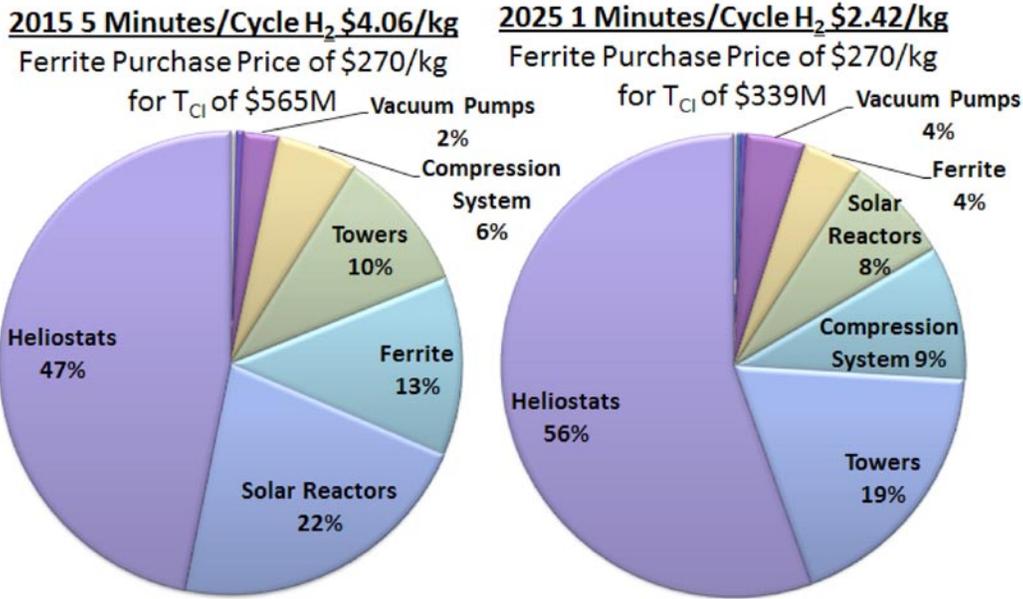

FIGURE 4. Capital Cost Breakdown

H₂ Selling Price for 20, 35, & 50% Ferrite Purchase Price Markup

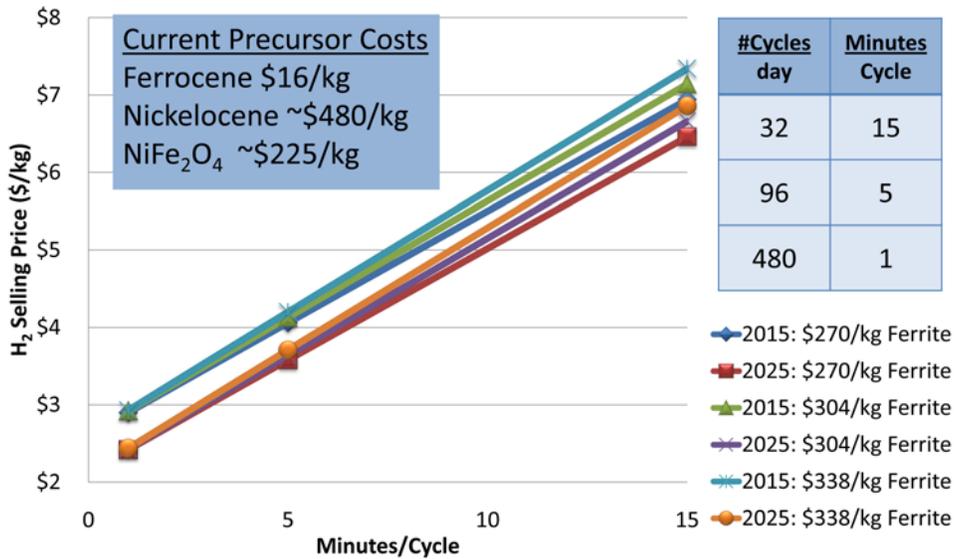

FIGURE 5. H₂A Results of H₂ Selling Prices

Conclusions and Future Directions

- ALD materials remain active for up to 30 water spitting cycles with no sign of deactivation after initial aggregation.
- ALD thin films are ~100X more active than conventionally produced bulk ferrites; the challenge is holding them together.
- Ferrite process is anticipated to meet H2A cost projections of less than 6/kg and \$3/kg for 2015 and 2025, respectively, if performance metrics are met [1].
- Future work will focus exclusively on the “hercynite” cycle which has been shown to be more stable than conventional ferrites and to operate over a lower temperature range (upper temperature limit ~1,300°C).

Project Start Date: December 18, 2008
 Projected End Date: September 30, 2011

Fiscal Year (FY) 2011 Objectives

- Develop a high surface area, transparent conducting (TC) scaffold as a broadly applicable substrate for photoelectrochemical (PEC) devices, as well as a scalable route to fabricate them.
- Plan, develop, and perform synthesis and characterization, both physical and PEC, of nanoscale transition metal dichalcogenides.
- Correlate atomic scale characterization of dichalcogenides with performance to iteratively optimize materials for water splitting efficiency and stability.
- Merge TC and dichalcogenide materials to yield enhanced performance high surface area catalyst systems and demonstrate their efficacy under standard operating conditions.
- Correlate physical characterization results of complete device with its PEC performance to tune subsequent syntheses in an effort to optimize water splitting efficiency and photoelectrode stability.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(Y) Materials Efficiency

- (Z) Materials Durability
 (AA) PEC Device and System Auxiliary Materials
 (AB) Bulk Materials Synthesis

Technical Targets

The focus of this project is the development of a PEC device that incorporates a 3rd generation nanostructured absorber with a high aspect architecture support that enables efficient solar absorption and charge transport. If successful, this project will address the following DOE technical targets as outlined in the Multi-Year RD&D Plan.

TABLE 1. Progress towards Meeting Technical Targets for PEC Hydrogen Production

Characteristics	Units	2013 Target	2018 Target	2011 Status
Usable semiconductor bandgap	eV	2.3	2.0	1.8
Chemical conversion process efficiency	%	10	12	TBD
Plant solar-to-hydrogen efficiency	%	8	10	TBD
Plant durability	hr	1,000	5,000	TBD

TBD – to be determined

FY 2011 Accomplishments

- Developed a facile, scalable synthetic route to fabricate high surface area electrodes (HSEs) of transparent conducting oxide (TCO) materials.
- Electrochemically quantified relative enhancement of HSE surface area. Synthetic control garners 20-600 times surface area increase.
- Patent application pending for novel HSE fabrication method.
- Developed a facile, scalable, room temperature synthesis of quantum confined MoS₂ nanoparticles with bandgaps of 1.8 eV.
- Demonstrated accelerated stability of MoS₂ catalysts over 10,000 voltage cycles to simulate diurnal conditions.

Introduction

PEC water splitting is a promising route to produce high purity hydrogen (H₂) from a renewable resource [1].

Hydrogen produced in this manner represents a means of chemical storage of solar energy; the H_2 can potentially be used as a fuel. Current costs of H_2 production by photoelectrochemistry are not competitive with H_2 produced by the reformation of fossil fuels. However, a recent techno-economic analysis has shown that if high performance, stable, low-cost materials can be developed, the DOE target of \$2-\$4/gasoline gallon equivalent for dispensed hydrogen could be reached using solar photoelectrochemistry [2].

Development of high purity electrochemical H_2 generation systems requiring lower capital costs with sunlight as the sole energy input is the end goal of PEC water splitting research. Steps toward this goal include discovery and optimization of efficient, inexpensive, stable electrocatalysts, (photo)electrode materials, and high surface area electrode substrates on which to coat them. Integration of these components could result in a complete system capable of efficient, cost-effective, and sustainable production of solar-derived hydrogen.

Approach

Development of transparent HSEs to act as supports for both electrocatalyst and photoelectrode materials is an enabling technology at both the fundamental and applied research levels. In electrocatalysis, HSEs allow more electrocatalyst to be packed into a given area which increases the rate per projected area at which product is generated. For photoelectrochemistry, HSEs coated with ultra-thin layers of light absorbing material allow for more complete absorption of incoming light as compared

to flat electrodes – a major challenge in thin-film solar technologies (see Figure 1) [3]. Enabling ultra-thin layers to completely absorb solar photons is particularly advantageous as only a short distance needs to be traversed by photo-excited charges in order for them to reach the solid-liquid interface (for minority carriers) or the back contact (for majority carriers). This should yield much improved charge collection efficiency, translating to improved external quantum efficiency (QE). The end result is an enhanced overall performance due to greatly increased interfacial area.

Such HSE structures require integration of materials that effectively absorb light to produce electronic charges that can efficiently drive the catalytic turnover of hydrogen and oxygen via water splitting. While high efficiency devices have been developed in this field [4], the costly processes and rare materials used in their production limit large scale deployment. Thus, it is imperative that new materials are discovered based on earth-abundant elements and produced using low cost methods. The approach used herein focuses on the development of MoS_2 , a material which decades ago was studied and not considered a promising candidate for solar PEC water splitting as it is limited by an inadequate electronic band structure as well as poor hydrogen evolution kinetics at its surface [5]. The approach herein is to use nanostructuring to improve the relevant bulk and surface properties of MoS_2 for (photo)electrochemical applications [6]. By synthesizing nanoparticles of MoS_2 , one can engineer the electronic band structure and light absorption properties through a quantum confinement effect [7], and expose edge sites for the improved catalytic turnover of hydrogen [8].

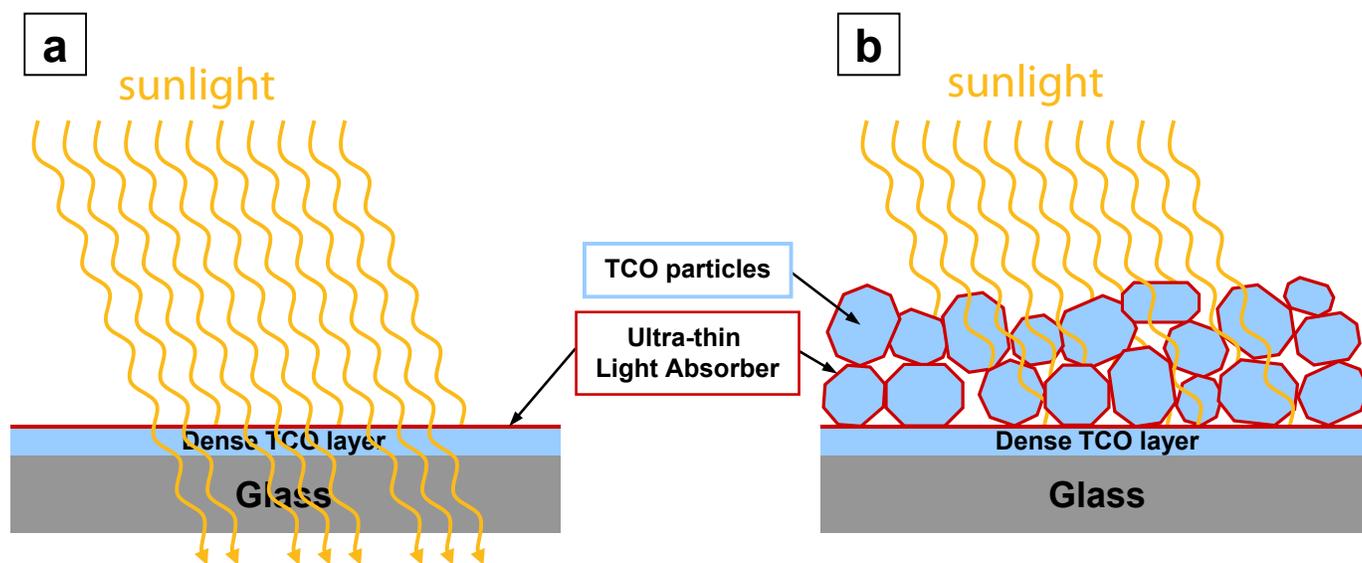

FIGURE 1. Quantum efficiency for photon-to-product conversion in PEC devices made from semiconductor absorber materials with poor electronic charge transport is maximized with ultra-thin semiconductor layers (a). However, the overall photon absorption (optical density) of these electrodes is typically very low (a), which limits the overall solar conversion efficiency. By conformally coating HSEs with ultra-thin absorber layers (b), the optical density is maximized while simultaneously maintaining high QE.

Results

One of the primary results of this project has been the development of an extremely high surface area TCO substrate that can be used with a wide variety of devices—namely those employed for PEC water splitting. In demonstrating this new development for the very first time, we have concurrently developed a synthetic route applicable to large-scale fabrication of HSE TCO electrodes. These TCOs include indium tin oxide (ITO), fluorine doped tin oxide (FTO), aluminum zinc oxide and many other well utilized electrode materials in the PEC, photovoltaic and electrochemical fields. The synthetic route involves spray deposition of a two part mixture containing solid TCO powder (~1-100 μm diameter particles) and TCO sol-gel precursors in an acidified ethanolic solvent, followed by heat treatment. Figure 2a exhibits a schematic representation of the resulting film morphology. The amount of mixture sprayed onto the appropriate conductive substrate controls the final surface area of the HSE. These TCO HSEs are capable of enabling PEC materials to simultaneously address three of the DOE technical barriers for Production

(Y, AA, AB). Compared to more classical HSE fabrication techniques such as lithographic patterning, spray deposition offers significant cost savings and scalability – absolute necessities for an emerging solar energy technology seeking to generate copious domestic fuel.

The key performance criteria for TCO HSEs are three fold: surface area, electrical conductivity and transparency to visible light. Our proof-of-principle HSEs spray fabricated from ITO have demonstrated excellent performance in all three categories. Figure 2b reveals their optical transparency and Figures 2c and 2d show the general morphology as viewed by a scanning electron microscope (SEM). The faceted geometric shapes seen by SEM indicate good crystallinity of the ITO which translates into superior electrical conductivity while the porous, open network results in high surface area. This surface area is quantified by performing electrochemical capacitance (EC) measurements in 1.0 M NaOH (Figure 3). Here we see the EC of a planar, commercial ITO film compared to spray deposited HSEs of controllably higher surface area. The capacitance current, which is proportional to surface area, is read as the oxidative current at 0.3 V vs. saturated

SEM

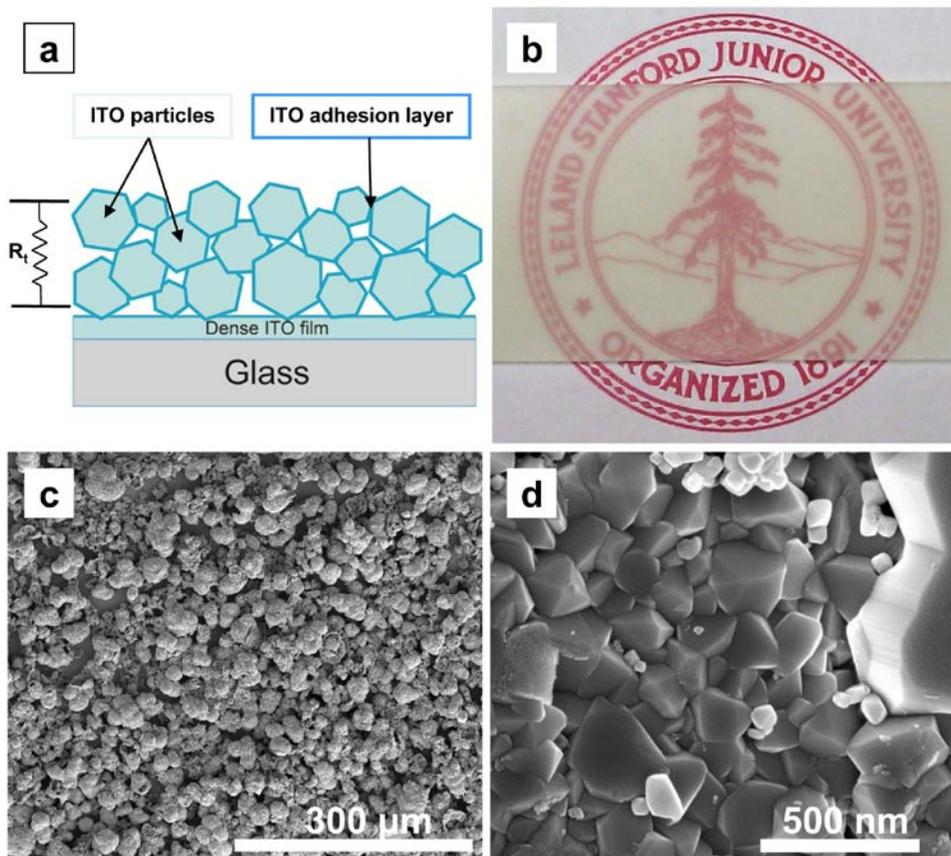

FIGURE 2. A schematic cross section (a) and optical photograph showing transparency (b) of the ITO HSE. SEM images show the textured particulate HSE surface (c) and the crystallinity of the ITO adhesion layer (d).

calomel electrode (SCE) (linear region) on Figure 3a. The relative ratio of capacitances or surface areas (roughened vs. planar) is termed roughness factor (RF) and is plotted against square root of scan rate for several typical spray films in Figure 3b. For the HSEs, capacitance charging is limited by solute diffusion at higher scan rates and the RF appears smaller. Therefore, extrapolation of the data to zero scan rate yields the true RF values. The EC data presented here shows HSEs that have RFs ranging from 250 to 800 relative to the planar ITO film. We have succeeded in fabricating films with RFs from ~20-800 via spray deposition, the right order of magnitude for roughness needed to maximize performance according to our calculations.

Electronic resistance measurements of these spray films indicate that resistance in the transverse direction, R_p , (see Figure 2a) is $\sim 1 \Omega/10 \mu\text{m}$, or only about 10Ω for the average film thickness. This resistance is superb given the low cost, low quality fabrication method employed.

We have just begun to coat these HSEs with ultra-thin layers of semiconductor material including manganese oxide and iron oxide, two excellent absorbers of visible light. The challenge here is that these absorber materials are performance limited by electronic charge transport. Therefore, ultra-thin layers will help facilitate extraction of photogenerated charge carriers to the back contact (the TCO) with a high QE. By conformally coating the HSEs with that same ultra-thin layer of absorber material we can combine the high QE carrier extraction of an ultra-thin layer with full absorption of incoming light because of the many layers coated across the high surface area. This device design has an optical density equivalent to an absorber layer X times thicker where X is proportional to the RF of the HSE.

Using an entirely room temperature synthetic procedure, we have produced nanoparticles of MoS_2 only several nanometers in size that exhibit a visible shift in light absorption towards lower wavelengths (Figure 4a) with an estimated bandgap of $\sim 1.8 \text{ eV}$ for the smallest nanoparticles as a result of quantum confinement. Transmission electron microscopy (TEM) reveals a range in nanoparticle size from 2.4 to 8.3 nm. In addition, PEC measurements of these nanoparticles have shown that they possess proper conduction and valence band alignments relative to the hydrogen and oxygen evolution potentials to enable unassisted water splitting.

We have also studied the long-term performance of highly nanostructured MoS_2 as an electrocatalyst for hydrogen evolution at current densities relevant to efficient solar conversion ($\sim 10 \text{ mA/cm}^2$). By carefully controlling the extent of thermal sulfidization treatments, we can optimize the growth of ultra-thin MoS_2 shell structures that are only a few nm thick at temperatures as low as 200°C on a high aspect ratio MoO_3 nanowire core support. These catalysts remain stable over ten thousand voltage cycles that simulate the diurnal conditions of solar irradiation (Figure 4b). Furthermore, they exhibit this stability in strongly acidic environments, a feature not possessed by other Earth-abundant hydrogen evolution catalysts such as nickel.

Conclusions and Future Directions

In order to reach our goal of developing a fully operational PEC water splitting device, we have been developing a 3rd generation light absorber material (MoS_2) while also producing a TC scaffold onto which it can be incorporated. We have achieved the following:

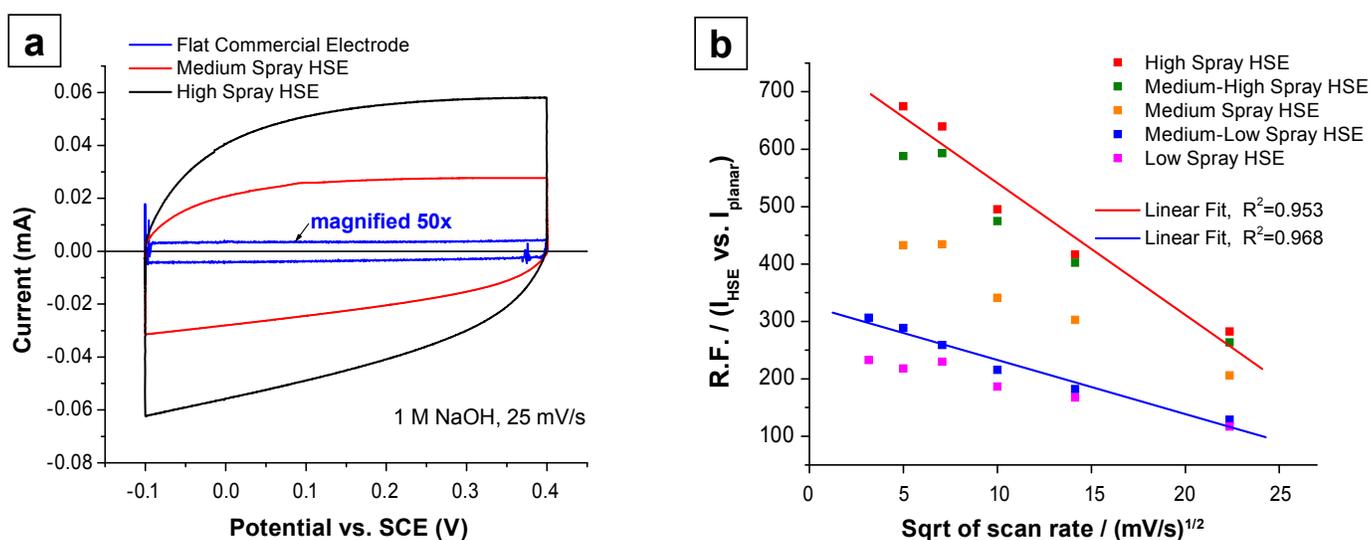

FIGURE 3. Advanced cyclic voltammograms (a) swept from -0.1 to 0.4 V vs. SCE where the scan is held at each vertex potential for 30 seconds. The third in a series of scans for each electrode is shown. Roughness factor as a function of square root of scan rate (b). Linear fits of two sample data sets are shown.

Nanostructured MoS₂

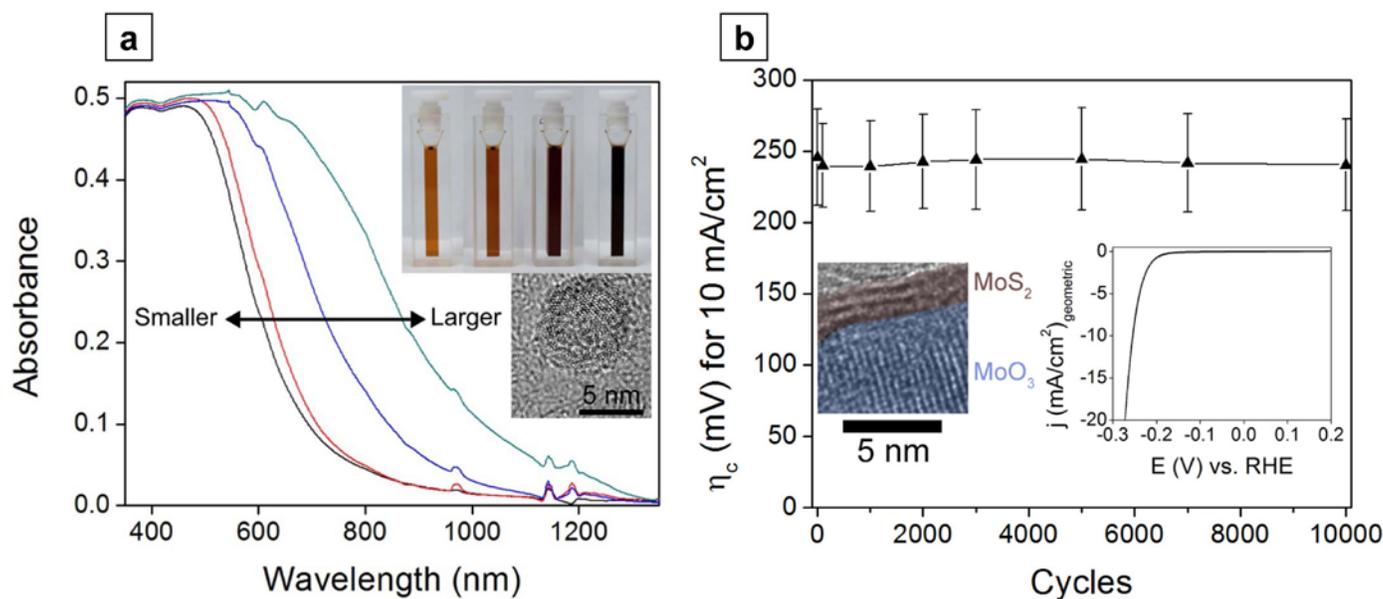

FIGURE 4. Spectroscopy, microscopy, and electrochemical performance of nanostructured MoS₂. Ultra-violet visual absorbance (a) of quantum confined MoS₂ nanoparticles with an inset photograph of solutions containing nanoparticles of increasing size towards the right, and an example TEM image of the nanoparticles. Electrochemical stability (b) of ultra-thin MoS₂ shell structures surrounding a MoO₃ core, assessed as a function of overpotential required to drive 10 mA/cm² of current density over the course of 10,000 potential cycles from -0.3 to 0.2 V vs. the reference hydrogen electrode. The inset shows a TEM image of the core-shell structures along with a cyclic voltammogram detailing their electrochemical performance for the hydrogen evolution reaction.

- A low-cost, scalable, facile route to fabrication of high surface area transparent conducting electrodes has been developed and a patent application is pending.
- Physical and electronic characterization of these electrodes indicates roughness factors of ~20-800 and electrical conductivity commensurate with requirements for PEC and many other electronic applications.
- Developed bandgap engineered nanoparticles of MoS₂ which possess the correct energetic for water splitting.
- Demonstrated long-term stability of highly nanostructured MoS₂ hydrogen evolution catalysts.

The next step in our work is the incorporation of nanostructured materials and thin films into our HSE platforms. We will accomplish this task through various objectives:

- Incorporate MoS₂ nanoparticles into the HSE and characterize their water splitting properties with respect to light absorption, charge transport, and stability.
- Demonstrate the broad applicability of the HSE platform for various other PEC materials.

FY 2011 Accomplishments

- Improved the world-record water splitting efficiency of GaInP₂/GaAs tandem cells by using a more active RuO₂ counter electrode. Confirmed a maximum solar-to-hydrogen efficiency of 16.3% under real solar (outdoor) conditions, a significant improvement over the 12.4% previous record and greatly exceeding the MYP 2013 10% technical target.
- Identified potential surface nitride passivation of GaInP₂ by nitrogen ion bombardment and electrochemical routes. Nitrated surfaces exhibited less corrosion than untreated samples.
- Validated stability of low-cost amorphous Si/SiC hybrid photoelectrodes synthesized by our corporate partner MVSystems, Inc. The electrode was still able to generate photocurrent after 500 hours of testing at an applied current density of -1 mA/cm², and is half way to the MYP 2013 technical target of 1,000 hours of durability.
- Synthesized CuO, Cu₂O, and Ti alloyed Cu-Ti oxides with various structures and band gaps by reactive radio frequency (RF) magnetron sputtering. PEC characterizations of the Ti-Cu mixed oxide revealed improved performance and greater stability than Cu oxides alone.
- Characterized corrosion resistant p-In_xGa_{1-x}N alloys synthesized by our collaborator at Los Alamos National Laboratory.

Fiscal Year (FY) 2011 Objectives

Identify, synthesize, and characterize new semiconductor materials that have the capability of meeting the criteria for a viable photoelectrochemical (PEC) hydrogen-producing device, either as a single absorber or as part of a high-efficiency multi-junction device.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cells Technologies Program Multi-Year Research, Development and Demonstration Plan (MYP):

- (Y) Materials Efficiency
- (Z) Materials Durability
- (AB) Bulk Materials Synthesis
- (AC) Device Configuration

Technical Targets

This project is a materials discovery investigation to identify a single semiconductor material that meets the technical targets for efficiency and stability. The 2013 technical targets from the MYP PEC hydrogen production goals are as follows:

- Bandgap of 2.3 eV
- 10% conversion efficiency
- 1,000-hour lifetime

Introduction

Photoelectrochemistry combines a light harvesting system and a water splitting system into a single monolithic device. A semiconductor immersed in aqueous solution comprises the light-harvesting system. The catalyzed surface of the semiconductor is one part of the water splitting system, and the other part is another electrode in a separate compartment. The key is to find a semiconductor system that can efficiently and sustainably collect solar energy and direct it towards the water splitting reaction.

The goal of this work is to develop a semiconductor material set or device configuration that (i) splits water into hydrogen and oxygen spontaneously upon illumination, (ii) has a solar-to-hydrogen efficiency of at least 5% with a clear pathway to a 10% water splitting system, (iii) exhibits the possibility of 10 years stability under solar conditions, and (iv) can be adapted to volume-manufacturing techniques.

Approach

Our approach has two thrusts, i) the study of current material sets used in commercial solar cells as well as related materials, and ii) the discovery of new semiconducting materials using advanced theoretical calculations to identify promising candidates, closely coupled with synthesis and state-of-the-art characterization. A major component of (i) focuses on III-V semiconductor materials that meet the efficiency target and engineering the surface to meet the durability target. Area (ii) has focused on chalcogenide and Cu-, W-, Ti-, and Bi-based multinary oxides.

Results

The GaInP₂/GaAs tandem cell has held the world-record efficiency (12.4%) for unbiased PEC water splitting for several years [1]. This benchmark for efficiency was established using platinum as a counter electrode anode material. We were able to improve upon this efficiency by using a counter electrode that is more active for oxygen evolution. Ruthenium dioxide (RuO₂) has a lower overpotential than platinum for the water oxidation reaction at the current densities relevant to PEC water splitting. The reduction in overpotential results in enhanced efficiencies. We electrodeposited RuO₂ from RuCl₃ solution on to a platinum electrode and gathered solar-to-hydrogen efficiency data under real-solar conditions at NREL's Solar Radiation Research Laboratory. Using a portable potentiostat in a two-terminal configuration we measured the current and applied circuit bias between the GaInP₂/GaAs working electrode and RuO₂ counter electrode. The current was due to water reduction (to hydrogen) at the photocathode and oxidation (to oxygen) at the counter electrode. The efficiency was calculated from the photocurrent density, circuit bias, and corresponding real-time measurement of solar irradiance. Two wafers were synthesized by metal organic chemical vapor deposition at different growth temperatures and each was subdivided into about twelve electrodes. The averaged two-electrode photocurrent-voltage measurements were used to calculate ensemble efficiencies for each wafer (Figure 1). The champion electrode, from the wafer that was grown at a lower temperature, had a peak solar-to-hydrogen efficiency of 16.3%. This efficiency greatly exceeds the MYP 2013 technical target of 10% and demonstrates very high solar-to-hydrogen efficiencies are possible through PEC conversion.

Although the GaInP₂ system is capable of high-efficiency conversion, it is prone to corrosion under operating conditions and does not meet the MYP technical target for durability (1,000 hours). We have previously observed that incorporating nitride into III-V semiconductor epilayers can provide enhanced stability [2] to water splitting photocathodes. However, this nitride incorporation through the bulk of the light absorber causes a reduction in conversion efficiency [3]. We hypothesize that surface nitridation might protect the interface with the electrolyte while not compromising the material's

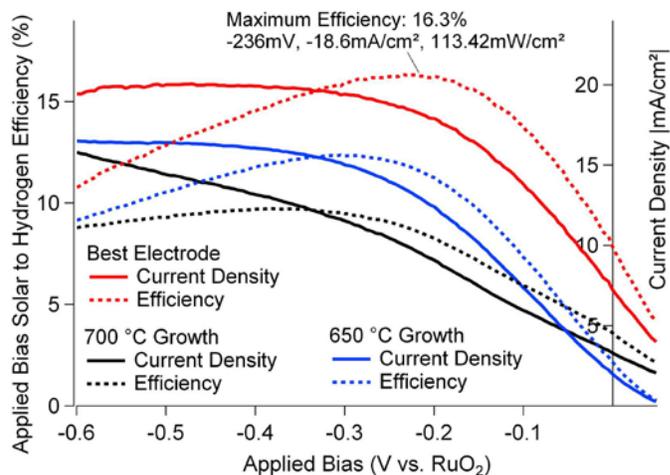

FIGURE 1. Two-electrode outdoor photocurrent-voltage testing of p-GaInP₂/GaAs tandem cells coupled with a RuO₂ counter electrode. Dashed lines are calculated efficiencies as a function of circuit bias. Data presented are the average of twelve electrodes from each wafer and the champion electrode plotted independently. The champion electrode was from the wafer grown at a lower temperature. The electrolyte used for testing was 3M H₂SO₄ with the fluorosurfactant Zonyl FSN-100.

high-efficiency bulk absorption properties. We achieved promising preliminary results from surface nitridation of GaInP₂ by two distinct routes; electrochemical and ion bombardment. The semiconductor surface appeared to be protected when (NH₄)₂SO₄ was used as the electrolyte for a 24-hour durability analysis. Afterwards, X-ray photoelectron spectroscopy (XPS) detected ammonia (NH₃) on the surface. Depth profiles, made by alternating sputtering with XPS analysis, found the control (unprotected) sample was gallium deficient and indium rich while the sample tested in (NH₄)₂SO₄ had a composition identical to as-grown material. Bombarding GaInP₂ surfaces with low-energy N₂⁺ ions also appeared to provide some protection from corrosion. We performed ion surface treatments for 20, 45, and 60 seconds and all prevented a decline in photocurrent after operation for 24-hours in pH 0 sulfuric acid where untreated samples had a notable loss in performance. We also analyzed the durability solutions for trace levels of semiconductor components by inductively coupled plasma mass spectrometry (ICP-MS). In two of the three electrodes tested, the 45-second treatment was effective in reducing the amount of corrosion detected by ICP-MS (Figure 2). We are continuing to investigate surface nitridation as a potential route to achieve both the efficiency and durability targets in the MYP.

We continued to work with our private industry collaborator, MVSystems, Inc. to develop a potentially low-cost, high-volume water splitting material system with good durability. These amorphous (a-Si/SiC) semiconductors are synthesized by plasma enhanced chemical vapor deposition on transparent conductive substrates. The p-SiC is the capping layer and forms a PEC contact with the electrolyte.

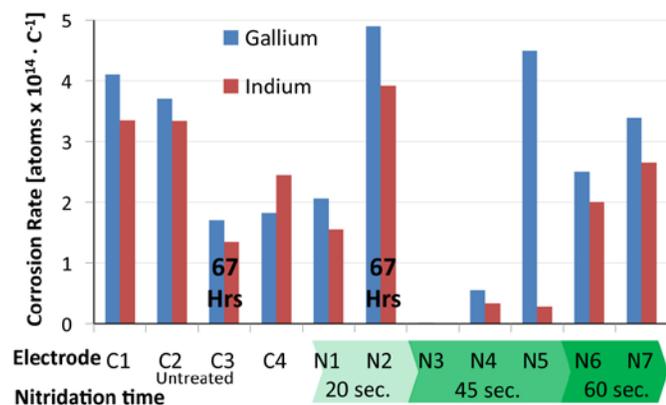

FIGURE 2. ICP-MS detected gallium and indium from control and ion bombardment nitrided p-GaInP₂ electrode corrosion solutions. The durability testing consisted of galvanostatic testing at -10 mA/cm² in 0.5M H₂SO₄ under AM1.5G illumination for 24 hours (except in the two noted durations of 67 hours). The analytes were detected in parts per million (mass) units and converted to atoms/Coulomb to normalize for variation in electrode surface area, charge passed, and solution volume.

It has a wider band gap and better stability than amorphous Si. There are two amorphous p-i-n buried photovoltaic (PV) junctions that provide the necessary potential difference needed for water electrolysis. The PV/PEC layers, known together as a hybrid photoelectrode, are stacked vertically in an integrated monolithic device. This device configuration is able to split water at 1.6% efficiency without an external bias. Recently, we were able to demonstrate this system is capable of extended durability. In one test we applied -1 mA/cm² in pH 2 buffer under AM1.5G (from a tungsten lamp) for 310 hours and the surface appeared almost completely unaltered by the testing, except for some streaking likely caused by hydrogen bubble evolution (Figure 3). The electrode did suffer a moderate (~30%) reduction in photocurrent magnitude after 310 hours of testing, but there was no dark current under high reverse bias, a common feature of damaged electrodes. We also performed a 500-hour test on a different electrode under the same conditions described above. After 500-hours of durability analysis, three-electrode current-potential curves exhibited both a decreased magnitude of photocurrent and dark current onset at a low potential. The electrode surface also appeared degraded afterwards. Even though the durability electrodes suffered a performance loss, the results demonstrate that the 2013 MYP technical target of 1,000-hours of operation could be achieved with this material. However, the testing conditions are relatively mild, compared to what a real-world electrode might see under operation. The goal for this material is 5% solar-to-hydrogen efficiency, which correlates to -4 mA/cm², a current density four times higher than these electrodes were subjected to.

We also synthesized and characterized several oxide and chalcopyrite semiconductors that theoretical calculations had identified as good candidates for photoelectrolysis. We

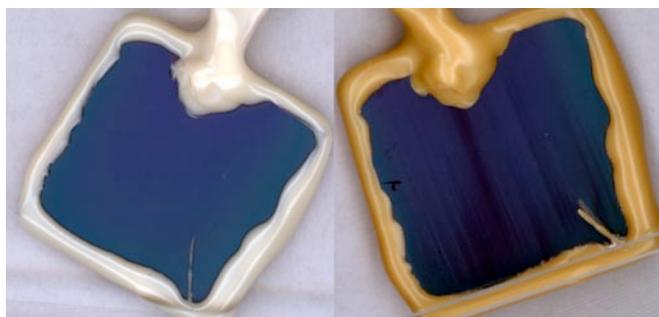

FIGURE 3. Photographs of an a-Si/a-SiC hybrid photoelectrode before (left) and after (right) 310 hours of durability testing showing a relatively unaltered surface. The semiconductor is about 4 cm² and encased in insulating epoxy.

synthesized CuO, Cu₂O, and Ti alloyed Cu-Ti and found that the band gaps of CuO and Cu₂O could be engineered by incorporating Ti. We found that Ti incorporation improved the film quality and as a result, Ti incorporated CuO films exhibited much lower dark current than the pure CuO, indicating enhanced stability. Despite band gaps in the visible portion of the electromagnetic spectrum, the overall magnitude of photocurrent for these films is well below what is necessary to be considered viable for solar photoconversion.

We also synthesized BiVO₄ thin films by co-evaporation of Bi₂O₃ and V₂O₅ and evaluated their PEC performance. We observed that a Bi:V ratio of roughly 1:1 leads to n-type conductivity behavior and very low dark current. When the Bi:V ratio was increased to 1.1:1 the result was a compensated film. A compensated semiconductor exhibits both n-type and p-type behavior, depending on the bias. It is known that cation vacancies can form easily in BiVO₄ and the act as acceptors. It is possible that under certain vapor pressures, Bi or V vacancies may form and lead to p-type conductivity. This effect might be exploited for developing a solid-state, oxide p/n homojunction photovoltaic cell.

Ternary I-III-VI₂ chalcopyrite materials have drawn great interest in recent years due to their potential application for solar cells. In general, I-III-VI₂ chalcopyrite materials have a variety of direct band gaps and have excellent optical absorption coefficients, good carrier transport properties, and stability. We synthesized and characterized chalcopyrite CuAlTe₂ thin films by both co-evaporation and sequential deposition methods. Several films were synthesized that had ideal band gaps for photoelectrolysis, in the range of 1.64 - 2.25 eV. Energy dispersive X-ray spectroscopy detected oxygen in all CuAlTe₂ samples. The oxygen contamination during the evaporation seems to deteriorate the film quality and lead to serious carrier recombination resulting in poor photoconversion efficiencies. In addition to low photocurrents, the CuAlTe₂ films were unstable during PEC characterizations and are, therefore, not viable for photoelectrolysis using these synthesis conditions.

Pure nitride semiconductors (instead of mixed group V) are also an area of interest as they have high stability and potentially high efficiency. We characterized p-doped $\text{In}_x\text{Ga}_{1-x}\text{N}$ synthesized by our collaborator at Los Alamos National Laboratory. The p-doping allows the semiconductor to operate as a photocathode, a generally more stable operating configuration that pushes highly corrosive, oxidizing holes towards the bulk of the material and away from the interface. The photocurrents achieved by these materials were very low due to growth on an insulating sapphire substrate. We are currently characterizing a set of $\text{In}_x\text{Ga}_{1-x}\text{N}$ that was synthesized on conductive substrates and are evaluating the stability under current densities in the 10 mA/cm^2 range, a magnitude equivalent to what a deployed device would see.

Conclusions

- p-GaInP₂/GaAs is capable of over 16% solar-to-hydrogen conversion efficiency and could meet the MYP efficiency and durability technical targets with an appropriate corrosion mitigation treatment, even if the treatment results in a loss of efficiency.
- Surface nitridation of GaInP₂ has demonstrated the ability to offer protection to the semiconductor surface after 24-hours of simulated operational conditions.
- Thin film a-Si-based carbides have the potential to be inexpensive water splitting electrodes and have demonstrated good durability over several hundred hours of low current density water splitting.
- The Cu-Ti alloyed oxides that we synthesized have variable band gaps, but have poor photoconversion properties and inadequate stability.

Future Direction

- We plan to continue to investigate stabilization of the GaInP₂ interface through nitridation. We will work in collaboration with theory and advanced characterization groups to identify the corrosion mechanism and develop a passivation strategy.
- Because of their stability, we plan to investigate other III-V nitride semiconductor configurations and evaluate efficiencies.
- We plan to continue to work with MVSystems, Inc. on improving efficiency and stability of a-Si/a-SiC hybrid photoelectrodes through targeted surface modification techniques.
- We plan to synthesize and photoelectrochemically characterize new oxide and chalcopyrite semiconductors and evaluate their potential for water splitting photoelectrodes.

Project Start Date: March 1, 2010
Project End Date: Project continuation and
direction determined annually by DOE

Fiscal Year (FY) 2011 Objectives

- Develop theoretical tool chest for modeling photoelectrochemical (PEC) systems, including experimental validation using model III-V systems.
- Compile publications database of research on relevant photoelectrode materials.
- Uncover key mechanisms of surface corrosion of semiconductor photoelectrodes.
- Understand dynamics of water dissociation and hydrogen evolution at the water-photoelectrode interface.
- Evaluate electronic properties of the surface and water-electrode interface.
- Elucidate relationship between corrosion and catalysis.
- Provide simulated X-ray spectra to the University of Nevada, Las Vegas (UNLV) for interpretation of experimental results and validation of theoretical models.
- Share research insights with the PEC Working Group members

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section (3.1) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (Z) Materials Durability
- (Y) Materials Efficiency

Technical Targets

This project is conducting fundamental theoretical studies of mechanisms of corrosion and catalysis in III-V

semiconductor-based photoelectrode materials for PEC hydrogen production. Insights gained from these studies will be applied toward the optimization and design of semiconductor materials that meet the following DOE 2013 PEC hydrogen production targets:

- Usable semiconductor bandgap: 1.8-2.3 eV
- Chemical conversion process efficiency: 10%
- Plant solar-to-hydrogen efficiency: 8%
- Plant durability: 1,000 hrs.

FY 2011 Accomplishments

- Compiled, reviewed, and shared available information on III-V electrode materials (ongoing).
- Performed quantum molecular dynamics of water-electrode interfaces:
 - Evaluated importance of surface oxygen in determining reactivity. In FY 2010, we discovered that bonding topology of oxygen at InP(001) surface dictates the catalytic activity for water splitting. In FY 2011, we expanded this study to include different III-V (GaP), and on wider variety of surface morphology. Quantitative reaction energetics were provided.
 - Established validity of local topological model and used it to extract model surfaces for further study (FY 2011).
- Group discussion of results led to formulation of three possible corrosion mechanisms (FY 2011).
- Recruited four external collaborators to develop theory/computational tool chest for PEC hydrogen research.
- Began joint theoretical/experimental study on III-V electrode surface (continue through FY11).

Introduction

Development of efficient processes for the carbon-free production of hydrogen is key to sustainable realization of a future hydrogen economy. One particularly promising approach is to use sunlight to catalyze direct evolution of hydrogen from water in a PEC cell. Semiconductor-based PEC devices are particularly attractive, thanks to a relatively simple device design and a wealth of data available for engineering efficient photon harvesting [1]. Results have demonstrated that one can achieve solar-to-fuel conversion efficiency in excess of the 2013 DOE targets (>12% using a tandem GaAs/GaInP₂ cell); however, this has come at the expense of short device lifetime due to fast degradation

of the electrode [2]. Further progress has been hindered by a poor understanding of the fundamental chemical processes operating at the electrode-water interface. Our research addresses this need from a theoretical perspective, leveraging realistic *ab-initio* simulations to determine the key mechanisms governing corrosion and catalysis at the water-semiconductor interface.

Approach

Further progress in semiconductor-based PEC photoelectrodes requires in-depth understanding of the complex relationship between surface stability and catalytic activity. This in turn relies on knowledge of the fundamental nature of the electrode-water interface, and of the chemical pathways explored during surface-active hydrogen evolution. As such, we are carrying out finite-temperature *ab-initio* molecular dynamics simulations and energetics calculations based on density-functional theory to understand the chemical, structural, and electronic properties of water/ electrode interfaces under equilibrium conditions, as well as to understand the competing chemical reaction pathways visited during photocatalysis. Our approach uses (001) surfaces of InP, GaP and GaInP₂, which have known water-splitting activity, as model semiconductor electrodes. We are investigating on effect of the foreign chemical species on the stability and reactivity of the electrode surfaces, as suggested by our collaborators in J. Turner's group at the National Renewable Energy Laboratory (NREL) [3] and reports in the literature that surface oxygen may play a key role in motivating both the surface photocorrosion and the catalytic water splitting reaction [4,5]. Accordingly, we are evaluating the stability, structure and reactivity of the III-V(001)/water interfaces in the presence of surface oxygen, hydroxyl, and nitrogen, in order to correlate the results to experimentally observed surface compositions and morphologies. We also provide *ab-initio* derived X-ray spectroscopic data to enable direct comparison with experimental results from Prof. Heske's group at UNLV. This information is intended to suggest a strategy for device improvement.

Results

Over 700 papers related to PEC hydrogen research have been collected, indexed, and stored. Those deemed especially relevant to III-V semiconductor-based approaches have been summarized and shared with members of the III-V Surface Validation Team (LLNL/NREL/UNLV) of the DOE Photoelectrochemical Hydrogen Production Working Group using a limited-access community web forum and traditional email communication. Particularly detailed reviews were completed on GaInP₂, In₂O₃, and the growth interface between the two. We have discovered literature that points to competition between ordered and disordered surface phases, which can rationalize inconsistencies in device performance observed in NREL experiments. We have also reviewed literature suggesting the relevance of surface oxide growth for realizing both device performance

and corrosion resistance. However, we also found reports that thin native oxide formation on III-V semiconductors can give rise to undesirable electrical properties if the oxide/ III-V interface is rough [6]. Based on this review, it was suggested that careful, controlled growth of a high quality oxide layer on III-V semiconductor might improve the durability without compromising the hydrogen production efficiency.

In FY 2010, we studied (meta)stable surface structures of oxide and hydroxide on InP(001). We found that there are two categories of oxygen bonding configurations, In-O-In and In-O-P, consistent with experimental observations [7]. We then studied the reactivity of a water molecule on these surfaces and found that spontaneous dissociative adsorption is observed only at the In-O-In site. In FY 2011, we significantly expanded this study in order to have a more complete understanding, accounting for a wider variety of possible surface structures and looking at other III-V semiconductors, including GaP. Despite minor differences, we were able to definitively conclude that the strong correlation between the chemical activity and the local bonding topology is universal, and that III-O-III is chemically active against H₂O adsorption, while III-O-V is not (Figures 1 and 2).

When immersed in electrolyte, the electrode surface adopts a very complex morphology containing combinations of surface oxide and hydroxide. As such, efficient computational modeling using *ab-initio* techniques becomes very challenging due to exponential growth of the number of possible configurations. To address this issue, we have employed the Cluster Expansion method [8], in which the surface adsorption energetics is modeled by an Ising-type Hamiltonian, with interaction parameters fitted to total energies obtained using density functional theory. Using this method, we calculated the total energies of hydroxylated InP(001) surface as a function of OH coverage. We found that the ground-state energy varies little over a wide range of OH coverage, meaning varying concentrations of surface OH can be expected under realistic operating conditions (Figure 3). In contrast, the oxidized surface carries significant coverage dependence.

In addition, several *ab-initio* molecular dynamics simulations of III-V/water interfaces have been performed during FY 2010/FY 2011. These have led to the following findings: (1) On oxidized or hydroxylated cation (III group)-rich (001) surfaces, the hydrogen bonding network formed by the electrolyte in contact with surface O or OH is strengthened and becomes considerably less dynamic compared to the same network in bulk water; (2) Water molecules nearby oxygen atoms in a In-O-In bonding configuration show a high probability of dissociative adsorption, whereas the reactivity is negligible near oxygen sites in a In-O-P bonding topology, confirming our previous findings; and (3) Dissociative adsorption of H₂O is accompanied by collective motion of surrounding water molecules, which acquire enhanced hydrogen-bond strength.

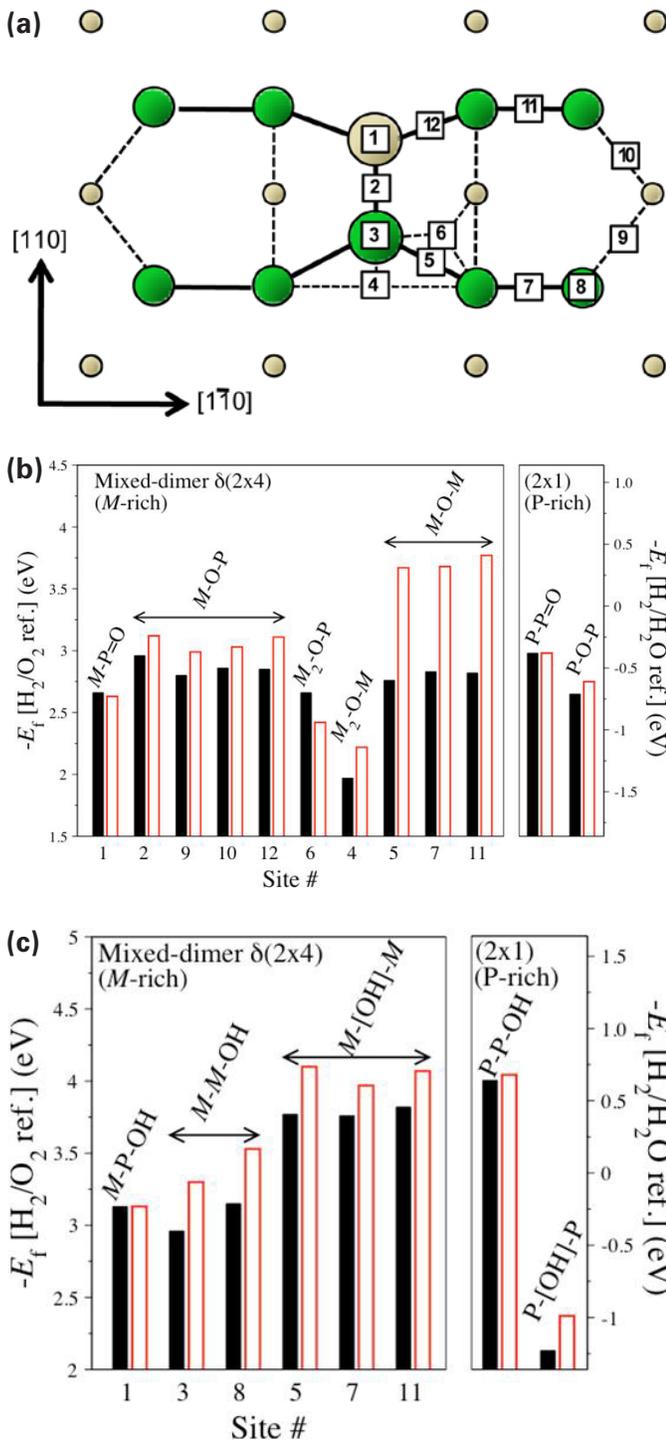

FIGURE 1. Oxygen and hydroxyl adsorption energies on δ -(4x2) type InP and GaP (001) surfaces. (a) Schematic diagram of δ -(4x2) reconstructed surface. Green spheres correspond to cation atoms (In or Ga), and grey spheres correspond to phosphorus atoms. (b) Oxygen adsorption energies and (c) hydroxyl adsorption energies for the sites defined in (a). In (b) and (c), filled bars are for InP and open bars are for GaP.

At the III-V Surface Validation Team meetings and teleconferences, we have discussed three possible corrosion

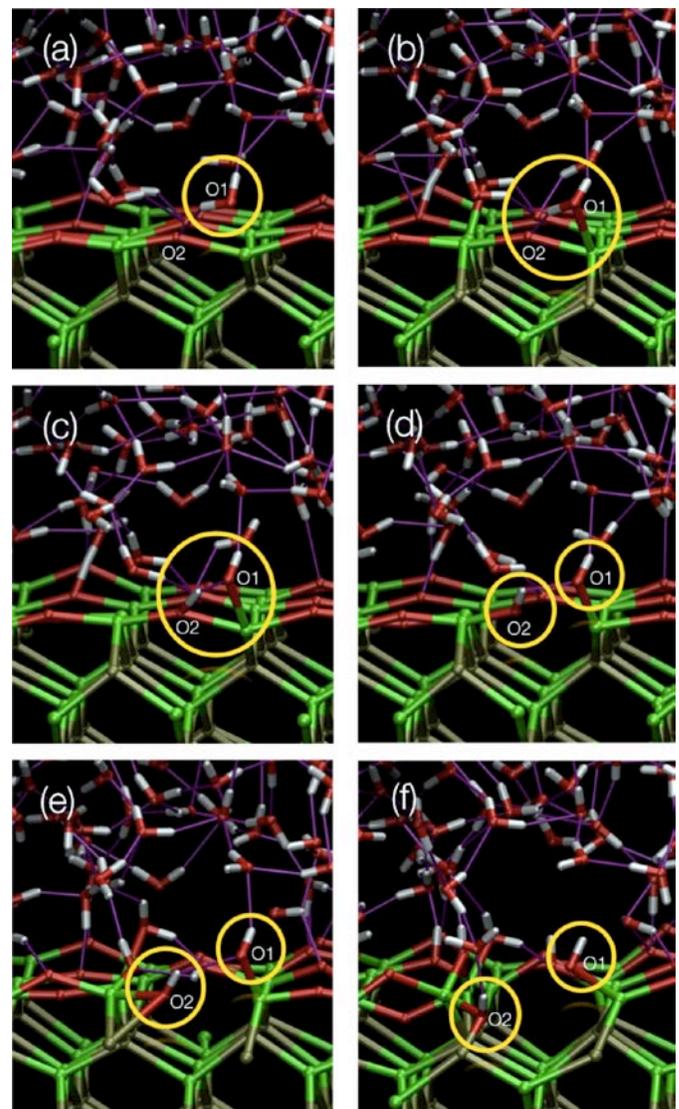

FIGURE 2. Snapshots of dissociative adsorption of a water molecule observed during our *ab-initio* dynamics simulation of the water-InP(001) interface. The yellow circles highlight the water molecule of interest (O1) and the oxygen atom that induces the dissociative adsorption (O2). (a) The water molecule (O1) is pulled toward an oxygen bound to two In atoms (O2). (b) O1 is bound to an In atom, with a hydrogen bond between its attached proton and O2. (c) The proton is transferred from O1 to O2. (d) One of the In-O bonds of O2 is broken. (e), (f) Two OH species are formed.

mechanisms based on combined results from our theoretical study, available information in literature, and experiments performed by other members of the Team. (1) The presence of hole-trap states introduced by defects and impurities are a known cause of semiconductor device degradation. We found two possible scenarios that could contribute to hole trapping in our III-V models: first, formation of specific atomic configurations that lead to the spatially and energetically localized surface states near the Fermi level, which we found could be induced either by chemically or mechanically; and second, an accumulation of anions at

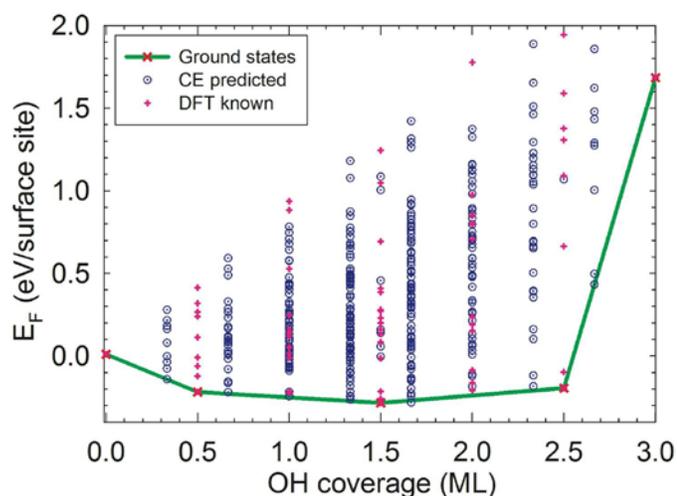

FIGURE 3. The OH adsorption energies as a function of OH concentration calculated by the Cluster Expansion (CE) method and Density Functional Theory (DFT).

the oxide/III-V interface, which is known to take place during natural oxide growth of III-V semiconductors [7]. (2) The formation of locally anodic regions can cause dissolution within the cathode due to loss of cathodic protection from a short-circuit current. Such regions can be formed by intrinsic inhomogeneity in the composition of the cathode material itself, or else by concentration gradients of adsorbed chemical species, such as OH. The former could be particularly relevant for GaInP₂ since this material is known to exhibit incomplete ordering, with ordered and disordered regions displaying distinct electronic properties (e.g., different bandgaps). (3) Undercoordinated cation atoms, which are often observed in our *ab-initio* molecular dynamics simulations as a consequence of local finite-temperature fluctuations in surface composition, can facilitate rapid direct dissolution of surface metal atoms.

In order to formulate an effective corrosion mitigation strategy, it is necessary to assess the likelihood of each of the aforementioned proposed corrosion mechanisms with appropriate experimental methods. Accordingly, the III-V Surface Validation Team plans to perform in situ X-ray spectroscopy studies of the photoelectrode-electrolyte system under illumination. Our contribution to this effort will be provide *ab-initio* derived theoretical spectra for interpretation of experimental results. In preparation, we have performed an initial assessment on accuracy of theoretical X-ray emission spectra using three reference bulk systems: InP, GaP and GaInP₂. We have confirmed that the calculated spectra show satisfactory agreement with the experimental data obtained by our III-V Surface Validation Team collaborators at UNLV, (Figure 4).

In order to develop a complete theoretical/computational tool chest for PEC hydrogen production research, we have established collaborations with the

following four external researchers with specialized expertise: (1) Dr. David Prendergast at The Molecular Foundry (TMF), LBNL—First-principles X-ray Absorption/Emission Spectrum calculations of water-electrode interfaces (with whom we have a peer-reviewed TMF user project); (2) Prof. Chris Wolverton, Northwestern University—Cluster Expansion [8] for realistic modeling of III-V surfaces; (3) Dr. Minoru Otani, National Institute of Advanced Industrial Science and Technology, Japan—First-principles Effective Screening Medium method [9] to simulate interfaces under a bias voltage (part of the Japan-U.S. Ministry of Economy, Trade and Industry-DOE Clean Energy Technology Action Plan [10]). (4) Dr. Yoshitaka Tateyama, National Institute for Materials Science, Japan—First-principles methodology for simulation of redox potentials for charge transfer reactions at liquid/solid interfaces [11]. All collaborators have external research funding and do not require any additional cost to DOE.

Conclusions and Future Directions

- We have conducted extensive first-principles studies on native oxide formation on III-V (001) surfaces (III: In, Ga; V: P), and identified similarities and differences in the local bonding arrangement around the oxygen atom.
- Gas-phase water molecule adsorption simulations as well as *ab-initio* molecular dynamics simulations of water/III-V interfaces consistently show that III-O-III type local bonding arrangement induces dissociative adsorption of bound water, while III-O-V does not.
- We will investigate the link between the local chemical activity and the known macroscopic chemical behaviors, namely, corrosion and hydrogen evolution. The key technique will be to compare simulated spectral data to experiments by UNLV/NREL, with the specific goal of validating our proposed corrosion mechanisms. We will also work to ascertain the effect of surface nitridation on the relevant chemical reactions, motivated by its proven corrosion protection in recent experimental studies by NREL.
- We will design additional theoretical studies to refine our models of interfacial charge transfer reactions, leveraging the expertise of our separately-funded external collaborators. This will focus on the impact of photo-illumination, since the studies conducted to date considered only the properties of the interface precursory to illumination.

Special Recognitions & Awards

1. Best Poster Award, “Materials for Energy Applications: Experiment, Modeling, and Simulation” Conference, Los Angeles, CA, (2011).
2. Best Poster Award, LLNL Postdoctoral Poster Symposium (2010).

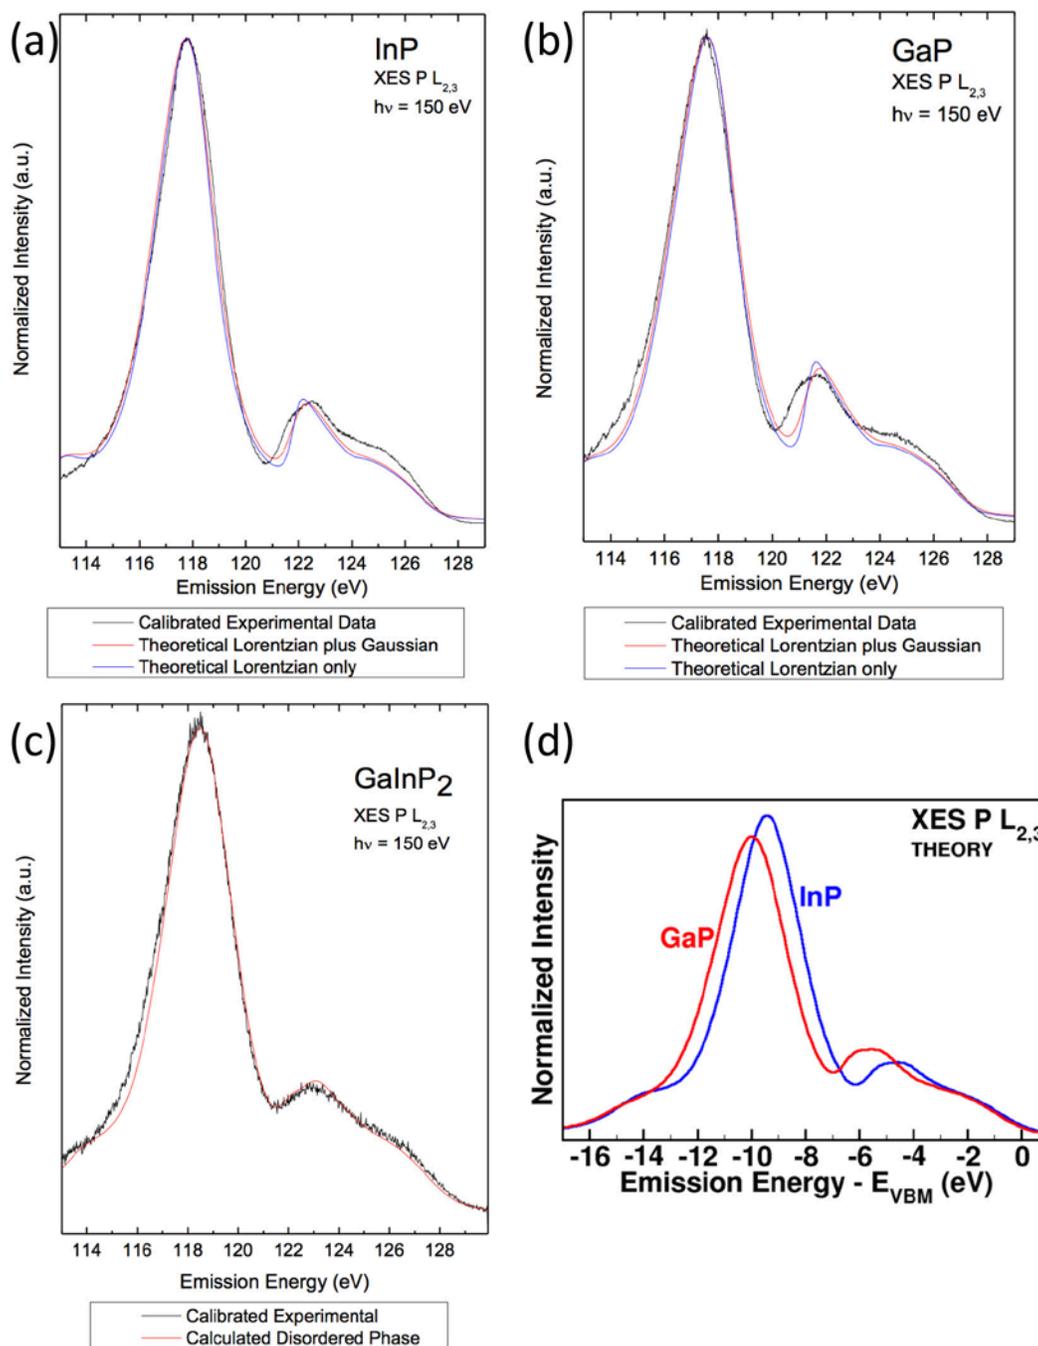

FIGURE 4. Calculated and measured phosphorus $L_{2,3}$ edge X-ray emission spectroscopy (XES) of bulk (a) InP, (b) GaP, and (c) GaInP₂. The experimental data is from Prof. Heske, UNLV. (d) The XES spectra of InP and GaP show clear differences. This indicates that a phase segregation of GaInP₂ into GaP and InP is detectable using XES measurements.

contract DE-AC36-99GO10337

Project Start Date: May 6, 2008
Project End Date: September 30, 2011

- Monitor deliberately introduced modifications of PEC candidate materials in view of the electronic and chemical structure.

FY 2011 Accomplishments

- Investigation of the chemical and electronic surface properties of GaInP₂ thin films and their variation after PEC testing (with the National Renewable Energy Laboratory, NREL, and Lawrence Livermore National Laboratory, LLNL, in the joint NREL/LLNL/UNLV surface validation group).
- Development of the benchmark electronic surface structure of a Fe₂O₃ thin film (with University of California, Santa Barbara).
- First exploratory experiments for the (Mo,W)(S,Se)₂ materials class (with Stanford University).
- First steps towards developing in situ PEC capabilities in soft X-ray spectroscopy (XPS).

Fiscal Year (FY) 2011 Objectives

Enhance the understanding of PEC materials and interfaces and promote break-through discoveries by:

- Utilizing and developing cutting-edge soft X-ray and electron spectroscopy characterization.
- Determining electronic and chemical structures of PEC candidate materials.
- Addressing materials performance, materials lifetime, and capital costs through close collaboration with partners from the PEC working group.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (H) System Efficiency
- (K) Durability
- (G) Capital Cost

Technical Targets

- Collaborate closely with partners within the DOE PEC Working Group to determine the electronic and chemical structure of candidate materials for solar water splitting.
- Aid the collaboration partners in the development and modification of novel candidate materials.

Introduction

This project is embedded into the Department of Energy's efforts to develop materials for PEC water splitting. If successful, PEC will provide an important route to convert the energy supplied by solar irradiation into a transportable fuel. In order to achieve this goal, suitable materials need to be developed that simultaneously fulfill several requirements, among them chemical stability and optimized electronic structure, both for absorption of the solar spectrum and for electrochemical water splitting at a solid/electrolyte interface. This project experimentally derives the chemical and electronic structure information to (a) judge the suitability of a candidate material, (b) show pathways towards a deliberate optimization of a specific material, and (c) monitor whether deliberate modifications of the material indeed lead to the desired changes in electronic and chemical structure.

Approach

A unique "tool chest" of experimental techniques is utilized that allows us to address all technical barriers related to electronic and chemical properties of various candidate materials. With these techniques it is possible to measure surface and bulk band gaps, the energy level alignment at interfaces, the chemical stability of the materials, and the impact of alloying and doping.

The tool chest includes photoelectron spectroscopy (PES) with XPS [1] and ultraviolet (UPS) excitation to

determine the occupied electronic states (core levels and valence electrons) and inverse photoemission (IPES) to determine the unoccupied electronic states. These techniques, performed in the lab at UNLV, are surface-sensitive and allow a complete determination of the electronic and chemical *surface* structure. They are complemented by X-ray emission (XES) and X-ray absorption spectroscopy (XAS), performed at Beamline 8.0 of the Advanced Light Source, Lawrence Berkeley National Laboratory. XES and XAS also probe the occupied and unoccupied electronic states, but with a larger information depth. Furthermore, they also give insight into the chemical structure, again complementary to the electron-based techniques performed in the lab at UNLV.

Results

In collaboration with our partners within the DOE PEC Working Group, we have investigated a variety of PEC candidate materials. Results were immediately shared with the collaboration partners and discussed in detail through powerpoint presentations, at phone conferences, and working group meetings. In this report, we will focus on the chemical surface properties of GaInP₂ samples obtained from NREL (T. Deutsch and J. Turner) and the electronic structure of Fe₂O₃ samples obtained from University of California, Santa Barbara (A. Forman, A. Kleiman-Shwarscstein, and E. McFarland). Further results, also for other material classes, are shown in the annual review presentation.

For the GaInP₂ experiments, two lines of work were pursued. First, we analyzed a series of samples that were deliberately exposed to PEC-relevant conditions, as listed in Table 1.

TABLE 1. Experimental Details of the GaInP₂ Samples Tested at NREL

Sample	Treatment	Electrolyte
MJ247-4	30 sec etch in concentrated sulfuric acid	none
MJ247-3	-8 mA/cm ² , 22 hrs, AM1.5G	0.1M HNO ₃ + 0.5M NH ₄ NO ₃ with Zonyl FSN-100
MJ247-2	-8 mA/cm ² , 22 hrs, AM1.5G	1M KOH with Zonyl FSN-100
MJ247-1	-8 mA/cm ² , 22 hrs, AM1.5G (+8 mA/cm ² applied for ~1 sec prior to run)	0.5M H ₂ SO ₄ with Zonyl FSN-100
MJ200	as-grown	none

An XPS surface chemical characterization of the samples is presented in Figure 1. The survey spectra in Figure 1 are normalized to the same height and offset for presentation. In addition to the expected Ga, In, and P peaks, the spectra also show O 1s and C 1s peaks of varying intensities. Samples MJ247-1 and MJ247-3 also show F 1s peaks, with this peak being the dominant feature in Sample MJ247-3. This is likely due to the Zonyl FSN-100

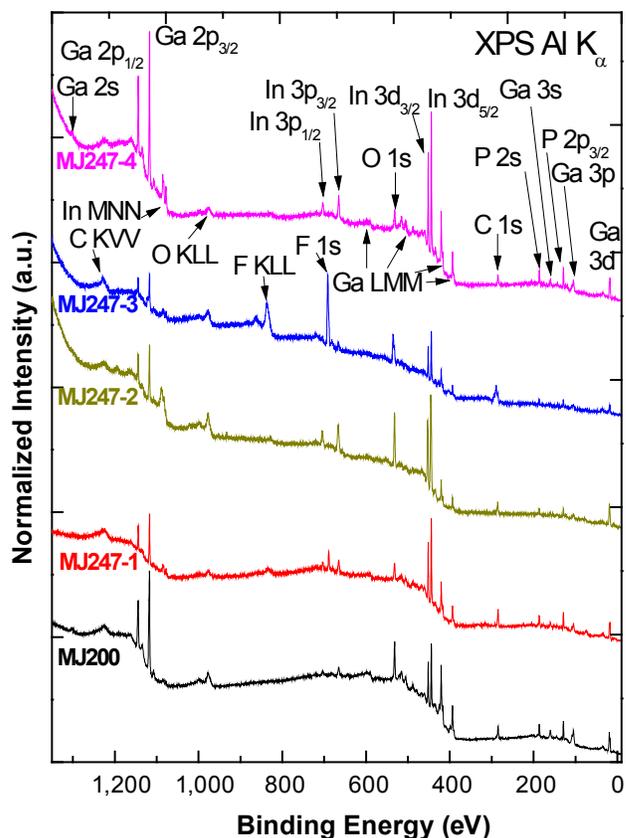

FIGURE 1. XPS survey spectra of selected GaInP₂ thin film samples after deliberate exposure to PEC-relevant environments, as listed in Table 1.

fluorosurfactant applied to the sample surfaces to facilitate movement of evolved H₂ from the electrode, but could also stem from the Teflon[®]-based environment of the sample surface during the tests.

As an example for the analysis of detail XPS spectra, we note that the Ga 2p region (not shown) clearly indicates the presence of multiple Ga species in the fluorine-rich sample MJ247-3 and, furthermore, exhibits variations in the lineshape of all samples, suggesting the presence of multiple chemical environments in those cases as well. For example, the MJ200 sample exhibits a shoulder at higher binding energy, most likely due to the native oxide- and carbon-containing surface contamination layer. Future experimental steps (currently being conducted in our lab at UNLV) thus focus on a removal of this surface contamination layer, such that “benchmark” spectra, e.g., of the Ga 2p core levels, but also of the valence and conduction band region of clean GaInP₂, can be obtained.

The second line of work on GaInP₂ focuses on a derivation of the electronic surface structure, as will be demonstrated below for the Fe₂O₃ system. In particular for the band gap determination, our experimental tool chest allows three different approaches, namely ultraviolet/visible light absorption (the “optical bulk band gap”), combining XES and XAS (the “electronic surface-near

band gap”), and combining UPS and IPES (the “electronic surface band gap”, see discussion of Fe_2O_3). In fact, a combination of all three approaches can be used to follow band gap gradients [2]. Here, we show first experiments to combine XES and XAS studies on the same samples. For this purpose, we have studied the P $L_{2,3}$ edge of (air-exposed) GaP and InP reference powders, as well as one (untreated) GaInP₂ thin film. Figure 2 shows the associated spectra, demonstrating that it will be possible to determine both valence-band maxima (VBM) and conduction band minima (CBM) with this method. Note that, due to the above-mentioned surface contamination, the derived band gaps are not yet representative of functioning PEC devices (in which electrolyte exposure is expected to “clean” the surfaces), and hence no band gaps are given here. In future

steps (currently being performed at UNLV), samples will be cleaned with an ion-stimulated desorption approach, which will allow us to determine depth-dependent band gaps of representative GaInP₂ surfaces. These can then be compared with theoretical results from our project partners at Lawrence Livermore National Laboratory (T. Ogitsu and B. Wood).

Having elucidated the impact of calcination (as shown in Figure 3) on the chemical surface properties of the University of California, Santa Barbara thin films in the previous FY, in particular uncovering significant Ti and Pt segregation processes, we focused on the analysis of the *electronic structure* of a Fe_2O_3 sample that demonstrated particularly high solar water splitting performance.

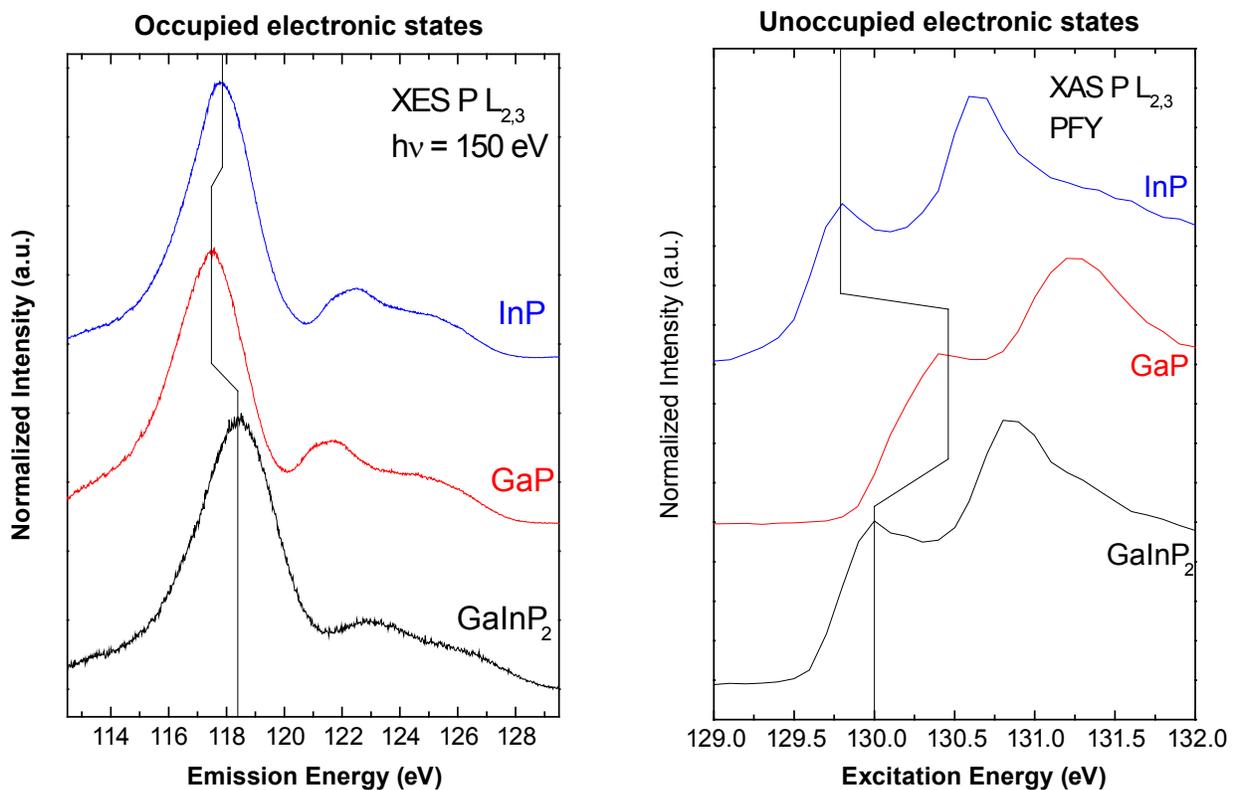

FIGURE 2. P $L_{2,3}$ XES (left) and XAS (right) of InP and GaP reference powders, as well as a GaInP₂ thin film (after air exposure, but without additional PEC testing). XES spectra probe the occupied states of the valence band, while XAS spectra give insights into the unoccupied conduction band states.

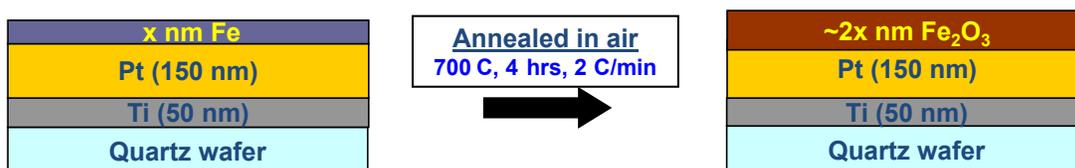

FIGURE 3. Schematic Calcination Process to Prepare Fe_2O_3 Thin Films at the University of California, Santa Barbara

The occupied and unoccupied electronic states were probed with UPS and IPES, respectively, as shown in Figure 4, left. The binding energies (abscissa) were adjusted relative to the Fermi Energy and plotted within the same graph. The leading edges of each spectrum were then extrapolated to the baseline. The positions of the intercepts with the baseline determine the positions of the VBM, in the UPS spectrum, (left) and CBM in the IPES spectrum, (right). The combination of both band edges allows a determination of the electronic surface band gap (2.0 ± 0.2 eV). Combining the band edge positions with the work function (4.23 ± 0.05 eV) of the sample, the band edge positions can be given with respect to the vacuum level. Furthermore, by applying an International Union of Pure and Applied Chemistry recommendation [3] and as done earlier for the case of WO_3 [4] and Mo:WO_3 [5], the vacuum level scale can be related to the normal hydrogen electrode (NHE) scale. By plotting the position of the VBM and CBM relative to the Fermi energy, vacuum level, and NHE on one plot, a comprehensive picture of the electronic picture can be painted, as shown in Figure 4 on the right.

Note that the plot in Figure 4 is derived from vacuum-based measurements and thus includes a potential surface band bending at the solid/vacuum interface. It does not,

however, include potential variations of this band bending upon formation of the liquid-solid interface in an electrolyte environment. As is well known, a Helmholtz layer is formed in this case, and experimental and theoretical approaches to assess the impact of this layer on the electronic structure will need to be performed in subsequent experiments. In the current state, the plot in Figure 4 shows that the Fe_2O_3 sample surface simultaneously satisfies two conditions necessary for solar water splitting: the CBM and VBM straddle the H^+/H_2 reduction and $\text{H}_2\text{O}/\text{O}_2$ oxidation potentials, and the surface band gap lies in the optimal range for PEC hydrogen production with a single-gap material. However, a bias will clearly be needed to drive significant currents during PEC water splitting using this surface, since the CBM lies only slightly above the H^+/H_2 reduction level.

Conclusions and Future Directions

Conclusions:

- Successfully maintained operations of our multi-chamber ultra-high vacuum spectroscopy system despite limited funding.

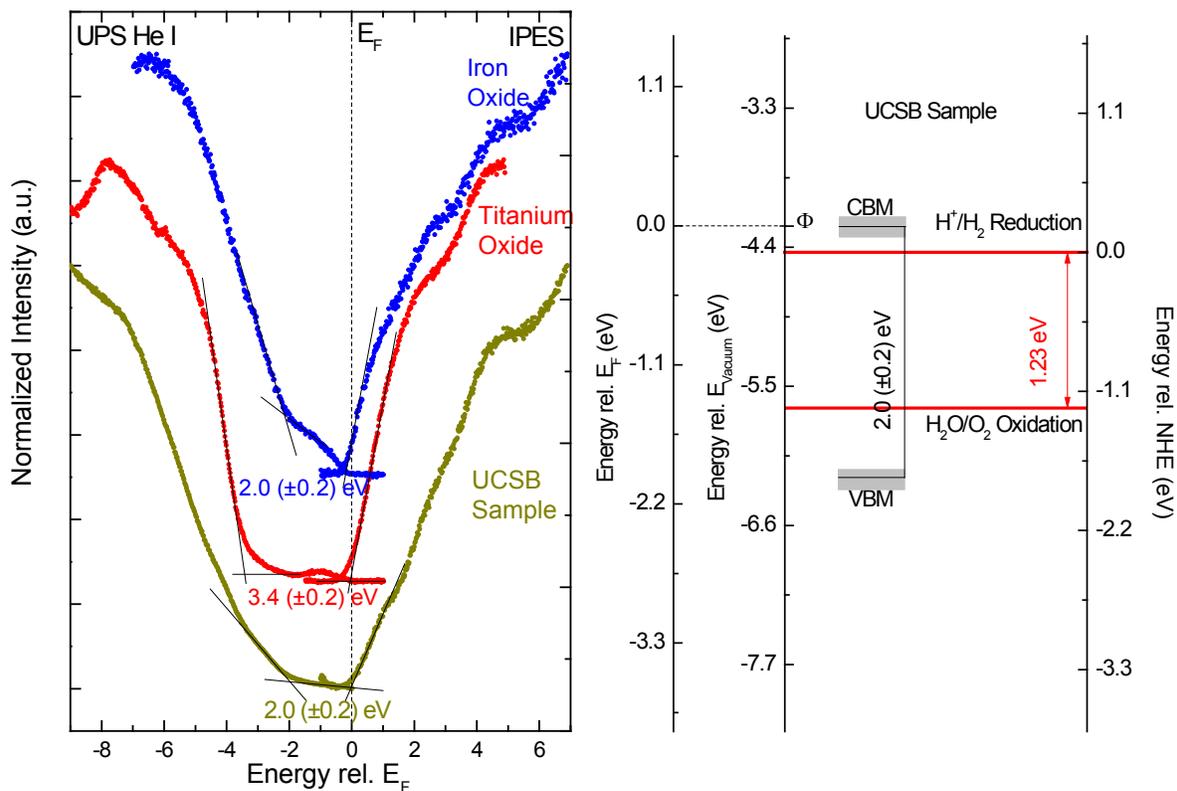

FIGURE 4. Left panel: UPS (left) and IPES (right) spectra of an Fe_2O_3 thin film grown at University of California, Santa Barbara (UCSB), and two *in-vacuo* grown reference systems (iron oxide and titanium oxide). Right panel: tentative electronic surface structure of the University of California, Santa Barbara Fe_2O_3 thin film.

- Continued experiments with select partners of the DOE PEC Working Group, primarily focusing on GaInP₂ and Fe₂O₃ thin films.
- Evaluated PEC candidate materials in view of their electronic and chemical properties, with primary focus on band gaps and level alignment.

Future Directions:

- Future directions will depend on availability of funding.
- If possible, we will continue the collaborations with our existing partners and bring new partners “on board”.
- We will continue to determine electronic and chemical properties of various PEC candidate materials manufactured by the collaboration partners within the DOE PEC Working Group.
- For GaInP₂, we will focus on establishing a benchmark electronic structure of optimally cleaned thin film surfaces, which will allow us to monitor deliberate modifications of the GaInP₂ material and to correlate our results with theoretical calculations and predictions.

Contract Number: DE-FC36-07GO17105, A00

Subcontractor:
 University of Hawaii at Manoa (UH), Honolulu, HI

Project Start Date: September 1, 2007
 Project End Date: December 31, 2012

- Demonstrate functional multi-junction device incorporating materials developed.
- Explore avenues toward manufacture-scaled devices and systems.

Technical Barriers

This project addresses the following technical barriers from the Photoelectrochemical Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (Y) Materials Efficiency
- (Z) Materials Durability
- (AA) PEC Device and System Auxiliary Material
- (AB) Bulk Materials Synthesis
- (AC) Device Configuration Designs

Technical Targets

Table 1 lists the technical targets for PEC hydrogen production using amorphous silicon carbide-compound (a-SiC), tungsten-compound (WO₃) and copper-chalcopyrite compound (CGSe) films.

Fiscal Year (FY) 2011 Objectives

- Work closely with the DOE Working Group on Photoelectrochemical (PEC) Hydrogen Production for optimizing PEC materials and devices.
- Develop new PEC film materials compatible with high-efficiency, low-cost hydrogen production devices.

FY 2011 Accomplishments

1. Improvement in performance of the hybrid photovoltaic (PV)/a-SiC device:
 - Good durability in pH2 buffered electrolyte for up to 310 hr.

TABLE 1. Technical Targets

Task #	Milestone	a-SiC	WO ₃	CGSe
Year 1	Material photocurrent ≥3 mA/cm ²	Achieved	Achieved	Achieved
	Durability ≥100 hr	Achieved	Achieved	10% Achieved
Year 2	Material photocurrent ≥4 mA/cm ²	Achieved	90% Achieved	Achieved
	Durability ≥ 200 hr	Achieved	Achieved	Achieved
	Device STH efficiency ≥5%	32% Achieved	60% Achieved	62% Achieved
Passed Go/No-Go decision evaluation in November, 2010				
Year 3*	Device STH efficiency ≥5%	32% Achieved	60% Achieved	85% Achieved
	Durability ≥300 hr	100% Achieved	83% Achieved	66% Achieved
Year 4	Device STH efficiency ≥5%			
	Durability ≥500 hr			
	Completion of Final Energy/Economics report on scale up and commercialization toward a \$22/kg-H ₂ plant production cost			

* As of writing this report.

- Surface treatment by methylation (CH_3) termination and titanium (Ti) nano-particles increases photocurrent of the hybrid PV/a-SiC device by nearly two order of magnitude.
2. Improvement in performance of the WO_3 photoelectrode, including:
 - Synthesis of WO_3 -based material with near to optimum band gap (CuWO_4).
 - Identification of an innovative monolithic integration scheme for WO_3 -based PEC devices.
 3. Improvement in performance of the I-III-VI₂ photoelectrode, including:
 - Highly durable down to pH0 sulfuric acid (200 hr resulting in improved performance).
 - Successful integration into a novel coplanar device approaching 5% solar-to-hydrogen (STH) efficiency.
 - Identification of possible surface modifications to decrease required voltage bias.

Introduction

Based on its potential to meet long-term goals, research and development (R&D) centering on multi-junction hybrid photoelectrode technology defines the scope of this collaborative project. Within this scope, particular emphasis is the development of low-cost photoactive materials integrated with a-Si-based solar cells as a driving force with photocurrents greater than 4 mA/cm^2 , and with sufficient durability to meet lifetime requirement, i.e., ≥ 500 hours. In addition to the materials R&D activities, development of laboratory-scale demonstration devices and generation of preliminary energy/economic analysis for hydrogen production cost based on the developed PEC technology is included in the project scope as second-level priorities. To support the device-demonstration activities, appropriate auxiliary components are being developed for incorporation in PEC photoelectrode designs, including attention to the necessary process integration techniques.

Approach

The general approach of this collaborative effort focuses on the DOE PEC Working Group's "feedback" philosophy of integrating state-of-the-art theoretical, synthesis and analytical techniques to identify and develop the most promising materials classes to meet the PEC challenges in efficiency, stability and cost. Materials modeling, bulk-film optimization, film-surface enhancement, along with comprehensive material and device characterization is being employed to facilitate the R&D process. Specifically, the feedback approach is being applied to our focus material classes, including the tungsten-, copper-chalcopryrite- and silicon-based compounds, to enhance understanding of fundamental performance

parameters, and expedite development of process-compatible forms of these materials. The most promising candidate materials are being identified, with the short-term goal of demonstrating laboratory-scale water-splitting devices, and with a long-term goal of transferring the fabrication processes toward the commercial scale.

Results

During this reporting period (June 2010–June 2011), extensive studies of the three material classes under investigation have focused on understanding and improving PEC behavior, specifically by applying our theoretical, synthesis and analytical techniques in identifying relevant aspects of structural, optoelectronic and electrochemical properties.

1. Amorphous Silicon Carbide-Based Compound Films

Surface methylation of the hybrid PV/a-SiC devices was accomplished by first eliminating SiOx from the a-SiC surface via HF (hydrofluoric acid) etching followed by immersion in NH_4F (ammonium fluorine) to produce hydrogen (H)-termination. Next, the H-terminated a-SiC surface was treated with a CH_3 -containing species and then coated with Titanium (Ti) nanoparticles sputtered at 60 W direct current for 60 s. The treatment resulted in an anodic shift of $\sim 0.3 \text{ V}$ in flatband potential, as measured by the National Renewable Energy Laboratory (NREL). Figure 1 shows current-voltage (J-V) characteristics of the hybrid devices for various surface treatment conditions measured under AM1.5G illumination. Compared to the non-treated sample, the fill factor of the J-V curves in the surface-treated sample is improved greatly. At zero potential, the photocurrent density changes by as much as two orders of magnitude, from $\sim 11 \text{ }\mu\text{A/cm}^2$ to $\sim 1 \text{ mA/cm}^2$. This clearly shows that surface methylation reduces the a-SiC/electrolyte barrier allowing more photocurrent. More work to optimize this process is underway.

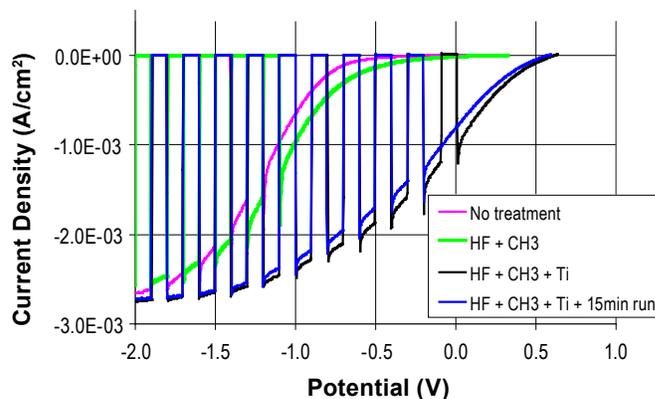

FIGURE 1. Two electrode PEC J-V curves of untreated, CH_3 -terminated, and CH_3 -terminated + Ti coated hybrid devices. The blue J-V curve was measured after 15 min of the first scan (black curve) in order to confirm the reproducibility.

In addition, the hybrid PV/a-SiC device exhibits good durability for up to 310 hr in pH2 electrolyte and under AM1.5G at 1 mA/cm², as confirmed by NREL.

2. Tungsten Oxide-Based Compound Films

During this reporting period, efforts were focused on copper tungstate (CuWO₄), known to have a bandgap (2.1 eV) ideal for PEC applications. CuWO₄ synthesized at 275°C using conventional reactive co-sputtering were p-type and amorphous with a bandgap of 2.1 eV, but exhibited poor PEC performances as shown in the inset in Figure 2. However, an 8 hr anneal at 500°C in argon led to a polycrystalline CuWO₄ structure with n-type conductivity, while optical bandgap remained unchanged. Finally, PEC performance improved with photocurrent density achieving ~0.5 mA/cm² (see Figure 2). It is noted that the flat-band potential (which determines photocurrent onset potential) is much lower than that expected for metal oxides (-0.3 V vs. saturated calomel electrode (SCE) for CuWO₄ versus +0.15 V vs. SCE for WO₃). Thus, it is expected that CuWO₄ could be integrated into a hybrid PEC device design comparable to what is currently used for a-SiC and WO₃ hybrid devices. Future doping studies with foreign elements to improve charge carrier separation and extraction are on going with the help of NREL's theory group.

Durability tests were also performed on WO₃ photoelectrode, under AM1.5G at 1.8 V, in pH2.5 H₃PO₄ electrolyte. High corrosion resistance of WO₃ in acidic solution for up to 250 hr has been observed.

3. I-III-VI₂ (Copper Chalcopyrite-Based) Films

It was observed in a successful 200 hr durability test that this material is highly stable in very acidic (pH0) sulfuric acid. In addition, such an extended operation

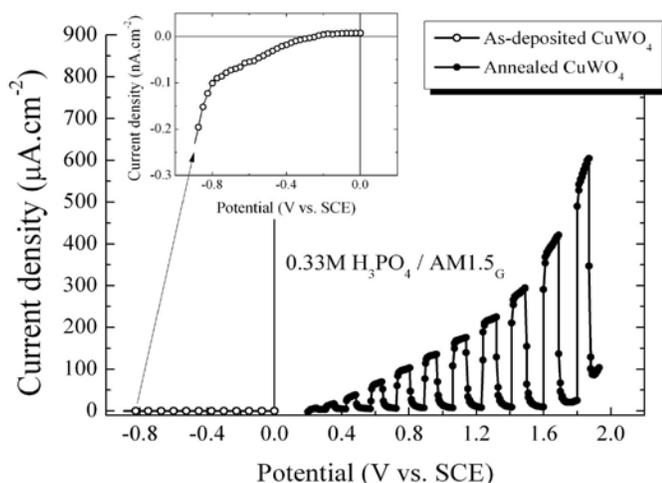

FIGURE 2. Three electrode PEC J-V curves of as-deposited and annealed CuWO₄ thin films. Test was done in 0.33M H₃PO₄ under AM1.5G simulated illumination.

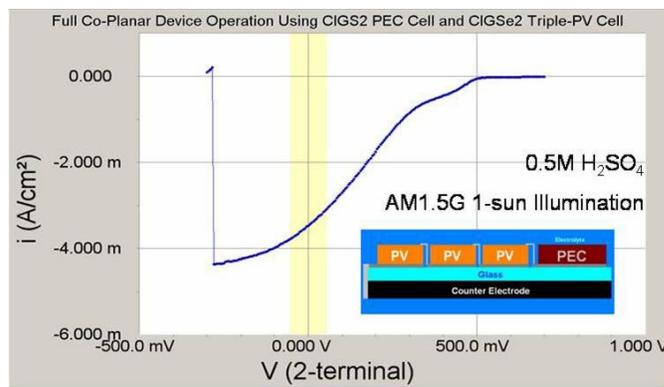

FIGURE 3. J-V characteristics of a coplanar device integrating three CIGSe₂ PV cells with a CIGS₂ PEC cell (as shown in schematic). Device indicated a 3.46 mA/cm² operating point at 0 V, equivalent to 4.3% STH efficiency.

improves the performance of CGSe₂ (i.e., photocurrent increased by 22%), possibly due to light-soaking or a surface sulfurization, detected by X-ray emission spectroscopy soft X-ray spectroscopy at the University of Las Vegas. Collaboration with Stanford University aims to perform a more controllable surface sulfurization (by annealing in an H₂S atmosphere). Figure 3 shows the J-V characteristics of a coplanar device integrating three CIGSe₂ PV cells with a CIGS₂ PEC cell (as shown in schematic). The device was tested in 0.5M H₂SO₄ and under AM1.5G 1-sun illumination, and produced a new material class record photocurrent of 3.46 mA/cm² at 0 V, equivalent to 4.3% STH efficiency.

Conclusions and Future Directions

Surface treatment of the hybrid PV/a-SiC device using CH₃ termination was found to reduce the photocurrent onset and enhance photocurrent by as much as two orders of magnitude at zero potential. In WO₃-based compound such as CuWO₄, the post-deposition annealing improves its conductivity and photo-response while the bandgap remains unchanged (2.1 eV). Finally, a STH efficiency of ~4.3% is achieved in the co-planar integrated PV/CGSe₂ device. The hybrid PV/a-SiC device, and other two photoelectrode thin film materials (WO₃ and copper chalcopyrite) show good durability in electrolyte for ≥200 hr.

In order to improve the STH efficiency, three main tasks will be performed: (1) improve interface energetics and kinetics with appropriate surface treatment for a-SiC photoelectrodes. Our goal for this year is to achieve 2.5-3% STH efficiency with 400-hour durability in the hybrid PV/a-SiC device; (2) identify a suitable foreign element for CuWO₄ doping and increase photocurrent density beyond 3.5 mA/cm² while passing the 400 hours durability mark; and (3) further lower valence band edge via Cu and Se (partial) substitution in I-III-VI₂ photoelectrode materials to surpass 5% STH efficiency while maintaining material

durability for 400 hours this year. Surface treatment will be evaluated for all three material classes to prevent possible degradation beyond 250 hours. Such treatment may include CoMo for photocathodes (a-SiC and I-III-IV₂) and RuO₂ for photoanode (WO₃ and CuWO₄).

- University of Toledo, Toledo, OH
- National Renewable Energy Laboratory, Golden, CO

Project Start Date: April 1, 2005

Project End Date: December 31, 2012

Fiscal Year (FY) 2011 Objectives

- To develop critical technologies required for cost-effective production of hydrogen from sunlight and water using thin film (tf)-Si-based photoelectrodes.
- Two approaches are taken for the development of efficient and durable photoelectrochemical (PEC) cells:
 - An immersion-type PEC cell in which the photoelectrode is immersed in electrolyte.
 - A substrate-type PEC cell in which the photoelectrode is not in direct contact with electrolyte.

Technical Barriers

This project addresses the following technical barriers from the Production section (3.1.4) of the Hydrogen, Fuel Cells and Infrastructure Technologies Program Multi-Year Research, Development and Demonstration Plan:

(Y) Materials Efficiency

(Z) Materials Durability

(AB) Bulk Materials Synthesis

(AC) Device Configuration Designs

(AD) Systems Design and Evaluation

Technical Targets

This project focuses on the development of photoelectrode materials and tf-Si-based PEC cells required to achieve or exceed DOE's technical targets. The status of the MWOE project towards the DOE technical targets for PEC production of hydrogen for 2013 is:

TABLE 1. Progress towards Meeting Technical Targets for Immersion- and Substrate-type PEC Cells and Systems

Characteristic	Units	DOE 2013 Targets	MWOE 2011 Status
Solar-to-Hydrogen Efficiency	% Efficiency	8	5 (4"×12" module) (Substrate-type)
Durability	Hours	>1,000	1,000 (Cobalt Oxide)
Cost	\$/gasoline gallon equivalent	2-4	To Be Determined
Photocurrent of TCCR	mA/cm ²	>8 (MWOE Target)	37.8 (Cobalt Oxide)
Photocurrent of PAS	mA/cm ²	>8 (MWOE Target)	0.0334 (Indium Iron Oxide) (Down-selected)
Deposition Temperature	°C	<250 (MWOE Target)	180-200 (Cobalt Oxide)
Transparency of TCCR	% Transmission	>90 (MWOE Target)	90 (Cobalt Oxide)
Voltage drop across TCCR/PV-cell layer stack	Volts	≤0.15	0.07 (Cobalt Oxide)

TCCR - transparent, conducting and corrosion resistant; PAS - photoactive semiconductor; PV - photovoltaic

FY 2011 Accomplishments

- A 12"×12" substrate-type PEC cell prototype was fabricated and has been tested.
- TCCR were developed (Task 1):
 - From a Go/No-Go meeting Co₃O₄ and In₂O₃-Fe₂O₃ were identified as the major material classes of study moving into the final grant period.
- Facilities and procedures for large-area deposition of Co₃O₄ for use in immersion-type PEC cells have been established and some runs have been carried out with very promising results (Task 1).

- Large-area electroplating of porous Ni as H₂ evolution catalyst has been developed using precursor salts in order to optimize the porous structure of the catalyst films (Task 4):
 - Many new precursors were studied for Ni electroplating and it was found that using (NH₄)₂SO₄ yielded the best results due to the increased porosity of the Ni layer.

Introduction

In this project, MWOE and its subcontractors are jointly developing the critical technologies required for cost-effective production of hydrogen from sunlight and water using tf-Si-based photoelectrodes. These triple-junction tf-Si-based electrodes include triple cells with either amorphous silicon germanium alloy (a-SiGe) or microcrystalline silicon (μ c-Si) as the narrow band gap absorber material.

In this project two separate approaches have been pursued for the development of immersion- and substrate-type PEC photoelectrodes:

- In one approach, triple-junction tf-Si-based photoelectrodes (a-Si/a-SiGe/a-SiGe or a-Si/a-SiGe/ μ c-Si) are used to generate the voltage bias necessary for hydrogen generation. A TCCR coating is deposited on top of the photoelectrode for protecting the semiconductor layers from corrosion while forming an ohmic contact with the electrolyte.
- The second approach uses a hybrid structure, in which two tf-Si based junctions (middle and bottom junctions of the present triple-junction tf-Si cell) provide a voltage bias of about 1.1 V, and a third junction (the top junction) forms a rectifying junction between a PAS and the electrolyte. This approach was down-selected during a Go/No-Go review in December 2010.

State-of-the-art a-Si/a-SiGe/a-SiGe and/or a-Si/a-SiGe/ μ c-Si devices are used as photoelectrodes. The corrosion resistance and PEC mechanisms for a range of oxide-, nitride- and carbide-materials, and II-VI compounds are under investigation. High-performance, durable PEC cells and systems will be developed, optimized and demonstrated in this project.

Approach

Five technical tasks are being performed under this grant in order to accomplish the project objectives:

- Task 1: Transparent, conducting and corrosion resistant coating for a triple-junction tf-Si-based photoelectrode.
- Task 2: Hybrid multi-junction PEC electrode having semiconductor-electrolyte junction.

- Task 3: Understanding and characterization of photoelectrochemistry.
- Task 4: Development of device designs for low-cost, durable and efficient immersion-type PEC cells and systems.
- Task 5: Development of device designs for large area, substrate-type PEC cells.

During the Go/No-Go review in December 2010, it was decided that the immersion-type PEC work (Task 4) will proceed into the second phase and the substrate-type PEC work (Task 5) would come to an end. It was also determined the TCCR work (Task 1) will proceed and the PAS work (Task 2) will be halted.

Results

Tasks 1 focuses on the preparation of TCCR coatings deposited onto the top of the tf-Si photoelectrode. Many different material classes have been studied, including Fe₂O₃, TiO₂ and WO₃. Co₃O₄ has been identified as a promising candidate for use as a TCCR material: it can be sputtered at temperatures <250°C and provides sufficient transparency if the layer thickness is kept below ~30nm; Co₃O₄ layers are corrosion resistant in alkaline electrolytes which are used in immersion type PEC cells, and these layers provide good electrical conductivity. Co₃O₄ layer (sputtered onto Tec 15 glass) provides a current density of 37.8 mA/cm² at 1.8 V, which is the voltage of the PEC cell under operating conditions. The voltage drop across the TCCR layer for the TCCR/PV cell stack is ~0.07 V. For small-area studies, the TCCR films were deposited using radio frequency magnetron sputter deposition in argon and oxygen using multiple sputter guns simultaneously. From the completed work, the results indicate that samples made at 250°C with 100 W and a sputter deposition time of 30 minutes produced optimal results. These Co₃O₄ layers have demonstrated 1,000 hours of stability in ~30% KOH as electrolyte at the time of this report. During this reporting period emphasis was focused on fabricating and characterizing Co₃O₄ films and on developing a large-area deposition process for Co₃O₄ using Xunlight's roll-to-roll deposition system (Figure 1, Figure 2). Xunlight's roll-to-roll deposition system allows large-area fabrication of PEC electrodes including the deposition of TCCR layer without breaking the vacuum: the equipment simulates processing conditions which are comparable to a manufacturing environment. Process parameters such as sputtering power, line speed and oxygen content in the sputtering gas were optimized in order to achieve the best performing Co₃O₄ TCCR layer and PEC electrodes. Transmission measurements performed on the Co₃O₄ layer deposited onto glass slides showed that reducing the layer thickness by increasing the line-speed to 6"/min improved the transparency of the Co₃O₄ layer significantly. Reducing the sputtering power to 1.5 kW lead to transmission values of 80-100% in a wavelength range between 300-900 nm. The average thickness of these Co₃O₄ layers were ~135 nm.

FIGURE 1. Xunlight's Roll-To-Roll Deposition System For Large-Area Fabrication of PEC Electrodes

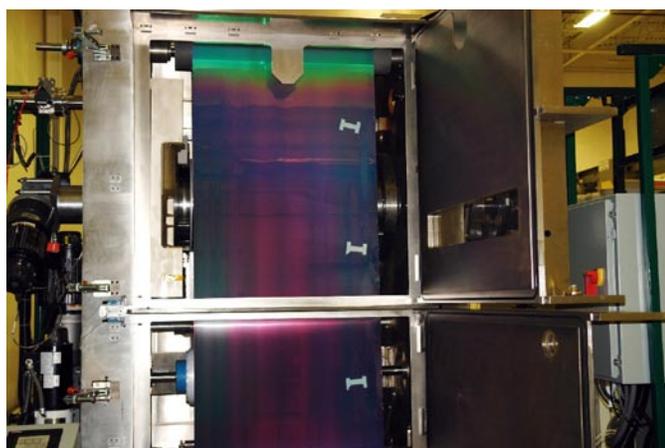

FIGURE 2. Opened Pay-Out Chamber of Xunlight's Roll-To-Roll Machine with Inserted Stainless Steel Web after Co_3O_4 Sputtering

Noteworthy is that the transmission of the Co_3O_4 layer does not change with the oxygen flow in the sputtering gas.

Under Task 4, a method for large-area electroplating of porous Ni used as H_2 -evolution catalyst has been developed. Over the past year work has focused on the continued study of the addition of precursor salts such as ammonium sulfate, cobalt chloride, zinc acetate, and zinc sulfate to the Ni plating solution in order to improve micro- and macro-structures of the porous nickel films. The method uses the co-deposition of Ni and a precursor metal (Zn, Co) onto the back-side of tf-Si photoelectrodes; after Ni/Zn or Ni/Co electrodeposition the precursor metal is leached out leaving a porous Ni-structure behind. At this stage of research, using ammonium sulfate as a precursor material shows the best result, which is illustrated in Figure 3. The porosity of the nickel catalyst is shown in Figure 4.

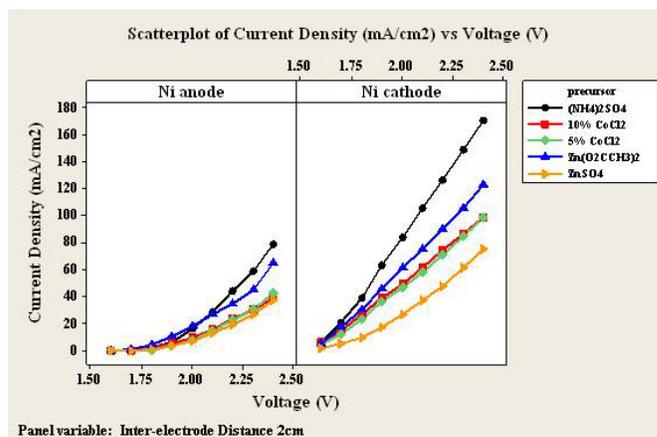

FIGURE 3. Current-voltage curves for porous Ni-electrodes used as anode or cathode with an electrode distance of 2 cm (counter electrode: Pt-mesh); precursor salts: $(\text{NH}_4)_2\text{SO}_4$, CoCl_2 (5% and 10%), $\text{Zn}(\text{O}_2\text{CCH}_3)_2$, ZnSO_4 .

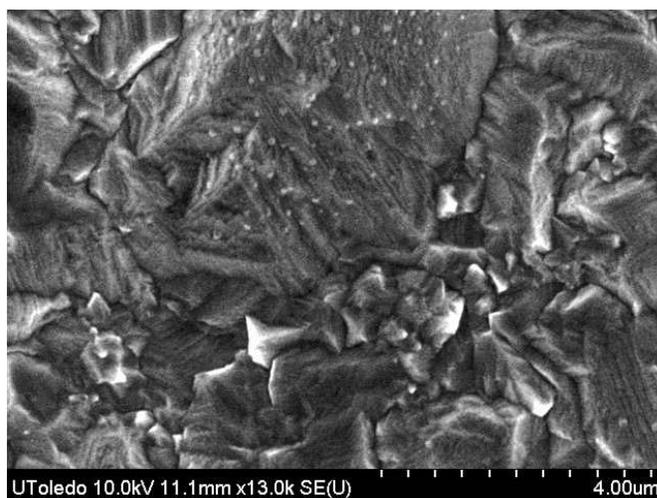

FIGURE 4. Scanning Electron Micrograph of Ni-Catalyst Prepared with $(\text{NH}_4)_2\text{SO}_4$ (10%)

Task 5 focuses on the development of large-area substrate-type PEC systems. Under this task several prototypes for $12'' \times 12''$ PEC cell assemblies were fabricated. The porous Ni layer used as a hydrogen evolution catalyst was electroplated onto the backside of a tf-a-Si device. The surface of the PEC electrode was encapsulated using a light-weight ethylene vinyl acetate-based encapsulation material, which protects the electrode from environmental impact under outdoor operating conditions. The generation of hydrogen and oxygen was confirmed under illumination. At this point of research solar-to-hydrogen efficiency data are not available for $12'' \times 12''$ PEC systems. However, earlier experiments showed that a solar-to-hydrogen efficiency of 5% has been obtained for a $12'' \times 4''$ substrate-type PEC system.

Conclusions and Future Directions

The proposed future work will include:

- Continue optimization of oxide materials suitable for TCCR coatings:
 - Material class studies will be focusing on In_2O_3 - Co_2O_3 .
 - Optimization work on Co_3O_4 TCCR will continue.
- Optimize large-area deposition of Co_3O_4 TCCR layer in the roll-to-roll system and fabricate large-area Si PEC electrodes with a Co_3O_4 TCCR coating:
 - Improve performance of large-area photoelectrodes.
- Demonstrate 4"×4" and 12"×12" immersion-type PEC systems:
 - Design of immersion-type PEC systems using triple-junction a-Si photoelectrodes with a TCCR layer.
 - The PEC system will employ porous Ni as H_2 evolution catalyst electroplated onto the backside of the triple-junction a-Si device.

- Long-term reliability studies and solar-to- H_2 efficiency measurements will be performed.
- Complete techno-economic analysis and energy analysis for the PEC systems for hydrogen production.

Project End Date: June 30, 2011

*Congressionally directed project

- Hybrid tandem heterostructured PEC suffer from inefficient charge carrier transfer process across the semiconducting electrode/electrolyte junction due to the presence of interfacial energy traps, and lattice constant mismatch between layered semiconductors.
- Other nanostructured devices involving oxynitrides, such as $(\text{Ga}_{0.88}\text{Zn}_{0.12})(\text{N}_{0.88}\text{O}_{0.12})$ with co-catalysts, such as $\text{Rh}_{2-x}\text{Cr}_x\text{O}_3$ shows considerable promise for hydrogen production but the cost of the materials and toxicity involved in some cases show further studies are needed to synthesize electrodes for commercial hydrogen production.

Technical Targets

Solar-to-hydrogen efficiency: 10% by 2015 by developing photoanodes having efficient light absorption in the visible range by reaching quantum yield of 30% at 600 nm and long-term corrosion resistance for commercial-scale H_2 production.

FY 2011 Accomplishments

- Synthesized nanotubular TiO_2 photoanodes with stepped voltage anodization and surface modification of TiO_2 photoanodes with He plasma which minimized charge carrier traps and contaminants.
- Surface cleaning and doping of the photoanode with helium plasma treatment followed by nitrogen plasma followed by He plasma treatment, to form $\text{TiO}_{2-x}\text{N}_x$ at the surface thus leaving the bulk semiconductor for high electron conductivity and created oxygen vacancies at the surface for improved photocurrent density.
- Increased photocurrent density by more than 80% by plasma treatments and enhanced light absorption by 55% with modified nanotubular structure by step-voltage anodization compared to the untreated TiO_2 photoanodes.
- Synthesis of tandem heterostructured layered electrodes with lower bandgap layer (e.g. WO_3 , TiSi_2) behind a wide bandgap semiconductor (e.g. TiO_2) facing the electrolyte.
- Development of self-cleaning solar concentrator for operating the PEC devices at irradiance level of 10 sun for enhancing hydrogen generation rate.

Fiscal Year (FY) 2011 Objectives

- Synthesize nanostructured $\text{TiO}_{2-x}\text{N}_x$ photoanodes and tandem heterostructured photoanodes with WO_3 and TiSi_2 to improve absorption of light in the visible spectrum in conjunction with TiO_2 film at the outer surface forming interface between the solid electrode and the liquid electrolyte.
- Improve photocatalytic properties of photoanodes by plasma treatments for (a) removing contaminants and unwanted surface states, (b) doping the photoanode surface with nitrogen to create oxygen vacancies and vacant acceptor states to enhance oxidation of water, and (c) optimizing surface structure of nanotubular electrodes for increasing photocurrent density.
- Design optical system with self-cleaning Fresnel-lens based solar concentrator to operate the photoelectrochemical (PEC) electrode at 10 sun irradiance.
- Optimize surface structure of the layered electrodes for minimizing the charge carrier traps.

Technical Barriers

- Metal oxide semiconductor photoanodes, such as TiO_2 , extensively studied for hydrogen production, cannot provide both the needed light absorption in the visible spectrum and yet provide resistance to photocorrosion.

Introduction

Hydrogen is an ideal renewable chemical fuel yet its production by splitting water using sunlight has been

one of the most formidable challenges for the last several decades [1–6]. While the potential advantages of PEC-based production of hydrogen have not yet been realized recent developments show emergence of new nanostructural designs of photoanodes and choices of materials with significant gains in photoconversion efficiency [7–16]. Significant efforts are being made for reaching the quantum yield of 30% and long-term durability needed for commercial production.

$\text{TiO}_{2-x}\text{N}_x$ meets nearly all the requirements for PEC-based hydrogen production with respect to its abundance, environmental safety, and durability [7], except for its wide bandgap and consequent poor absorption of sunlight in the visible spectrum. Until now, no single compound semiconductor photoanode has been found which satisfy both the critical needs of light absorption and the long-term durability against photocorrosion. For example, tantalum oxide and gallium nitrides have demonstrated better results for hydrogen production but their cost would be more than 50 times the cost of TiO_2 based catalyst [7]. Other nanostructured devices have surpassed the performance of TiO_2 for water splitting, but these materials involve, for example, La-doped NaTaO_3 and oxynitrides, such as $(\text{Ga}_{0.88}\text{Zn}_{0.12})(\text{N}_{0.88}\text{O}_{0.12})$ with co-catalysts, $\text{Rh}_{2-x}\text{Cr}_x\text{O}_3$ showing considerable promise for hydrogen production [15, 16] but the cost of the materials and toxicity involved in some cases are of concern.

Common to most of current investigations, are the studies on: (1) effects of nanostructural surface morphology (nanorods, nanotubes), (2) reduction of interfacial charge carrier traps, (3) increase in the effective surface area for enhancing light absorption at semiconductor-electrolyte interface, and (4) optimum level of sunlight irradiance for operation of the PEC devices at their maximum efficiency. The studies reported here are focused on the interfacial aspects of the PEC-based hydrogen production and optimization of solar irradiance at the photoanode surface.

Approach

To address the problem related to the wide bandgap of TiO_2 , one approach is to develop a hybrid nanostructured photoanode (Figure 1) comprised of thin-film layers of semiconductors with lower bandgap (e.g. WO_3 , TiSi_2) behind a wide bandgap semiconductor (e.g. TiO_2) facing the electrolyte [15]. Similar photoanodes can be synthesized with nanotubular structures with outer layer of titanium dioxide (TiO_2) covering nanotubes of WO_3 , CdS or TiSi_2 . The low bandgap semiconductors have high efficiency in light absorption covering the visible solar spectrum while TiO_2 provides corrosion protection. The layered nanotubular electrodes can be arranged in a patterned array for trapping sunlight more effectively compared to the densely packed nanotubular structures, providing large illuminated area effective for electrolysis. While the nanostructure greatly improves the interfacial surface area and light absorption, the efficiency of the charge carrier transport across the

interfaces and removal of charge carrier traps at the semiconductor-electrolyte interface need to be investigated for different heterostructures including layered films, nanotubes and nanoparticles.

Interfacial charge carrier transfer phenomena govern the PEC-based hydrogen generation process. Studies on the role of surface and interface states in the charge carrier transport and the necessity for matched lattice structure in using heterostructured semiconductors (such as TiO_2 and TiSi_2) have been reported in the literature [7], however, the chemical and physical control mechanisms for mitigating the losses due to the presence of charge carrier traps and for minimizing photocorrosion of the electrodes are yet to be established.

Optimization of the optical system for illuminating photoanode at the desired irradiance level with solar concentrator is needed for obtaining maximum efficiency at a low cost. For collecting sunlight at the maximum level it is necessary to use a solar concentrator with self-cleaning properties to avoid loss of light transmission efficiency due to the deposition of dust. It is expected that large-scale PEC-based hydrogen production facility will take place in semi-arid and desert locations where irradiance level is high but these places are often the dustiest locations.

Experimental Studies and Results

Our experimental studies consisted of: (1) synthesis nanotubular TiO_2 photoanodes by anodization of Ti foil followed by annealing under oxygen atmosphere; (2) surface modification of TiO_2 photoanodes with He plasma for removing organic contaminants and charge carrier traps; (3) surface doping of the photoanode surface with nitrogen plasma to form $\text{TiO}_{2-x}\text{N}_x$ (Figure 2a) and creating oxygen vacancies at the surface thus leaving the bulk semiconductor pristine in its crystalline TiO_2 structure for high electron conductivity for improved photocurrent density [17]; (4) optimization of the structure of the nanotubes by varying anodization voltage for increasing light absorption; (5) development of layered electrodes of WO_3 , TiSi_2 and TiO_2 ; (6) analysis of the photoanode structures (Figure 2b) using X-ray photoelectron spectroscopy (XPS); and (7) evaluation of surface-modified nanostructured photoanodes for PEC generation of hydrogen.

The test photoanodes prepared for evaluating the photoelectrolytic properties were annealed under both oxygen and nitrogen atmospheres achieve crystallization of TiO_2 in its anatase form. The PEC apparatus used for measuring photocurrent density of the test photoanodes under dark and illuminated conditions consisted of: (1) a potentiostat/galvanostat electrochemical instrument Model 283, (2) a Xenon lamp (30 mW/cm^2), (3) a 60 mm-diameter quartz optical window, and (4) a reference electrode (Ag/AgCl) placed close to the photoanode. The electrolyte used was 1M KOH (pH~14) + de-ionized water solution. The experimental arrangements are shown in Figure 1.

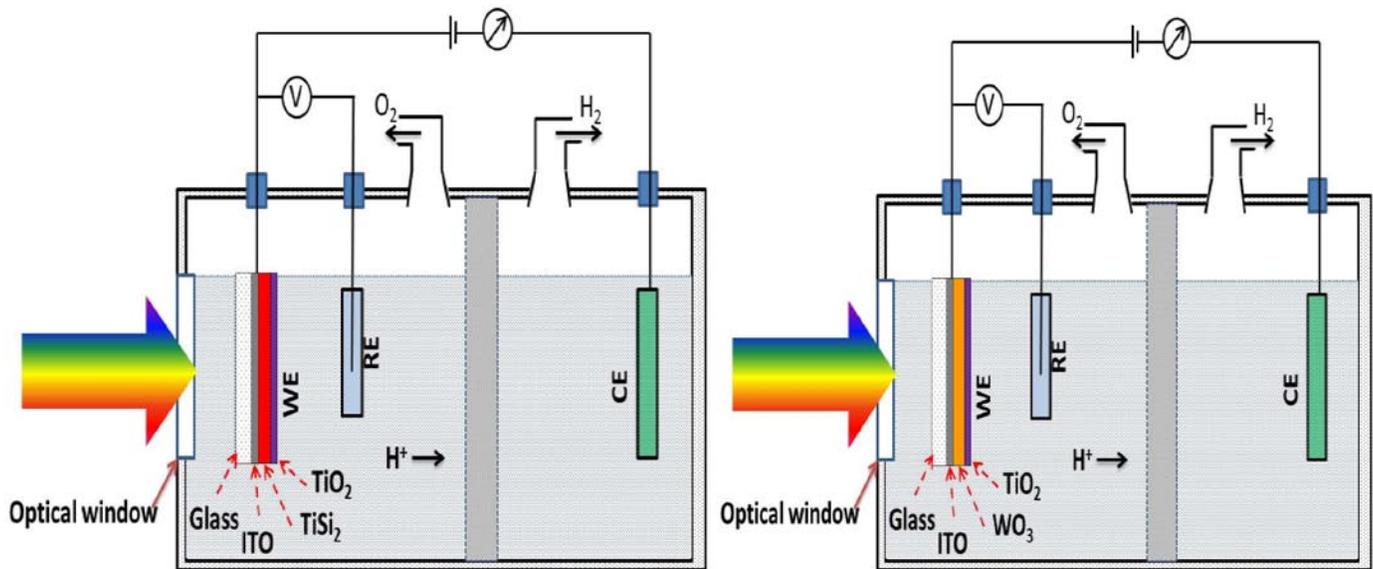

FIGURE 1. Experimental arrangement for PEC generation of hydrogen using different photoanodes (a) hybrid TiSi_2 and TiO_2 electrode (left) and (b) hybrid WO_3 and TiSi_2 electrode (right). A Pt counter electrode was used in both cases. WE, RE, and CE denote working electrode, reference electrode, and counter electrode respectively. The glass plate is coated with indium tin oxide (ITO) to form a transparent conductive substrate for depositing photoanodes.

An electrodynamic screen was developed for operating solar concentrators using Fresnel lens with self-cleaning properties against deposition of dust on the sunlight collector surface [8]. A transparent electrodynamic screen can remove the dust layer in less than two minutes without any need for water or mechanical method for cleaning.

Results

XPS analysis indicated the incorporation of N in titania lattice structure of the photoanode surface. As shown in Figures 2a and 2b, the narrow scan N 1s spectrum is demonstrated at 400 and 396 eV, which has been ascribed

to the presence of nitrogen in the lattice structure either as substitutional dopants for O, or as interstitial dopants in the TiO_2 crystal structure.

Stepped-voltage anodization was used to synthesize titania nanotubes of variable diameters. Photocurrent density vs bias voltage plotted for samples anodized at different voltages. Annealing of the photoanodes was optimized. Most significant improvement came from the nitrogen plasma treatment of titania photoanodes which resulted in 80% increase in photocurrent density. Plasma surface cleaning with helium plasma and surface doping by nitrogen plasma increased photocurrent density of titania nanotubular

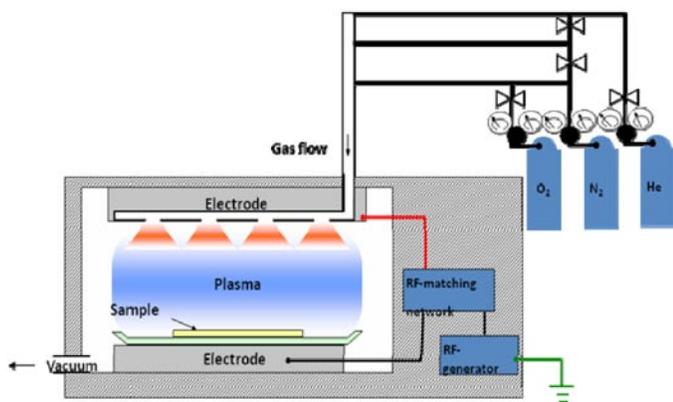

FIGURE 2a. Schematic of low-pressure plasma reactor used for surface modification including He-plasma for surface cleaning and minimizing surface charge carrier traps followed by surface doping of with N-plasma to form $\text{TiO}_{2-x}\text{N}_x$ at the photoanode surface.

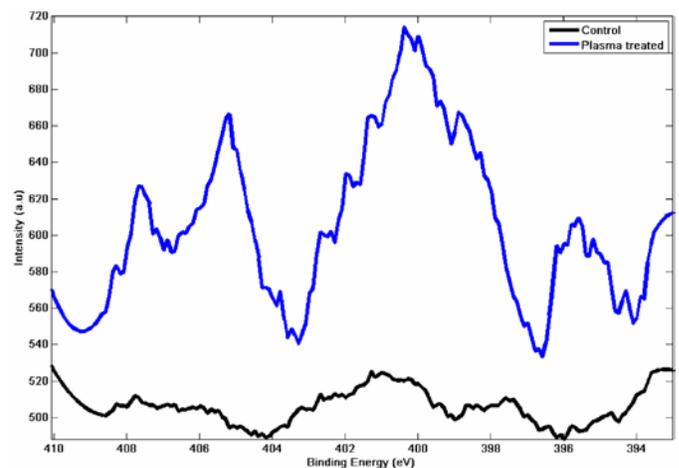

FIGURE 2b. XPS Spectrum (a) Control and (b) Nitrogen-Plasma treated $\text{TiO}_{2-x}\text{N}_x$ Photoanodes

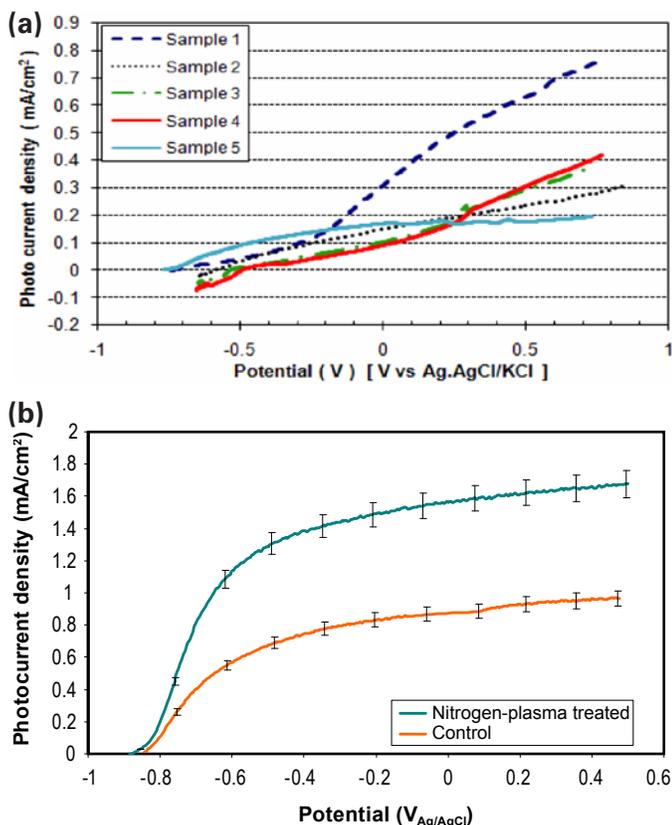

FIGURE 3. Photocurrent density measurements for evaluating photoanodes synthesized under different conditions. The electrolyte used was 1M KOH (pH~14) + de-ionized water solution. A Xe lamp was used to illuminate photoanodes at an irradiance level of 30 mW/cm². (a) Photocurrent density vs. stepped voltage anodization of TiO₂ nanotubular electrodes; sample #1 was anodized at three steps: at 20 V for 40 min, next 40 V for 10 min, and finally 60 V for 10 min, Sample #2 was anodized in one step, 60 V for 60 min, sample #3 was anodized at 40 V for 60 min, and samples 4 and 5 were both anodized in one step at 20 V for 60 minutes. (b) Photocurrent density measurements for control and nitrogen plasma treated titania photoanodes before and after N plasma treatment to form followed by He plasma cleaning. TiO_{2-x}N_x was formed at the surface of TiO₂ nanotubes. Photocurrent density increased from 0.93 mA/cm² to 1.68 mA/cm² at a bias voltage of 0.2 V.

electrodes [17]. The results showed enhanced light absorption and increased photocurrent density by 55% (Figure 3).

Several deposition processes for developing heterojunction TiO₂/TiSi₂ photoanodes have been studied; an e-beam deposition system has been used for depositing thin films of different photoanode materials. An electro spray system has been designed for electrostatic coating of TiSi₂ particles with nanoparticles of TiO₂.

Our experimental data show that deposition of fine atmospheric dust on solar collector with surface mass density of 4 g/m² can obscure sunlight by more than 40%. Design of a self-cleaning solar concentrator has been completed with mirrors and fiber optics for illuminating the photoanode surface at 10-sun level of irradiance is shown in Figures 4a and 4b.

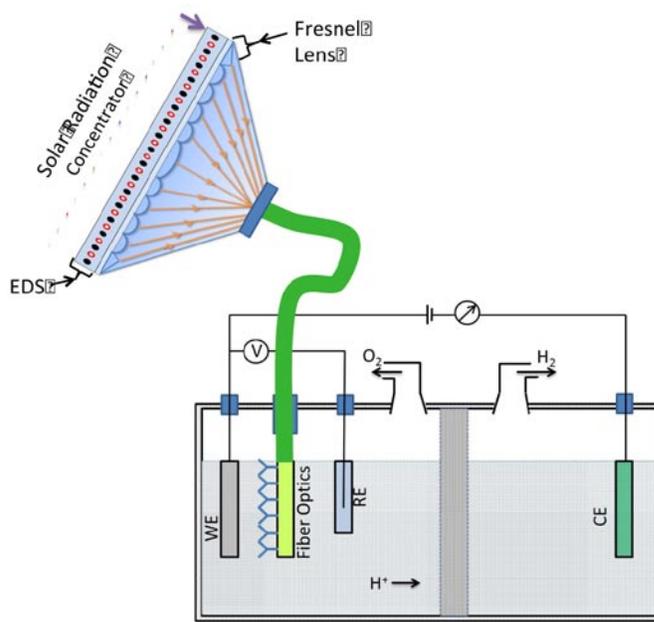

FIGURE 4a. Illumination of photoanode with self-cleaning solar concentrator at an irradiance level of 10 sun. A fiber optics-based light coupling is used to allow illumination of the photoanode at the front surface of the electrode to minimize reflection loss at the outer glass optical window and at the back surface of the inner indium tin oxide-coated glass substrate. An electrodynamic screen is used to remove dust deposited on the front surface of the Fresnel lens.

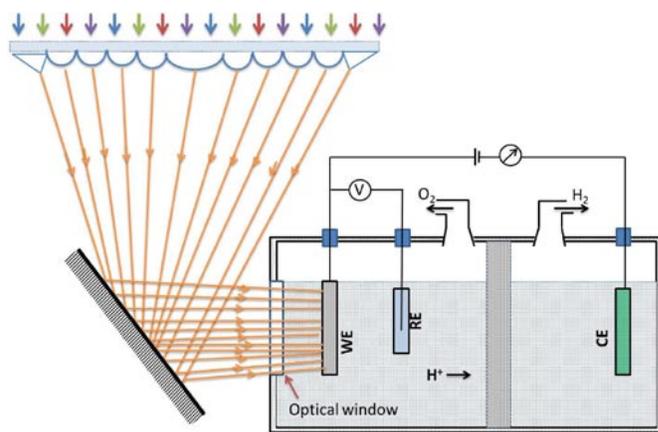

FIGURE 4b. Illumination of photoanode with self-cleaning solar concentrator at an irradiance level of 10 sun. A mirror is used to allow illumination of the photoanode at the back surface. This arrangement suffers from reflection losses at the outer glass window and the back surface of the inner indium tin oxide-coated glass substrate. There is no fiber optic coupling loss in this arrangement.

Conclusions

Our experimental studies with plasma surface treatments with helium and nitrogen gas show a significant

increase of $\text{TiO}_{2-x}\text{N}_x$ photoanode current density compared with the untreated surface of the electrodes. The nitrogen plasma treatment increased acceptor surface states and increased oxygen vacancies. Surface cleaning of the photoanode by low-temperature helium plasma treatment removed a major fraction of the contaminants (adsorbates) from the surface.

The present work reports the importance of systematic investigations of: (1) the morphological structure of the nanotube arrays, (2) the plasma treatment process for surface doping of TiO_2 nanotubular photoanode with N for increasing oxygen vacancies, and (3) optimization of the annealing process for crystallization of TiO_2 for improving photocatalytic generation of hydrogen from water. The test results show promising aspects of tuning several parameters involved in developing heterostructured photoanodes for PEC-based hydrogen production. Development and design of self-cleaning solar concentrator for increasing solar irradiance at the photoanode surface is reported.

Plan for Future Studies

Develop: (1) hybrid nanostructured photoanode comprised of thin-film layers of semiconductors with lower bandgap (e.g. WO_3 , TiSi_2 , CdS) behind a wide bandgap semiconductor (e.g. TiO_2) facing the electrolyte, (2) patterned array of nanotubular electrodes for trapping sunlight more effectively compared to the densely packed nanotubular structures, providing large illuminated surface area effective for electrolysis, and (3) encapsulated nanoparticles of core-shell design using narrow and wide bandgap materials.

We plan to investigate the charge carrier transport process across the interfaces and removal of charge carrier traps at the semiconductor-electrolyte interface by passivation of the dangling bonds for different heterostructures, including layered films, nanotubes and nanoparticles.

Study methods for: (1) optimizing the film thickness (in the nanometer to micrometer range, to improve tunneling and charge carrier transport); (2) matching the crystalline structures of the layered semiconductors; and (3) measuring the photocurrent conversion efficiency (incident photon conversion efficiency vs λ), corrosion resistance, and photo-generated carrier concentration decay rate (by using a radio frequency-conductivity probe); and (4) investigate the use of self-cleaning solar concentrator for operating the PEC at an optimum irradiance level.

Technical Targets

This project is investigating potential application of hybrid metal oxide nanotubes (NTs) for hydrogen generation by water photoelectrolysis. Insights gained from these studies will be applied toward the design and synthesis of high efficiency materials for hydrogen generation from water splitting that meet the following DOE targets:

- Usable semiconductor bandgap: 2.0eV by 2018.
- Chemical conversion process efficiency: 10% by 2013.
- Plant durability: 1,000 hr by 2013.

Approach

In this current project, utilization of hybrid metal (Ti, Fe, Ta) oxide nanotubular arrays for generation of hydrogen from water using sunlight is studied. The metal oxide nanotubular arrays are found to be robust, photo-corrosion resistant, and can be used efficiently to generate hydrogen and most importantly active in the visible light portion of the solar spectrum. It is envisioned that the process can be efficient and economical in the production of solar hydrogen. The nanotubular arrays are prepared by electrochemical anodization of solid metal in different inorganic and organic electrolytes in the presence of fluoride ions. The effect of voltage, time, and solution chemistry on the size, uniformity, and self-assembly of nanotube formation is studied. It is found from preliminary work that materials prepared in organic solvents such as ethylene glycol by an ultrasonic assisted process are very stable and form an efficient pattern of nanotubes that have excellent photo-efficiency. We have already developed processes to synthesize metal oxide nanotubes in inorganic, organic and ionic liquids as electrolytes. This process is also found suitable to prepare mixed metal oxide nanotubes e.g. TiFe , TiMn and TiW . In addition to the preparation of metal oxide based photoanodes, we have also shown that these nanotubes can work efficiently as a cathode by nanoparticle modification. In addition to the anodization process, we have also developed new mixed metal oxide compounds by sol-gel method. This project is integrating a highly efficient photoanode, a cathode, and a modified electrolyte to design a photoelectrochemical (PEC) cell to generate hydrogen with at least 10% efficiency by 2013. The scale up process looks highly promising for large scale hydrogen generation.

The hydrogen generation work is conducted using a hybrid metal oxide nanotubular or mixed metal oxide photoanode in alkaline solutions in the presence of simulated solar light. The material stability and

Fiscal Year (FY) 2011 Objectives

- Develop high efficiency metal oxide nanotubular array photo-anodes for generating hydrogen by water splitting.
- Develop density functional theory to understand the effect of morphology of the nanotubes on the photo-electrochemical properties of the photo-anodes.
- Develop kinetics and formation mechanism of the metal oxide nanotubes under different synthesis conditions.
- Develop combinatorial approach to prepare hybrid photo-anodes having multiple hetero-atoms incorporated in a single photo anode.
- Improve the durability of the material.
- Scale-up the laboratory demonstration to production unit.

Technical Barriers

This project addresses the following technical barriers from the Production section (3.1.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (Y) Materials Efficiency
- (Z) Materials Durability

photo-efficiency is determined as a function of time, electrochemical and analytical measurements. The photo-efficiency is determined by measuring current as well as volume of the hydrogen generated by gas chromatograph. The material stability and photo-efficiency is determined as a function of time, electrochemical and analytical measurements.

In the future our main focus for the research will be to understand:

- Synthesize photoanodes that can harvest the full spectrum of sunlight.
- Theoretical investigation on the materials synthesized.
- On-field testing under real solar irradiation.

On the basis of fundamental and applied research, a scale up experiment in the laboratory will be performed to elucidate the viability of the new catalysts for photo-electrochemical generation of hydrogen using sunlight.

FY 2011 Accomplishments

- The UNR team has developed a composite photocatalyst comprising of self-assembled titania (TiO_2) NTs coupled with titanium disilicide (TiSi_2) nanoparticles (NPs) for PEC hydrogen generation (Figure 1).
- A new approach is taken to synthesize TiO_2 NTs with bigger pore size and length so that more TiSi_2 particles can be loaded. Anodization of Ti to form TiO_2 NTs in the presence of a chelating agent disodium ethylenediamine tetraacetate ($\text{Na}_2[\text{H}_2\text{EDTA}]$) under

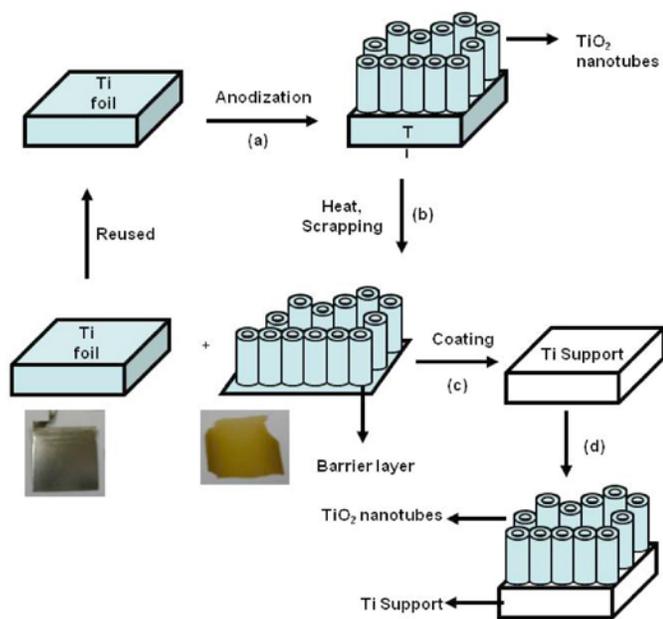

FIGURE 1. Schematic Showing the Formation of $\text{TiSi}_2/\text{TiO}_2$ NT Composite Structure

high voltage (80 V_{DC}) makes the diameter of the NTs bigger than the conventional process (Figure 2). The back side of the TiO_2 NTs is etched with 5% hydrofluorhydric acid to form a TiO_2 nanotubular membrane.

- TiSi_2 NPs are produced from commercial bulk particles by a multiple ball milling followed by ultrasonication process (Figure 3). The TiSi_2 nanoparticles are sintered into the TiO_2 nanotube array to prepare the $\text{TiSi}_2/\text{TiO}_2$ NTs. This catalyst is then annealed under a nitrogen atmosphere to form a composite of TiSi_2 nanorods inside TiO_2 NTs at 500°C for 6 h. The prepared TiSi_2 - TiO_2 material is then coated on Ti foil using a titanium tetrachloride solution followed by annealing at 500°C for 3 h under nitrogen. This also helped in sintering the TiSi_2 nanoparticles inside the TiO_2 nanotubes to form a nanorod array. The TiO_2 nanotubular array is found to be stable after the synthesis of TiSi_2 nanorods inside them (Figure 4). The TiSi_2 nanostructure is found to be homogeneously distributed throughout the TiO_2

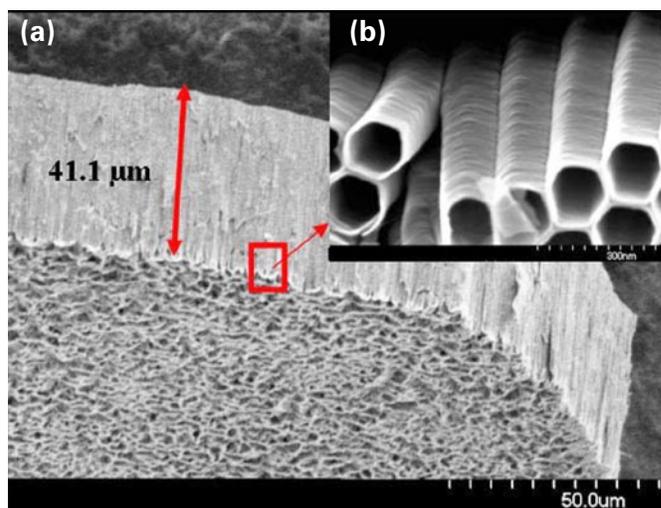

FIGURE 2. Field emission scanning electron microscope images of TiO_2 NTs prepared in organic medium at 80 V_{DC} for 30 min. (a) top view and (b) cross sectional view (close-up) view of the NTs.

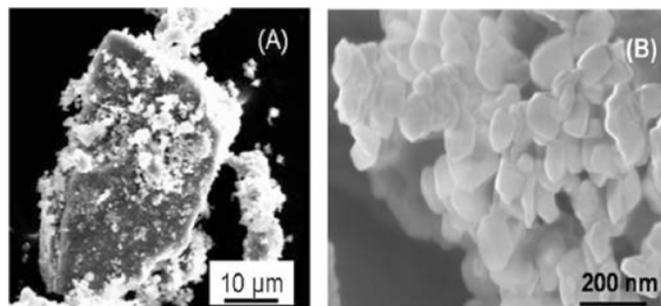

FIGURE 3. Field emission scanning electron microscope images of (A) as-received TiSi_2 particles ($<44 \mu\text{m}$), (B) ball-milled TiSi_2 particles ($\sim 50\text{-}60 \text{ nm}$).

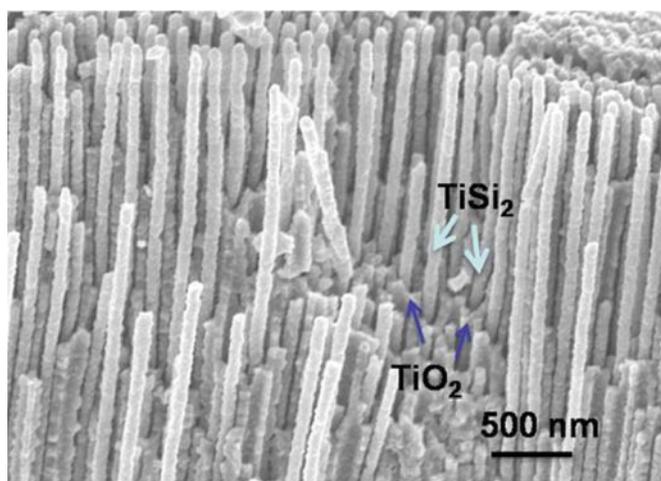

FIGURE 4. Field emission scanning electron microscope images of TiSi_2 particles sintered into the TiO_2 NT array.

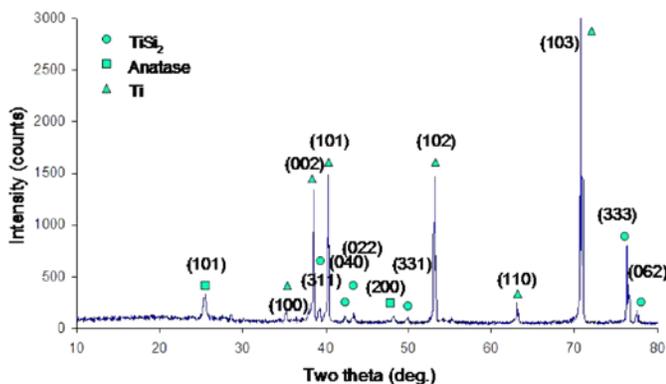

FIGURE 5. Glancing angle X-ray diffraction pattern of TiSi_2 NP/ TiO_2 NT. Orthorhombic TiSi_2 and anatase TiO_2 are observed in the heterostructure. A peak for the Ti base is also noticed.

nanotubular array. Energy dispersive spectroscopy analysis showed ~ 25 wt% TiSi_2 in the $\text{TiSi}_2/\text{TiO}_2$ NTs photocatalyst. Glancing angle X-ray diffraction pattern shows peaks corresponding to both TiSi_2 and TiO_2 (anatase) (Figure 5).

- The diffuse reflectance ultraviolet and visible spectrum of $\text{TiSi}_2/\text{TiO}_2$ NTs catalyst shows a sharp edge ~ 550 nm (band gap, $E_g = 2.25$ eV). The strong absorption peaks in both the ultraviolet and visible regions suggest that the $\text{TiSi}_2/\text{TiO}_2$ NT photocatalyst is prepared by combining the absorption properties of the TiO_2 NTs in the ultraviolet region and TiSi_2 in the visible region (Figure 6).
- The heterostructural composite photoanode exhibited an enhanced photocurrent density of 3.49 mA/cm^2 at 0.2 $\text{V}_{\text{Ag}/\text{AgCl}}$ compared to TiO_2 nanotubes alone (0.9 mA/cm^2) and can be considered as a potential possible candidate for water splitting reaction using visible light (Figure 7).

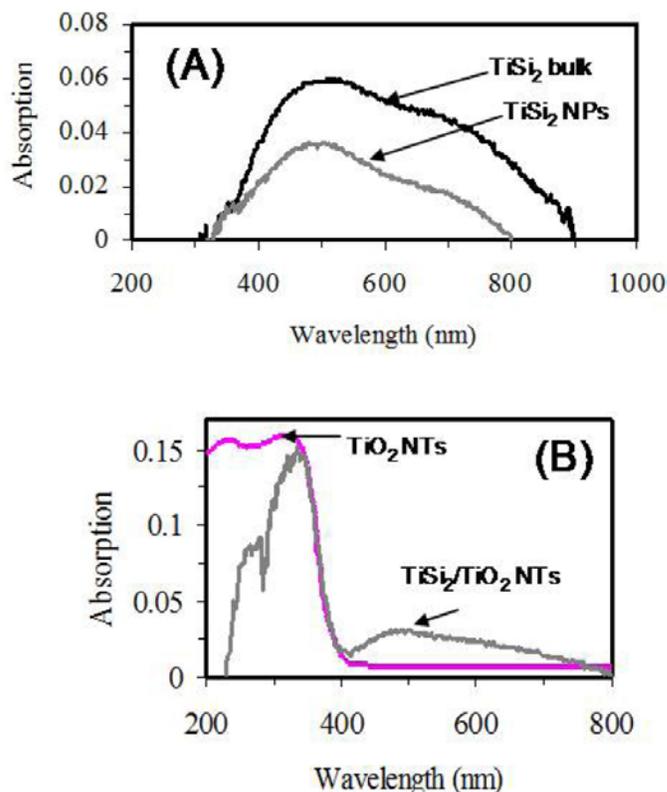

FIGURE 6. Diffuse reflectance ultraviolet and visible spectra of (A) TiSi_2 bulk and nanoparticles and (B) TiO_2 NTs and $\text{TiSi}_2/\text{TiO}_2$ NTs catalyst. TiSi_2 particles showed absorption in the visible light region and $\text{TiSi}_2/\text{TiO}_2$ NTs absorb light in both ultraviolet and visible region. Band gap = 2.25 eV.

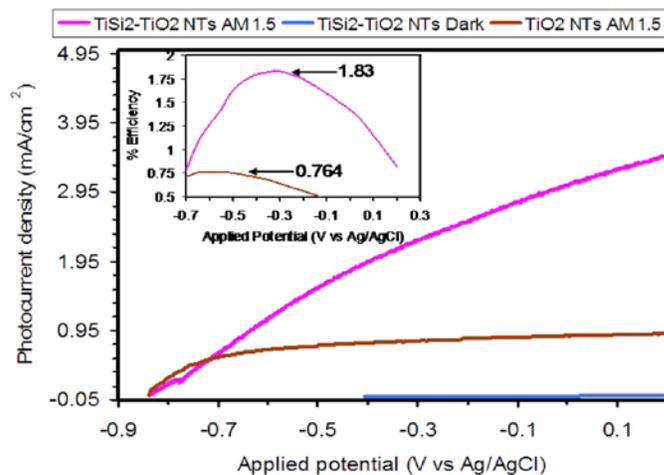

FIGURE 7. Potentiodynamic plot of annealed $\text{TiSi}_2/\text{TiO}_2$ NTs and TiO_2 NTs. Inset shows the solar-to-hydrogen conversion efficiency of $\text{TiSi}_2/\text{TiO}_2$ NTs and TiO_2 NTs under AM 1.5 illumination.

Conclusions and Future Actions

In the last year, we have developed a new type of coupled semiconductor photo-catalyst by coupling TiSi_2

nanoparticles and TiO₂ NTs by simple sintering method. A unique architecture, TiSi₂ nanorods inside TiSi₂ nanotubes, is prepared by this process. It showed four-fold enhancement in the amount of hydrogen generated compared to only TiO₂ NTs and ten times compared to P25 TiO₂ nanoparticles. The following bulleted list is indicative of the areas we will pursue in the coming year of the project:

- Synthesize visible light sensitive photoanodes.
- Kinetics studies of nanotube formation by titration using spectrophotometric analysis.
- Theoretical investigation of BiFeO₃ by density functional theory.
- To understand the ordering of oxygen vacancies and their role on charge transport properties and recombination losses in oxide and oxynitride semiconductors.
- Scale up the system.
- Design PEC system for on-field testing under real solar irradiation.
- Synthesize quantum dots incorporated inside TiO₂ NTs for PEC.

*Congressionally directed project

Fiscal Year (FY) 2011 Objectives

- Synthesize dye-sensitized TiO₂ nanorods with catalyst particles attached to the tips.
- Use Langmuir-Blodgett methods to incorporate nanorods as membrane-spanning units in lipid bilayers.
- Develop and test a prototype capillary reactor for photocatalysis of water-splitting.
- Synthesize high-surface area carbon nanofelt.
- Develop and test a prototype hydrogen fuel cell with carbon nanofelt incorporated as catalyst support material.

Technical Barriers

This project addresses the following technical barriers from the Photoelectrochemical Hydrogen Production and Fuel Cells sections of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

3.1.4 Photoelectrochemical Hydrogen Production

- (Y) Materials Efficiency
- (Z) Materials Durability

- (AA) PEC Device and System Auxiliary Material
- (AB) Bulk Materials Synthesis
- (AC) Device Configuration Designs
- (AD) Systems Design and Evaluation

3.4 Fuel Cells

- (A) Durability
- (B) Cost
- (C) Performance

Technical Targets

TABLE 1. Technical Targets: Photoelectrochemical Hydrogen Production (from Table 3.1.10)

Characteristics	Units	2006 status	2013 target
Usable semiconductor bandgap	eV	2.8	2.3
Chemical conversion process efficiency	%	4	10
Plant solar-to-hydrogen efficiency	%	Not available	8
Plant durability	hr	Not available	1,000

Our strategy is to utilize TiO₂ as semiconductor (bandgap ~3.0 eV) that is dye-sensitized with visible light chromophore such as N719 dye (~1.7 eV). Ideally, the chromophore would be a broad-spectrum absorber to allow utilization of near infra-red (NIR) and visible light. Our project does not focus specifically on dye improvement, only utilization of established sensitization protocols. Dye-sensitization has the advantage that band-edge potentials can match requirements for component half-reactions of water-splitting while utilizing the solar spectrum (visible/NIR photons).

FY 2011 Accomplishments

- Synthesis of anisotropic TiO₂ anatase nanocrystal with growth in <100>, <101>, or <001> direction with organo-carboxylate or organo-amine surface agent.

- Synthesis of mesoporous silica doped with Ti or W ions and demonstration of photocatalytic proton reduction in aqueous solution with methanol. Hydrogen turnover frequency was $0.0002 \text{ H}_2 \cdot \text{tungsten site}^{-1} \cdot \text{s}^{-1}$ ($220 < \lambda < 380 \text{ nm}$ transmitted).
- Synthesis of TiO_2 nanotube array double-layer. Pt nanoparticles were deposited on the TiO_2 surface. Demonstration of photocatalytic proton reduction in aqueous solution with methanol or iodide. Hydrogen evolution was $0.37 \text{ mL} \cdot \text{s}^{-1} \cdot \text{m}^{-2}$ ($220 < \lambda < 400 \text{ nm}$ transmitted).
- Electrospinning of polymer nanofibers, ceramic nanofibers, and thermal treatment to yield graphitic carbon nanofibers.
- Acquisition of Langmuir-Blodgett trough, total organic carbon analyzer, graphitization furnace, gas chromatograph, and fuel cell test station as part of South Dakota research infrastructure improvement effort.

Introduction

There is demand for abundant energy without consequences of pollution that can be met with solar energy utilization. While there are many ways to use sunlight, we focus on the use of materials that allow fast conversion of light to hydrogen and fast conversion of hydrogen to electricity. These two processes can be accomplished with two types of devices, a photoelectrochemical cell and hydrogen fuel cell, respectively. Both processes are complex, and research into their optimization is a priority. Our research into photoelectrochemical cells is an effort to develop new materials that can produce hydrogen from sunlight and water at high efficiency and low cost; our research into hydrogen fuel cells will mostly focus on development of new materials to make a longer-lasting and lower cost device.

Approach

Photoelectrochemical cells include catalysts that rapidly capture sunlight and convert the energy to a chemical fuel and chemical oxidizer. This can be done by ‘splitting’ water to hydrogen and oxygen. More specifically, water undergoes autodissociation to give protons and hydroxide anions. If electrons are added to protons, then hydrogen is synthesized; while taking away electrons from hydroxide anions yields oxygen. The catalyst speeds up these two chemical processes. The catalyst must also be able to absorb sunlight. Upon doing so, the light energy causes the excitation of an electron. The electron is more reactive after excitation, and it leaves an electron ‘hole’. The catalyst must be able to use the excited electron to synthesize hydrogen and to use the electron hole to synthesize oxygen. So far, no single material has been discovered that can accomplish all three tasks: light absorption, hydrogen synthesis, and oxygen

synthesis. Combination of several materials, however, working together can enable the photoelectrochemical cell. This is somewhat similar to photosynthesis, wherein plants convert sunlight to fuel (sugars) and oxidizer (oxygen), in that several molecular pieces work together. For this reason, photocatalysis within a photoelectrochemical cell is sometimes referred to as artificial photosynthesis. The materials that we plan to use include nanocrystals of TiO_2 , Pt, and RuO_2 , dye molecules, and lipids. The materials will be organized in chemical reactions and self-assembly steps to produce a reactive free-standing membrane capable of solar photocatalysis in which water is converted to hydrogen and oxygen.

Hydrogen fuel cells catalyze the reverse reaction of photoelectrochemical cells that split water. Instead of giving back a photon; however, the fuel cell produces electricity. Thus hydrogen (fuel) and oxygen (oxidizer) combine in a membrane-electrode assembly to produce water and electric current. The membrane-electrode assembly includes cathode, anode, and proton exchange membrane. At the anode, hydrogen gives up electrons to form protons. At the cathode, electrons and protons that formed at the anode combine with oxygen to form water. The protons reach the cathode through the proton exchange membrane. The electrons reach the cathode through an external circuit. The reaction at the cathode is the driving force for the fuel cell, and force the flow of electrons through the external circuit thereby producing electric current. The hydrogen fuel cell has many material components, and these are susceptible to degradation that limits the utility, lifetime, and value of the fuel cell. Our work is focused making new materials for the electrodes that extend the lifetime. We plan to use carbon nanofelts composed of carbon nanofibers. The carbon nanofibers can be produced upon thermal graphitization of polymer or ceramic (metal carbide) electrospun nanofibers.

Results

TiO_2 nanorods were synthesized via solvothermal synthesis. The nanorods were characterized with electron microscopy, powder X-ray diffraction (XRD), ultraviolet (UV)-visible and luminescence spectroscopy (Figure 1). Powder X-ray diffraction data indicated presence of anatase crystallites with broadened peaks. The 004 reflection had less line broadening than other reflections in the powder pattern, which is evidence of the anisotropic nature of the crystal. The electron microscopy data show the presence of high aspect ratio nanorods. High resolution micrographs show presence of lattice fringes that indicate the highly crystalline nature of the nanorod. The TiO_2 nanorods disperse in non-polar solvents such as hexane. The dispersion, in hexane, was used for spectroscopic analysis. The nanorods absorb strongly in the UV spectrum, with the unusual feature that the absorbance is blue-shifted by 100 nm compared to bulk anatase. This effect is due to quantum confinement in the crystal in which the Bohr exciton radius is less than the diameter of the nanorod

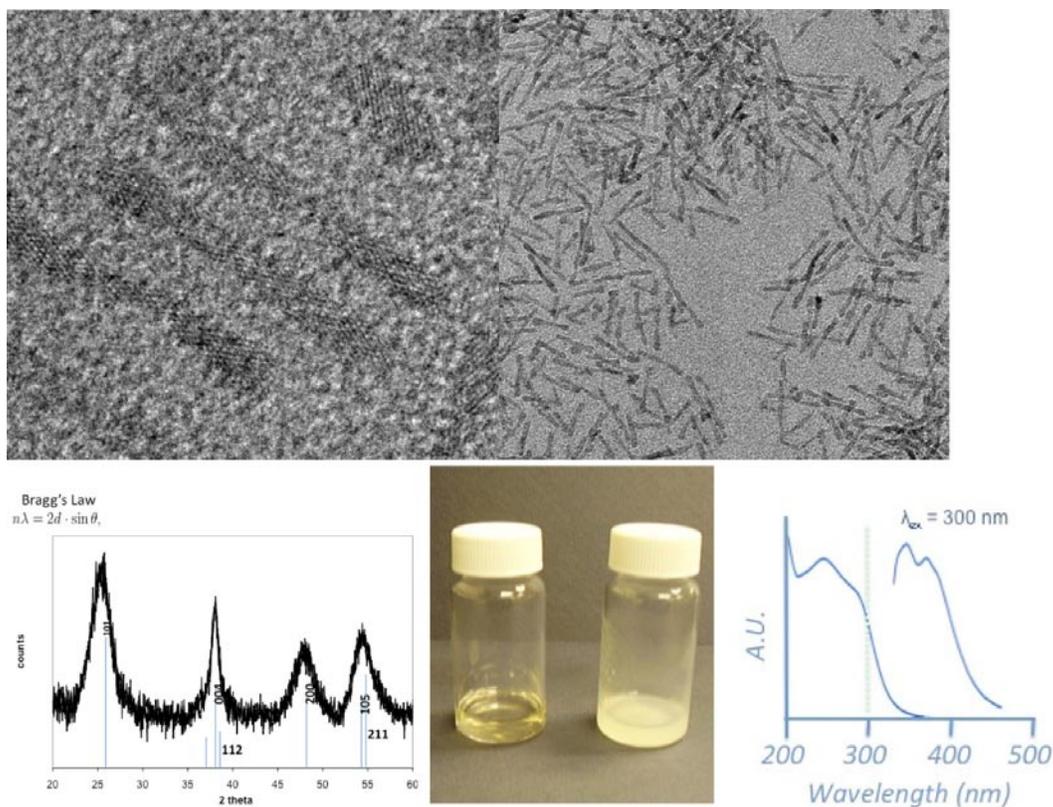

FIGURE 1. Characterization data of TiO_2 nanorods: (top) transmission electron micrographs, (bottom, from left to right) powder XRD, NR dispersion before and after exposure to visible light for 24 hrs, UV-visible and luminescence spectra.

(the effect was independent of nanorod length in the four fractions). The emission spectrum was recorded upon excitation at 300 nm. The TiO_2 nanorod dispersion is light sensitive. Over the course of several hours under visible light exposure, a white precipitate formed; whereas, dispersions protected from visible light exposure were stable for months. More recently, the growth of the anisotropic nanocrystal could be controlled to limit growth in $\langle 100 \rangle$, $\langle 101 \rangle$, or $\langle 001 \rangle$ directions dependent on conditions during synthesis.

We have attempted surface modification of the TiO_2 nanorods (NRs). One approach is selective nucleation of metal nanoparticles on the NR tips. The NRs were dispersed in high boiling solvent into which a metal precursor ($\text{Pt}(\text{acac})_2$ or $\text{Co}_2(\text{CO})_8$) was injected. The reactions led to formation of metal nanocrystals in solution; however, the nucleation did not occur on the NR tips (Figure 2). Another approach has been ligand exchange on the nanorods. TiO_2 NR were exposed to a solid support with dopamine chains. The NRs were attached to the surface of the support concomitant to displacement of linoleic acid. This may be due to two factors: 1) the chelating nature of the catecholate group may bind the TiO_2 surface more tightly, and 2) entropically, the reaction is favored due to the preorganization of ligands on the solid support. The solid support was washed to remove unbound TiO_2

NRs. The dopamine terminus of the solid support can be readily cleaved with trifluoroacetic acid, thereby liberating dopamine stabilized TiO_2 NRs. This was confirmed with transmission electron microscopy and nuclear magnetic resonance.

Synthesis of ordered mesoporous TiO_2 thin-film was performed using evaporation induced self assembly (EISA) and supercritical CO_2 assisted infusion methods. In EISA, a dilute solution containing Ti-butoxide, Pluronic123, HCl (38% in water), and butanol was spin coated on a glass substrate. The coated substrates were aged for 24 hr in a controlled humidity environment at 25°C. Films after aging were calcined at 350°C for 2 hr to remove the surfactant. In supercritical CO_2 infusion method, a glass substrate pre-coated with the Pluronic F108 surfactant film was loaded inside a PARR reactor, and it was heated to 60°C and pressurized to 3,000 psi with CO_2 . At these processing conditions, a known amount of Ti-butoxide followed by water was injected into the reactor. As a result, solubilized portion of Ti-precursor in supercritical CO_2 was infused and hydrolyzed inside the solid surfactant film coated on a substrate. After 1 hr, the reactor was depressurized and cooled down to room temperature and the substrates were removed and calcined at 350°C. The films synthesized by both methods were characterized by scanning electron microscopy (SEM), atomic force microscopy (AFM), X-ray

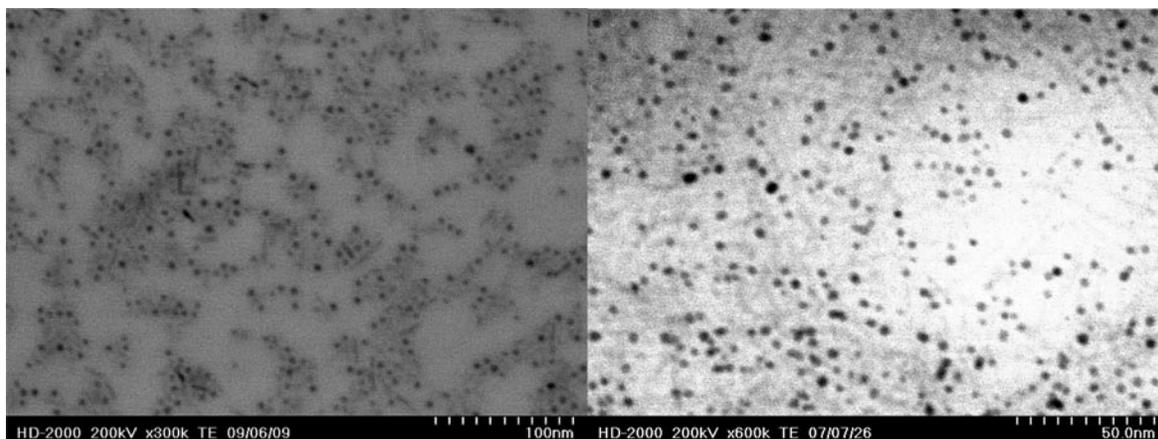

FIGURE 2. Nucleation of metals in the presence of TiO_2 NRs so far led to mixtures of metal nanocrystals and TiO_2 NRs with no evidence of metal-semiconductor interface: (left) Co nanoparticles and TiO_2 NRs (right) Pt nanoparticles and TiO_2 NRs.

diffraction, surface area, and ellipsometry. SEM images of TiO_2 film prepared by EISA reveal ordered mesoporous structure with three-dimensional cubic and two-dimensional hexagonal pore ordering with the d-spacing of 18.50 nm and 18 nm, respectively as determined by fast Fourier transform analysis. AFM images indicate highly ordered structure of the mesopores and partial pore ordering in the TiO_2 thin-films synthesized using supercritical CO_2 -assisted infusion. The smaller size pores as evident in SEM and AFM images may provide mass transfer limitation for charge transport. Consequently, experiments were performed to increase pore size using pore swelling agent; for instance, 1,3,5 trimethyl benzene. Crack-free ordered mesoporous TiO_2 thin films with different thickness were prepared using EISA method. The film thickness ranges from 400 nm to 3,100 nm depending on number of layers coated and the average refractive index for these films was 1.5 as determined by ellipsometry.

We successfully demonstrated that Ti-MCM-48 mesoporous materials can be used for the photosplitting of water to generate hydrogen. Furthermore, the coordination state of Ti in the MCM-48 materials could be easily controlled by changing the order of addition of the Ti precursor. Ti-MCM-48 catalysts were tested for photocatalytic hydrogen. We extended this preparative method for the synthesis and characterization of WO_3 dispersed on MCM-48 materials and found that the photocatalytic evolution of hydrogen is dependent on the loading of WO_3 . The long-range ordered mesoporous structure of MCM-48 was well preserved after tungsten incorporation. Tungsten oxide species were highly dispersed in MCM-48 matrix and no bulk crystalline WO_3 was formed. The as-prepared W-MCM-48 materials show notable photocatalytic activity for hydrogen evolution from methanol-water mixture under UV irradiation though commercial bulk WO_3 is not active for the reaction. The photocatalytic mechanism was studied by electron spin resonance spectroscopy. The tungsten oxide species that are

highly dispersed in MCM-48 matrix possess a suitable band gap and sufficient reduction potential for the photocatalytic reduction of H_2O to generate H_2 .

Efforts were made on the fabrication of double-sided TiO_2 nanotube membrane using electrochemical anodization method. Double sided TiO_2 nanotubes were grown using Ti foil (25 μm thick, 99.7% purity) purchased from Alfa Aesar. Ti sheet was degreased by sonicating sequentially in acetone, ethanol, and de-ionized water, followed by drying in a nitrogen stream. Electrochemical anodization of titanium was carried out at ambient conditions using a two-electrode system and a direct current power supply (Agilent Technologies, 0-60 V). Degree of anodization of Ti metal was controlled by limiting anodization voltage and H_2O content in the electrolyte. For anodization an organic electrolyte containing 0.3 wt% NH_4F and 2 vol% water in ethylene glycol was used. A platinum gauge electrode was used as a cathode in all the experiments. After anodization, the sample was washed in water to remove the impurities. The double sided TiO_2 nanotubes membrane was sensitized with 0.1 M dilute aqueous salt solution of hexachloroplatanic acid and sonicated for 5 minutes and finally annealed in argon environment containing 10 vol% H_2 at 400°C for 1 hr. The SEM image of annealed Pt/ TiO_2 nanotubes is shown in Figure 3A whereas SEM image for the cross section of double sided TiO_2 nanotube membrane is depicted in Figure 3B. These images revealed tube length of about 17 μm on both side of etched Ti metal foil.

Hydrogen generation by photocatalysis using double-sided TiO_2 nanotubes membrane sensitized with Pt was investigated. This membrane was placed in a quartz cell containing aqueous solution with methanol or iodide, degassed with Ar, and irradiated with a 500 W high pressure Xe lamp equipped with AM 1.5G and IR filter (220 nm < λ < 400 nm). Gas samples from the head space of the quartz cell were withdrawn periodically using a gas syringe and analyzed using a gas chromatograph equipped

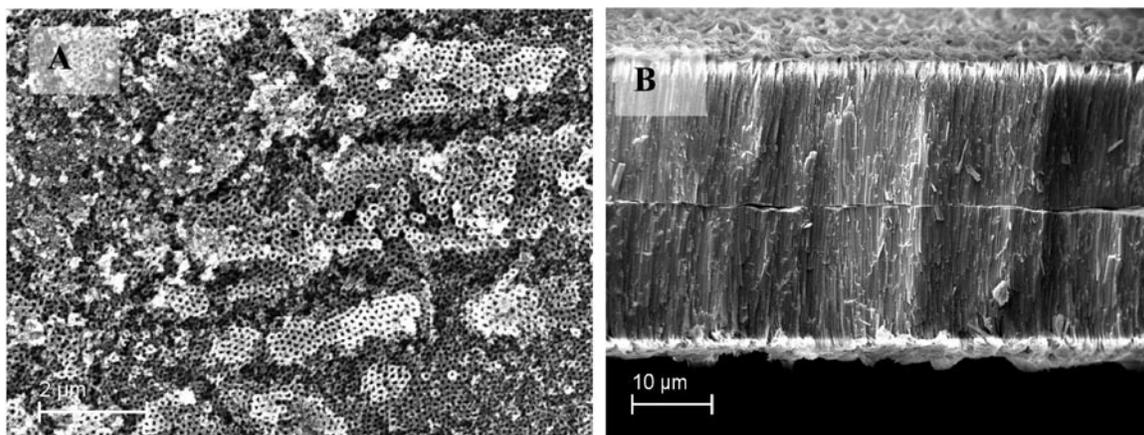

FIGURE 3. SEM images of A) TiO_2 nanotubes sensitized with Pt and B) cross section of double-sided TiO_2 nanotube membrane.

with a thermal conductivity detector. Hydrogen evolution rate was $0.37 \text{ mL} \cdot \text{s}^{-1} \cdot \text{m}^{-2}$.

Nonwoven fabrics made of electrospun polyacrylonitrile (PAN) polyvinyl alcohol, and titania carbide (TiC)-based carbon nanofibers, dubbed as Electrospun Carbon Nanofelt, with extremely high specific surface areas (up to $2,200 \text{ m}^2/\text{g}$) and other desired morphological and structural properties (e.g. high graphitic crystallinity), were synthesized. Conditions during electrospinning affect morphology of the polymer fibers such as diameter and porosity. Thermal treatment leads to carbon nanofibers (graphitization occurs at higher temperatures with retention of morphology). For example, electrospun PAN was graphitized thermally to yield carbon nanofibers (Figure 4). Owing to the unique morphology and structures, the electrospun carbon nanofelt is expected to out-perform carbon black as the catalyst support.

Conclusions and Future Directions

The work on photocatalyst materials for solar hydrogen involves use of high surface area TiO_2 to which functional

materials on the surface enable photocatalytic water splitting. So far, several forms of high surface area TiO_2 were obtained: ordered mesoporous thin film, nanorod, nanotube arrays, or single site Ti (or W) on SiO_2 -MCM-41. While doped MCM-41 was shown to catalyze proton reduction in aqueous solution, the materials still require catalyst sites and visible-light chromophore. Platinized TiO_2 nanotube arrays did show H_2 evolution under UV irradiation. So far, attempts toward selective nucleation of metals (Co or Pt) on the tips of TiO_2 NRs have proven unsuccessful despite reports in the literature. Thus one key challenge is the controlled organization of functional surface features on the TiO_2 . Future work will include:

- Ligand exchange on the surface of TiO_2 nanostructures.
- Selective nucleation of metal (Co, Pt, Ru) on TiO_2 NR tips with new surface ligands.
- Sensitization of TiO_2 nanostructures with visible light chromophores.
- Photocatalyst evaluation (under simulated solar radiation) with attention to quantify turnover frequency.

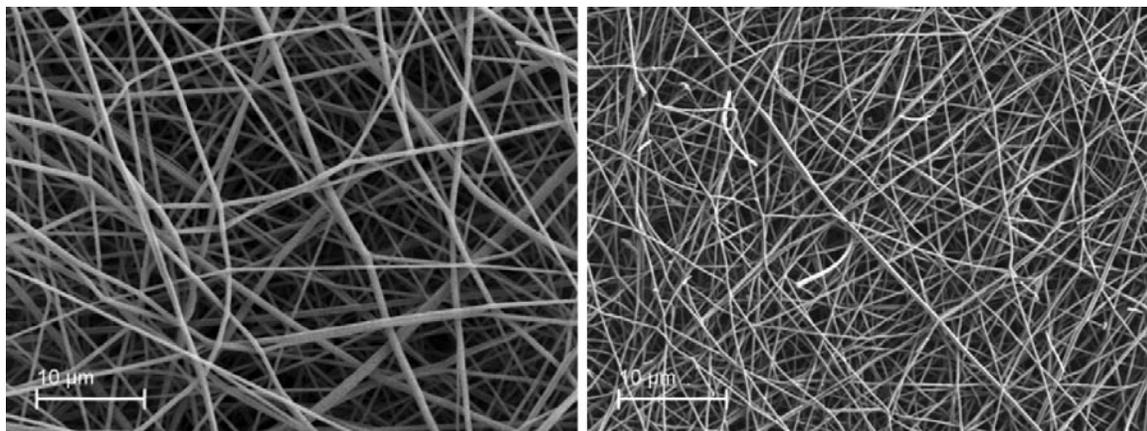

FIGURE 4. PAN-based electrospun nanofibers (left) and PAN-based carbon nanofibers (right).

The work toward carbon nanofelt for catalyst support in hydrogen fuel cell has been quite fruitful. Electrospinning of polymers is a viable technique to large-scale synthesis of nanofibers with tunable morphological properties. The polymer fibers could be graphitized to make carbon nanofibers with retention of morphology. Also, electrospun ceramic nanofibers could be produced, including TiC. Chemical oxidation of TiC led to extraction of the metal and formation of graphitic carbon nanofibers. The carbon nanofibers could show improved performance in working fuel cell environment. Future work will include:

- Construct a fuel cell that utilizes carbon nanofelt as electrode material (catalyst support).
- Test the prototype fuel cell.

- 8% plant-to-hydrogen solar efficiency
- Projected durability of 1,000 hours

FY 2011 Accomplishments

- Calculated the band structure and bandgap for cesium niobate.
- Developed a sol-gel synthesis route to fabricate cesium niobate.
- Commenced computer doping study.

Introduction

This work seeks to develop new solid-state photocatalysts for the decomposition of water into hydrogen and oxygen gas. The catalyst should have band edges appropriate for the oxidation and reduction reactions that occur during the decomposition process. Appropriate band edges would result in a bandgap of about 2.3 eV, in accordance with DOE technical targets. This bandgap would place the catalyst's absorption edge into the visible portion of the spectrum and render the catalyst more efficient than current catalyst at utilizing the available solar spectrum. Cesium niobate is a newly discovered photocatalyst but has band edges that are not optimized for the oxidation and reduction reactions that occur during water decomposition. We are seeking to optimize the band edges by examining various solid solutions through computer modeling.

Approach

We are examining cesium niobate and solid solutions thereof through computer simulations to determine the composition with an electronic structure most conducive for the photocatalytic decomposition of water into hydrogen and oxygen gas. We conduct our calculations through the density functional theory (DFT) method, which is a commonly adopted approach utilized by the condensed matter community. The method treats many-particle systems, such as ionic solids, by approximating their wave functions from spatially dependent electron density. The method is effective in deducing electronic, optical, and mechanical properties of materials and facilitates explanation to and comparison with experimental results. In this project, we combine DFT with different boundary conditions and generate very large unit-cell structures, which is both laborious and time-consuming but essential for accurate prediction of materials properties.

We examine compositions with cesium niobate as the base but with judicious substitutions of other metals and

Fiscal Year (FY) 2011 Objectives

- Develop improved solid-state photocatalysts.
- Model candidate metal oxides through computer simulations.
- Synthesize and characterize materials identified by models.

Technical Barriers

This project addresses the following technical barriers from the Photoelectrochemical Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (Y) Materials Efficiency
- (Z) Materials Durability

Technical Targets

Development of Semiconductor Materials for Photoelectrochemical Production of Hydrogen: This project is conducting theoretical studies of cesium niobate ($\text{Cs}_2\text{Nb}_4\text{O}_{11}$) and its solid solution modifications to discover new, more efficient oxide catalysts for photoelectrochemical production of hydrogen from water. Compositions identified by computer modeling will then be fabricated and characterized. The materials should meet the following DOE targets:

- 2.3-eV useable bandgap

nonmetals in order to adjust the electronic band edges to the desired values. Compositions with the desired properties are then synthesized in the laboratory and characterized for structure, optical absorption, and catalytic activity.

Results

We have completed the band structure calculations of both the high and low-temperature phases of cesium niobate (CNO). Figure 1 shows the results for the low-temperature phase, which is the one that occurs at room temperature; the phase transition occurs at 165°C. The calculated bandgap is about 3.1 eV. Understanding of the band structure allows us to calculate the optical absorption of CNO so as to monitor and modify the band edges as we engineer the CNO material to facilitate photocatalytic decomposition of water into its constituent gases.

The optical absorption spectra of CNO with polarized and unpolarized light are shown in Figures 2 and 3, respectively. In the range of 0-10 eV, two absorption peaks dominate all spectra: one around 4.8 eV and a second, higher one around 6.0 eV. The absorption intensity order is $[100] > [001] > [010]$ for polarized light and $[010] > [001] > [100]$ for unpolarized light, that is, in the opposite order. This is because, for unpolarized light, the spectrum of one incident direction (i.e., $[100]$) equals the spectrum average of polarized light in the vertical plane (i.e., $[100]$).

We have developed a sol-gel synthesis route to fabricate CNO at relatively short reaction times. In this procedure,

niobium(V) chloride, cesium carbonate, anhydrous citric acid, and deionized water are used as starting materials. At room temperature, the niobium chloride is dissolved in methanol with constant stirring to get a clear, colorless solution. Citric acid is then added to the solution. Separately, stoichiometric cesium carbonate and additional citric acid are dissolved in deionized water and added to the niobium chloride methanolic solution. The final solution is heated with constant stirring at 80-110°C to evaporate the methanol and water and produce a clear gel. The gel is then heated at 400°C for one hour to produce a black amorphous material. Heating this material at 700°C for two hours or at 900°C for as little as 0.5 hours produces single-phase CNO. In contrast, fabrication through standard solid-state reaction from the metal oxides requires several days of heating at

high temperature and with several intermediate grinding. Figure 4 shows X-ray diffraction patterns of sol-gel samples heated for two hours at various temperatures.

Conclusions and Future Directions

The bandgap of CNO is approximately 3.1 eV and must be modified to a smaller value so that it absorbs into the visible portion of the solar spectrum. We have commenced a computer study to engineer a smaller bandgap material through elemental substitution in the CNO structure. We will fabricate and characterize any material deemed suitable that the computer study identifies.

FY 2011 Accomplishments

- The dissociation of methane in the presence of a metal catalyst follows a sequence of dehydrogenation steps:
 - $\text{CH}_{4,s} \rightarrow \text{CH}_{3,s} + \text{H}_s$
 - $\text{CH}_{X,s} \rightarrow \text{CH}_{X-1,s} + \text{H}_s$ ($X = 3, 2, 1$; $s = \text{surface}$)
- The presence of Fe, Ni, and Co show hydrogen generation (Table 2).

TABLE 2. Hydrogen Conversion Percentages

Catalyst System	% Conversion at:		
	500°C	600°C	700°C
LiCl + KCl Eutectic	0	0	0
Fe Catalyst in LiCl + KCl	5	8	17.5
Ni Catalyst in LiCl + KCl	11.5	28.0	30
Co Catalyst in LiCl + KCl	7.2	11	16

Fiscal Year (FY) 2011 Objectives

- Quantify hydrogen yield from catalytic cracking of methane in the presence of molten salts.
- Determine the effects of different catalysts.
- Demonstrate hydrogen production at possibly reduced temperature.

Technical Barriers

- Salt mixture-catalyst stability.
- Reduce temperature for hydrogen generation.

The main objective of the proposed work is to examine the effects of exposure of a salt mixture to different temperature levels for an extended period of time (up to 8 hr). The 8 hr limit was established since the peak sun intensity is expected to last only that long in one continuous cycle. The parameters for this study and anticipated goals for hydrogen production are summarized in Table 1.

TABLE 1. Project Goals

Performance Measure	Units	Qtr 1 and 2	Qtr 3 and 4
Salt-Catalyst Thermal Stability	Hours	3	8
Temperature Range	Celsius	400-700	400-800
Volume of Hydrogen	Milli-liter	<10	100

Introduction

Conventional hydrogen generation process is often carried out at high temperature. This approach can be costly. The solar thermal approach seeks to use the high temperature obtained from solar energy with the help of concentrators. This process can, in principle, offset the need of fossil-based energy to produce high temperatures. A schematic of the approach to use solar energy in solar thermal process is given in Figure 1.

Approach

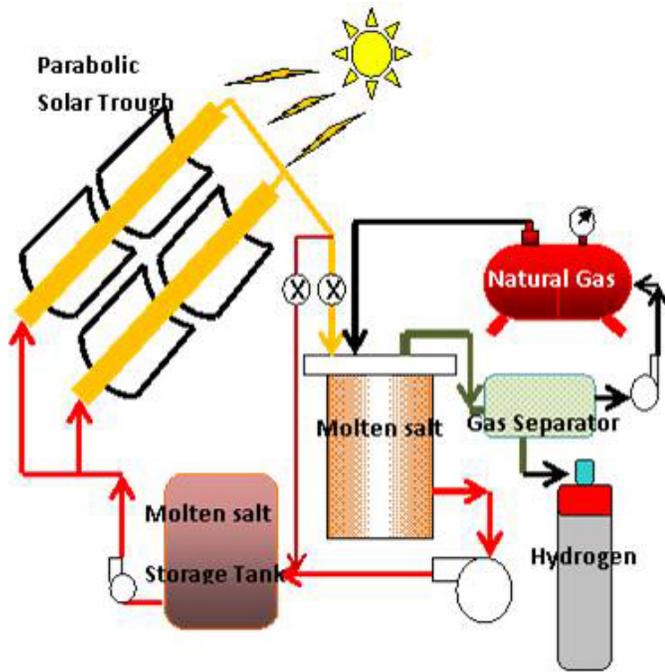

The approach is to use a simulated solar power condition using a box furnace. The furnace was customized to provide the necessary temperature ranges and the experimental conditions to perform catalytic cracking of methane. Summarily, the methane and carrier gas was delivered to a crucible containing the molten salt and the catalyst. The role of the catalyst and the temperature of the molten salt were monitored and its effects on methane cracking were monitored.

Figure 2 shows a schematic of the setup.

Results

The results (Figure 3) can be categorized into the following segments:

- Physical characterization of the eutectic.

Schematic Arrangement for Conversion of Natural Gas into Hydrogen Using Solar Heating of Molten Salt

FIGURE 1. General Schematic of the Approach to Utilize Solar Thermal Energy

- Reaction products were noted to have varying color at different depths.
 - Therefore, while the reaction products were in liquid state, they were poured out and shock cooled (salt pour).
- Visual inspection shows the formation of black precipitates at the bottom.

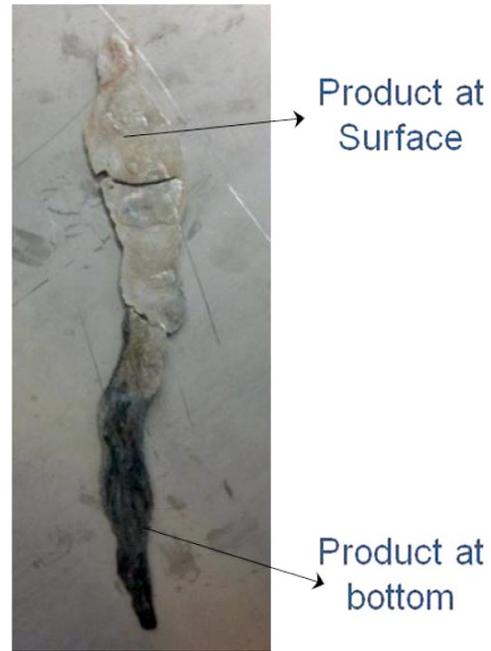

FIGURE 3. A representative photograph of the texture of the salt-catalyst mixture obtained after the catalytic cracking of methane.

- The possible products could be carbon-based materials and may have value.
- Surface characterization of the salt mixture (Figure 4):
 - X-ray diffraction (XRD) analysis was performed to identify the residue after the reaction.
 - Solid-salt mixture was washed several times with water and dried before analysis.

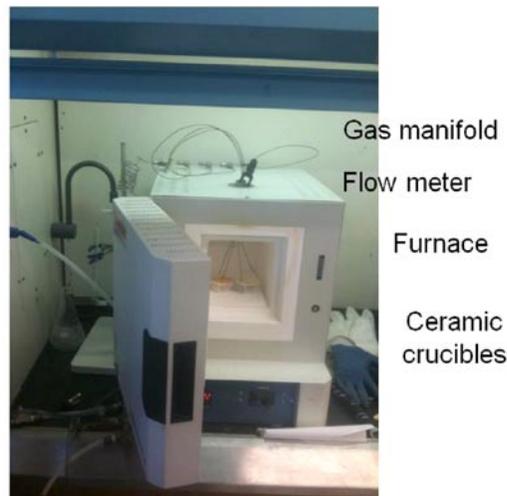

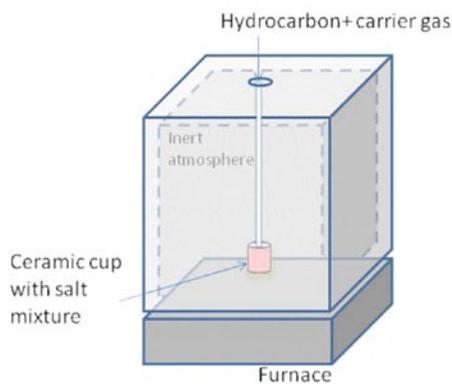

FIGURE 2. The setup that was developed to simulate a solar thermal process to produce hydrogen from methane using a catalyst.

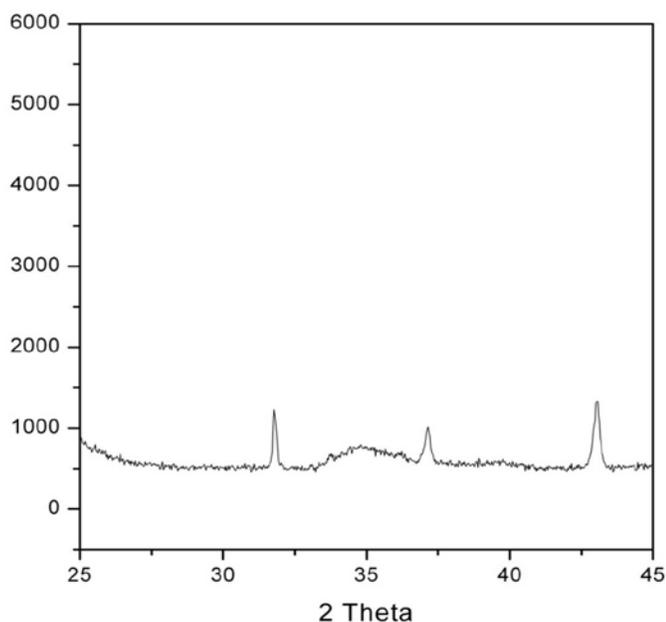

FIGURE 4. XRD of the products after the catalytic cracking indicates the formation of carbon-based residue.

- XRD suggests the formation of carbonaceous species possibly ordered structures as noted from the XRD peaks.
- Product analysis (Figure 5):
 - Hydrogen and oxygen peaks are detected together. Oxygen peaks are attributable to the leaks in the oven.
 - In general:
 - Hydrogen is detected upwards of 600°C in the absence of catalyst in the salt mixture.
 - Hydrogen has been detected at lower temperatures with catalysts.

Conclusions and Future Directions

The preliminary work has shown that:

1. Including Fe as a catalyst with Li/K salt mixture will reduce the temperature at which hydrogen is produced from methane. Ni and Co may be promising as well.
2. The formation of carbonaceous residue indicates that the system does lead to cracking of methane.
3. The temperature from cracking appears to be reduced by at least a 100°C (possibly up to 200°C).

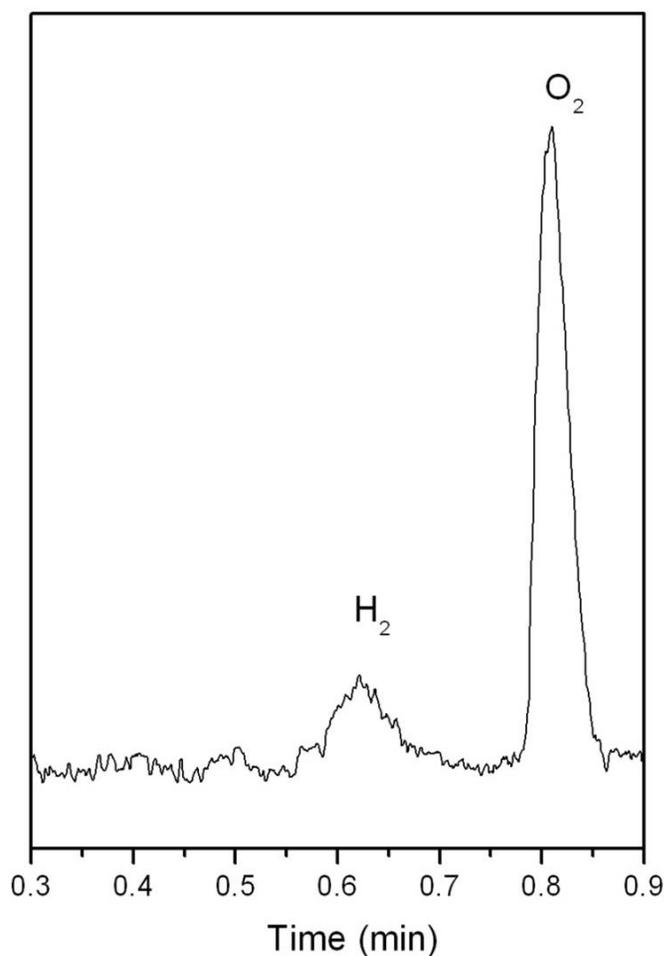

FIGURE 5. Representative gas chromatograph data indicating the products identified after the catalytic cracking of methane.

Future directions:

- To systematically interpret some of the compositional as well as the qualitative nature of the post cracking product(s).
- To finish an ongoing manuscript in this area based on this work.
- There are a few grant opportunities from state and federal agencies that will be explored for future funding.

FY 2011 Publications/Presentations

1. A poster titled “Solar thermal hydrogen production” was presented by Ravi Subramanian at the NVREC Project Meeting on August 20, 2010.
2. Ravi Subramanian also presented an update on this work at the annual DOE merit review meeting in Washington, D.C., May, 2011.

Project End Date: Project continuation and
direction determined annually by DOE

Fiscal Year (FY) 2011 Objectives

The main focus of the project is to:

- Understand the performance of current photoelectrochemical (PEC) materials.
- Provide guidance and suggest solution for performance improvement.
- Design and discover new materials.
- Provide theoretical basis for Go/No-Go decisions on PEC activities.

Technical Barriers

This project addresses the following technical barriers from the PEC water-splitting section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (Y) Materials Efficiency
- (Z) Materials Durability
- (AB) Bulk Materials Synthesis

Technical Targets

This project provides a theoretical understanding of the performance of current PEC materials and provides feedback and guidance for performance improvement.

FY 2011 Accomplishments

- Proposed the general strategies for the rational design of semiconductors to simultaneously meet all of the

requirements for high-efficiency, solar-driven PEC water splitting materials.

- Studied the intrinsic and extrinsic doping properties of BiVO_4 and proposed good candidates for *p*-type dopants (Sr_{Bi} , Ca_{Bi} , Na_{Bi} , K_{Bi}) and *n*-type dopants (W_{V} and Mo_{V}).

Introduction

The electronic band structures of semiconductors are crucial for the performance of semiconductor-based PEC water-splitting. The requirements of those semiconductors include the following tightly coupled material property criteria: appropriate band gap (1.6-2.2 eV), efficient visible light absorption, high carrier mobility, and correct band-edge positions that straddle the water redox potentials. Trial-and-error synthesis approaches have proven ineffective in discovering a viable material, and the band structure engineering for existing materials is necessary [1,2]. So far, most of existing work on band structure engineering is to reduce the band gap without considering other tightly coupled properties described above [2-4]. As a result, the PEC efficiency sometimes became worse when impurities were introduced. It is critical to develop general strategies to address all the requirements simultaneously rather than only reducing band gap.

As an example, anatase TiO_2 is one of the most studied materials owing to its good photocatalytic activity, ease of synthesis, long-term chemical stability, and demonstrated PEC applications. However, its large band gap (~3.2 eV) fails to absorb a significant fraction of visible light, resulting in poor solar-to-hydrogen conversion efficiency. Great efforts have been devoted to chemically engineer TiO_2 to reduce its band gap but with only marginal success. For example, monodoping with impurities such as N or C in TiO_2 has been applied to reduce the band gap of TiO_2 . However, the high concentration of these impurities needed for band gap reduction causes serious carrier recombination and produces inferior material quality, making efficient solar-to-hydrogen conversion impossible.

Our previous work demonstrated that donor-acceptor codoping can effectively enhance the PEC properties of ZnO due to the reduction of the recombination centers [5,6]. In the last year, we extended the donor-acceptor codoping concept to engineer the bandgap of TiO_2 . We explored how the codoping would affect the other tightly coupled properties. We found that the properties are connected tightly with the concentration of dopants.

BiVO_4 has shown particular promise for water photodecomposition with the presence of both a low bandgap (2.4–2.5 eV) and reasonable band-edge alignment

with respect to the water redox potentials [7-9]. For implementation in the real device, both of the good *n*-type and *p*-type doping properties should be required to form Ohmic contacts with contact materials. However, to date, the intrinsic and extrinsic doping properties of BiVO₄ haven't been systematically explored.

Approach

We employ density functional theory (DFT) to study the electronic properties of the anatase TiO₂ and BiVO₄ and how doping would affect their electronic properties. Generalized gradient approximation (GGA) to DFT and the projected augmented wave basis as implemented in the Vienna *ab initio* simulation package (VASP) [10] are used. The plane-wave cut-off energy of 400 eV was used, and the ion positions were always relaxed until the force on each of them is 0.01 eV/Å or less. For TiO₂, the impurity co-incorporation was modeled using (2×2×1) supercells with a total of 48 atoms which randomly include the impurity pairs. The supercell sizes were allowed to relax. The k-point sampling was 7×7×3 for the conventional cell of anatase TiO₂ and equivalent k points for large supercells. The band offset was calculated by aligning the average potentials of host elements far away from impurities with that in pure bulk cell. The GGA band gap error was corrected using a scissor operator. For BiVO₄, the dopants were incorporated into a (2×1×2) supercell with 96 atoms. The k-point sampling was 2×3×3 for the supercell. For defect formation energy and transition energy calculation, the combined schemes of both Γ -point and special k-points were used which could predict the transition energy more precisely [11,12].

For rational band structure engineering of TiO₂, we have proposed four general strategies: (i) utilizing charge balanced donor-acceptor alloying to overcome solubility limit, reduce charged defects, and improve the quality of materials; (ii) using higher 4*d*, 5*d* transition metals substitution on Ti sites to lift up the conduction band; (iii) using C, N with higher 3*p* substitution in O site to raise the valence band and thus reduce the band gap; and (iv) using high concentration of the alloying elements to enhance optical absorption and improve the hole mobility.

Results

We first discuss the energetic favorability of donor-acceptor codoping. The incorporation of a single foreign element can often be limited by the solubility limit in host materials. In the case of high concentration, it may create other detrimental issues such as undesirable charged defects, inferior materials quality, and too high carrier concentration. Our previous work on ZnO showed that the donor-acceptor codoping could enhance doping concentration while keeping good carrier mobility. The charge transfer between the donor and acceptor and the interactions between these two neighbors play key roles. We investigated the interaction behavior of donor and acceptor in TiO₂. Table 1

shows the binding energies of various donor-acceptor pairs considered in our work.

TABLE 1. Binding Energies of Various Donor-Acceptor Pairs

Pairs	E _b (eV)	Pairs	E _b (eV)	Pairs	E _b (eV)	Pairs	E _b (eV)
(Cr,C)	3.02	(Nb,N)	1.97	(Zr,S)	-0.50	(2Ta,C)	1.82
(Mo,C)	3.24	(Ta,N)	1.92	(Hf,S)	-0.56	(2Nb,C)	2.11
(W,C)	2.86	(Ta,P)	0.40	(Zr,Se)	-0.37	(Mo,2N)	4.78
(V,N)	2.25	(Nb,P)	0.58	(Hf,Se)	-0.44	(W,2N)	4.80

Except for the Zr and Hf, the binding energies of donor-acceptor pairs are positive which means that the donor and acceptors favor to combine with each other, thus enhancing the solubility. The reason for negative values for Zr and Hf is that the Zr and Hf are isovalent to Ti and the substitutions don't have large charge transfer between cation and anion dopants.

Taking (Ta, N) as an example, Figure 1 shows that concentration of the incorporated donor and acceptor can affect significantly the electronic properties of TiO₂. Increasing the alloy concentration not only can further reduce the band gap, but can also simultaneously enhance the optical absorption in the long-wavelength regions and reduce the carrier effective mass. The results clearly show that as the concentration increases, the N 2*p* band broadens, the band gap decreases, and the dispersion of the N 2*p* band increases, leading to higher carrier mobility. The GGA calculated band gap reduction increased to 0.70 eV when 12.5% O is replaced by N. Figure 2 shows calculated optical absorption coefficient spectra for (Ta,N) co-incorporated TiO₂ with various concentrations. The results show clearly that as the concentration of (Ta,N) pairs increases, the absorption in the longer-wavelength region is dramatically enhanced. Most previous calculations have only focused in the low-concentration regime. Our results show, however, that there is a strong dependence of the band gap on the alloy concentration. The band-gap reduction predicted at the low-alloy concentration may not be applicable to the high-alloy concentration cases. Therefore, to provide a rational prediction of the band gap and band-edge positions, the calculations should be conducted at both low- and high-alloy concentrations.

Figure 3 shows the calculated band gaps and band-edge alignments in both of the low (Figure 3a) and high (Figure 3b) concentration regime. The results show that the incorporation of Ta, Nb, Zr, and Hf as donors can lead to desirable upshifts of the conduction band minimum (CBM) (marked by red positive values). The incorporation of Cr, Mo, W, and V lead to an unwanted downshift of the CBM. The calculated trends for the valence band maximum (VBM) are also consistent with these atomic trends. The (2Nb,C), (2Ta,C), (Mo,2N), and (W,2N) combinations give both better band gap reduction and band-edge positions. However, the (Mo,2N) and (W,2N) combinations are expected to produce

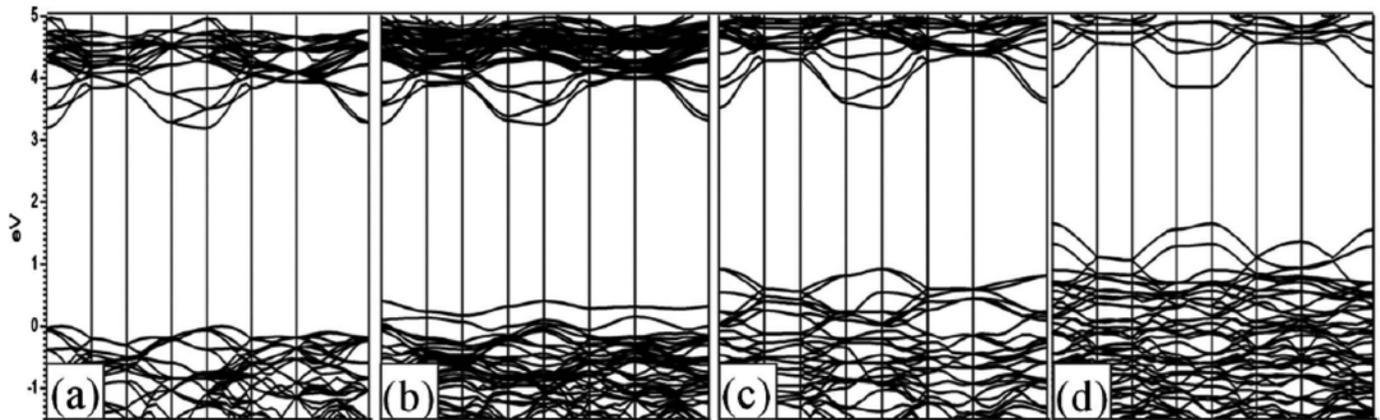

FIGURE 1. The band structures of (a) pure TiO_2 , (b) 3.1% (Ta, N) co-incorporated TiO_2 with 3.1% O replaced by N, (c) (Ta, N) co-incorporated TiO_2 with 12.5% O replaced by N, (d) (Ta, N) co-incorporated TiO_2 with 25% O replaced by N. The CBMs are aligned for guide of eyes as the conduction band structure characters near CBM are nearly unchanged.

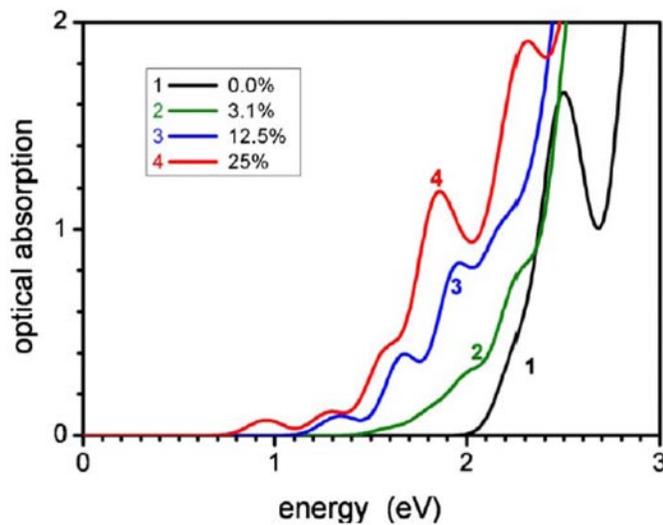

FIGURE 2. Optical absorption spectrum (the part near absorption edge) of pure TiO_2 and (Ta, N) co-incorporated TiO_2 with 3.1%, 12.5%, and 25% of O replaced by N, respectively.

more dispersive defect bands. At high concentration, TiO_2 co-incorporated with (Cr,C), (Mo,C), (W,C), and (V,N) becomes metallic due to too much band broadening of both unoccupied and occupied bands created by the donors and acceptors. The combinations used to give good band gaps in the low-concentration regime such as (2Nb,C), (2Ta,C), (Nb,P), and (Ta,P) now give band gaps that are too narrow due to their high VBM. While (Nb,N) and (Ta,N) combinations give the desirable band gaps estimated to be 2.68 eV and 2.50 eV, respectively, simultaneously with proper band-edge positions. Our results, therefore, suggest strongly that the band-edge positions and band gaps depend critically on the concentration of the incorporated donors and acceptors pairs. As a general guidance, one must consider carefully band gaps and concentration at the same

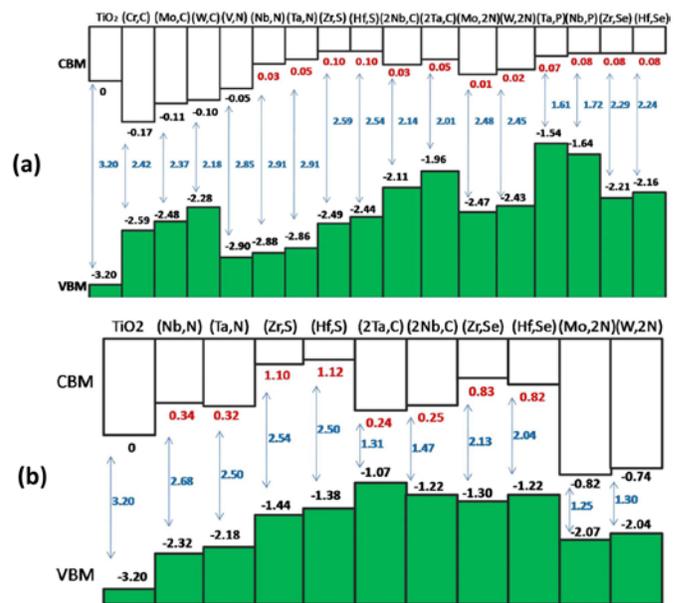

FIGURE 3. Calculated GGA band offset (at Γ point) for TiO_2 and TiO_2 alloyed with various donor-acceptor combinations in the (a) low-concentration regime and (b) high concentration regime. The CBM of pure TiO_2 is set to zero as the reference and the band gap is corrected by scissor operator.

time so that the appropriate donor-acceptor combinations can be chosen.

Simultaneously considering the band gap, band edge and binding energies, we predict that (Ta,N) and (Nb,N) pairs are the optimal donor-acceptor combinations in the high concentration regime, and (Mo,2N) and (W,2N) combinations are good candidates in the low-concentration regime for engineering TiO_2 for PEC water-splitting.

The properties of intrinsic defects in BiVO_4 were studied. Our results show that the Fermi level is always

pinned by Bi vacancy and O vacancy. Under O poor conditions, the Fermi level is pinned at ~ 0.35 eV below CBM and under O rich condition, the Fermi level is pinned at ~ 0.55 eV above VBM. As a result, without external doping, BiVO_4 should only exhibit moderate *n*-type or *p*-type conductivities, which is needed for good PEC absorbers.

We calculated the transition energies and formation energies for group-I, group-II, group-IV elements as dopants. We found that outstanding *p*-type conductivity can be achieved by Br, Ca, Na, or K doping at O-rich growth conditions because these impurities at Bi sites are shallow acceptors and have rather low formation energies. Excellent *n*-type conductivity can be realized by Mo or W doping at O-poor growth conditions, because they are very shallow donors at V sites and have very low formation energies. Figure 4a shows the formation energies of group-II (Zn, Mg, Ca, Sr) elements as p-type doping in O-rich conditions. The dashed lines are the curve of the lowest formation energy of the intrinsic defects. All the possible configurations of impurities, such as substitution and interstitials, are considered. It is seen that Ca and Sr exhibit excellent p-type doping properties, not only because their shallow transition energies (around 0.1 eV), but also because their formation energies are lower than that of intrinsic defects.

Figure 4 shows the formation energies of group-VI (Cr, Mo, W) elements doping in O-poor conditions. The Mo and W dopants exhibit good *n*-type properties. The $(0/1+)$ ionization energies of Mo_V is as shallow as 0.04 eV. W_V is even shallower (0.01 eV), but its formation energy is a little higher than Mo_V , making the Fermi level pinning with Bi vacancy and thus the Fermi level is located at ~ 0.2 eV below CBM. Therefore, Mo and W are good candidates that could lead to excellent *n*-type conductivity in BiVO_4 .

The impurities discussed in the above calculation are mostly on cation sites. On the other hand, *p*-type and *n*-type doping of metal oxides may also be realized by introducing impurities to O sites. In this case, C, N, and F are the most considered impurities. Because interstitials of these impurities usually have large formation energies, we will only consider substitutional defects, C_O , N_O , and F_O . However, these conventional dopants are not expected to lead to good *p*-type or *n*-type conductivities.

Conclusions and Future Direction

We have proposed general strategies for the rational design of semiconductors to simultaneously meet all of the requirements for a high-efficiency PEC water splitting material. As a case study, we apply our strategies for engineering anatase TiO_2 . Previous attempts to modify known semiconductors often focused on a particular individual criterion. Our theoretical results show that with appropriate donor-acceptor incorporation alloys with anatase TiO_2 hold great potential to satisfy all of the criteria for a viable PEC device. We predict that (Mo,2N) and (W, 2N) are the best donor-acceptor combinations in the low-alloy concentration regime whereas (Nb, N) and (Ta, N) are the best choice of donor-acceptor pairs in the high-alloy concentration regime.

Without external dopants, BiVO_4 exhibits moderate *p*-type in O-rich condition and moderate *n*-type in O-poor condition, which is just needed for good PEC absorber. On the other hand, for external dopants, Sr, Ca, Na, and K are proposed to be good *p*-type dopants and the Mo and W are proposed to be good *n*-type dopants for BiVO_4 , which is needed for forming Ohmic contacts between absorber and

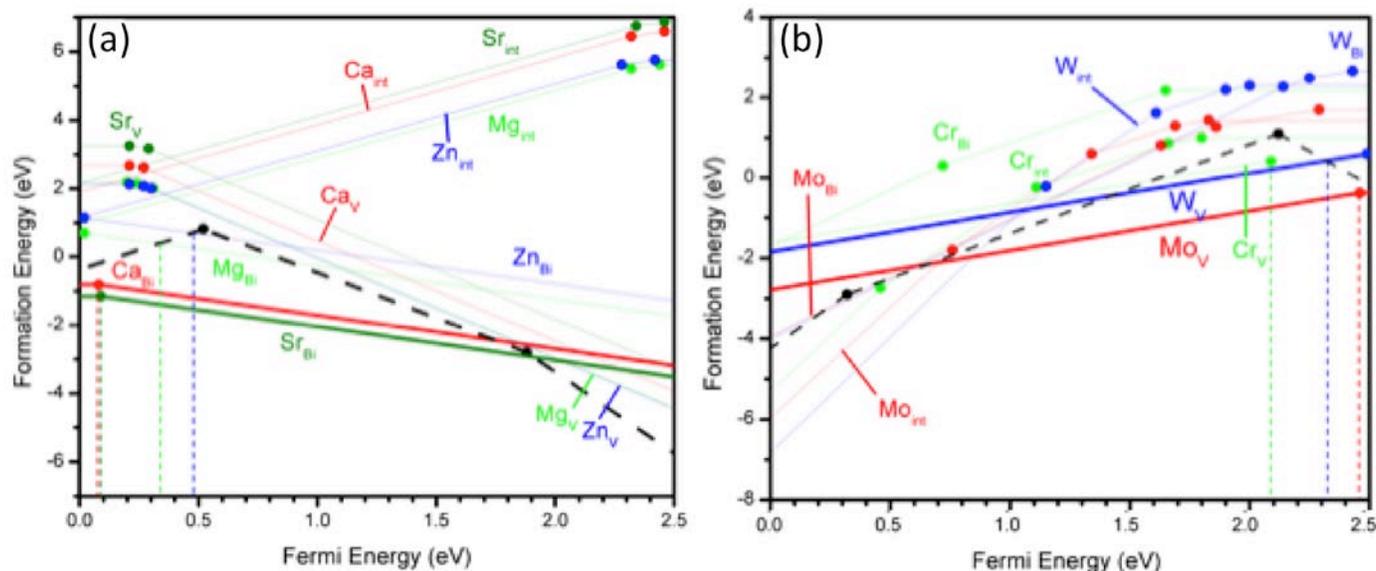

FIGURE 4. Calculated formation energies of (a) group-II (Zn, Mg, Ca, Sr) dopants in O-rich conditions and (b) group-VI (Cr, Mo, W) dopants in O-poor conditions.

contacts. C, N and F are found not to be good candidates for p-type or n-type doping of BVO_4 .

Future direction includes the following:

- Apply the design strategies to engineer other metal oxides, such as Fe_2O_3 .
- Understand the electronic properties of other metal oxides.
- Design new metal oxides for PEC applications.

National Renewable Energy Laboratory (NREL)
Golden, CO

Project Start Date: August 15, 2008

Project End Date: August 15, 2011

Fiscal Year (FY) 2011 Objectives

- Development of photoelectrochemical (PEC) material with required composition and architecture to achieve 5,000+ hour lifetime, 2.0 eV bandgap, and >10% conversion efficiency in the prototypes.
- Conformally deposit indium tin oxide (ITO) and Pt quantum dots inside nanoporous anodic aluminum oxide (AAO).
- Achieve bandgap ≤ 2.0 eV.
- Develop large area PEC samples.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Hydrogen, Fuel Cells and Infrastructure Technologies Program Multi-Year Research, Development and Demonstration Plan:

(AA) PEC Device and System Auxiliary Material

(AC) Device Configuration Designs

Technical Targets

This project is conducting studies of PEC hydrogen production by creating a hybrid design that combines multiple layers of materials to simultaneously address issues of durability and efficiency. As part of this effort, techniques are being developed that can manufacture devices at commercial scales. The overall goal of this project is to create a PEC device that meets or exceeds the DOE 2018 PEC hydrogen production targets in Table 1.

TABLE 1. Progress towards Meeting Technical Targets for PEC Hydrogen Generation

Characteristic	Units	2013 Target	2018 Target	Synkera 2011 Status
Usable Bandgap	eV	2.3	2.0	2.06
Chemical Conversion Efficiency	%	10	12	Not available
Solar to Hydrogen Efficiency	%	8	10	1.1%
Plant Durability	hr	1,000	5,000	Not available

FY 2011 Accomplishments

- Produced conformal transparent conductive oxide (TCO) and TiO₂ nanotubes in a layered manner inside pores of AAO.
- Demonstrated deposition of platinum nanodots inside the TCO and TiO₂ nanotubes.
- Demonstrated direct bandgap of 2.06 eV in Pt coated TiO₂.
- Developed new process for depositing highly conductive ITO inside AAO.
- Demonstrate 4x current increase for ITO-based PCE versus previous results.
- Demonstrated conformal deposition of WO₃ inside AAO nanopores.

Introduction

The cleanest method of hydrogen production is the use of sunlight to electrochemically split water into hydrogen and oxygen. Advances in photoelectrode materials are required to make PEC hydrogen production practical. Current materials representing the state of the art in this area suffer from significant lifetime limitation, bandgaps poorly matched with the solar spectrum, and low conversion-efficiency. The project aim is to develop and commercialize next-generation PEC materials that incorporate an innovative three-dimensional nanostructured architecture and a tailored bandgap.

Approach

The material architecture includes high-density, high-surface-area arrays of nanotubes formed inside the pores of the honeycomb-like, self-organized matrix of nanoporous AAO. The approach utilizes a synergistic combination of two technologies developed by the project team: (1) synthesis and integration of AAO with the required

porous structure; and (2) conformal atomic layer deposition (ALD) of materials inside the high-aspect-ratio pores to produce nanotubes with atomically controlled thickness of coaxial layers. The approach results in up to a 1,000-fold increase of the cross-section available for light absorption and the surface area available for electrochemical reactions, thus significantly increasing the hydrogen yield per area of the electrode.

The PEC materials developed in this project include a catalytic layer, surrounded by a layer of light absorbing material, surrounded by an outer shell of TCO (Figure 1). The architecture provides a long vertical path length for light absorption with a short lateral path length for efficient charge separation.

Results

Previously during this project we demonstrated that AAO membranes with larger pore periods and diameters were most effective as PEC scaffolds. All the development of PEC materials was conducted on free standing 13 mm diameter AAO coupons. In order to create functional PEC devices capable of meeting the cost targets for hydrogen, two issues must be addressed: 1) the area of AAO must be scaled up; and 2) the PEC device must be integrated into a system capable of capturing the generated hydrogen.

Synkera has addressed these two issues by creating 1"×5" AAO membranes that are integrated with an aluminum rim (Figure 1). The challenge in this effort was to create membranes with large pore diameters in this format and to anneal them to the required temperature prior to ALD. We have achieved both of these goals with 100% yield.

In earlier efforts we explored nitrogen and carbon doping of TiO₂ to reduce the bandgap of the material. We were able to reduce the bandgap from 3.1 eV to 2.5 eV

FIGURE 1. Annealed 1"×5" AAO Membranes Supported by Aluminum Rim

using nitrogen doping. Additional efforts at nitrogen doping did not lead to further reduction in the bandgap. In order to overcome this limitation we explored Pt quantum dots as a means of decreasing the bandgap. Figure 2A shows a conceptual drawing of the AAO cross section. The nanoporous AAO is first conformally coated with a TCO (to form TCO nanotubes) and provide a path for the generated electrons to reach the cathode. Inside the TCO, nanotubes of TiO₂ are deposited to produce the catalytic surface. Finally platinum quantum dots are deposited on the TiO₂ surface. Figures 2B and 2C show scanning electron microscope side and top views of the AAO after 100 cycles of Pt ALD. Both views suggest that Pt ALD forms polycrystalline domains similar to the domains formed during metallic tungsten ALD on oxide surfaces [1]. Experience with tungsten ALD suggests that the Pt ALD proceeds via the formation of individual islands that coalesce as the number of cycles increases. By only depositing a few cycles of Pt on the TiO₂ surface, individual quantum dots of Pt can be obtained.

PEC samples consisting of aluminum doped zinc oxide (the TCO), TiO₂, and a few ALD cycles of Pt were prepared (Figure 2A). These samples were sent to our consultant at NREL for analysis. NREL performed photocurrent spectroscopy by measuring the photocurrent while scanning the light wavelength from 550-900 nm. Direct electronic transitions are found by plotting the square of the normalized photocurrent (NPC) and extrapolating the linear regime to the abscissa (Figure 3). The figure shows that the PEC material had a direct bandgap of 2.06 eV. Additionally, plots of the square root of the NPC showed an indirect bandgap of 1.71 eV.

Additional tests at NREL using colored glass filters used to estimate wavelength dependent photoresponse. The Pt-coated PEC samples demonstrated the largest magnitude response to chopped illumination from photons with wavelengths longer than 695 nm ($h\nu < 1.78$ eV) while bare TiO₂ had none. This result confirms photocurrent spectroscopy results that these configurations are visible-light active, and is responsive to photon energies below what would be expected from pure TiO₂.

In other recent efforts Synkera has developed a new ALD chemistry for deposition of highly conductive ITO conformally inside the pores of AAO. PEC samples were made using ITO and TiO₂ and compared to AZO/TiO₂ samples as well as AZO/TiO₂/Pt samples. Figure 4 shows the photocurrent for all three types of samples during chopped light experiments conducted at Synkera. The figure shows that the photocurrent is four times higher for the ITO samples compared to the AZO samples and two times higher than the samples modified by Pt. The reason for the much higher current is unclear, but will be further explored during the last two months of the project.

Synkera has also just completed samples that have WO₃ as the photocatalyst instead of TiO₂. These samples are undergoing evaluation.

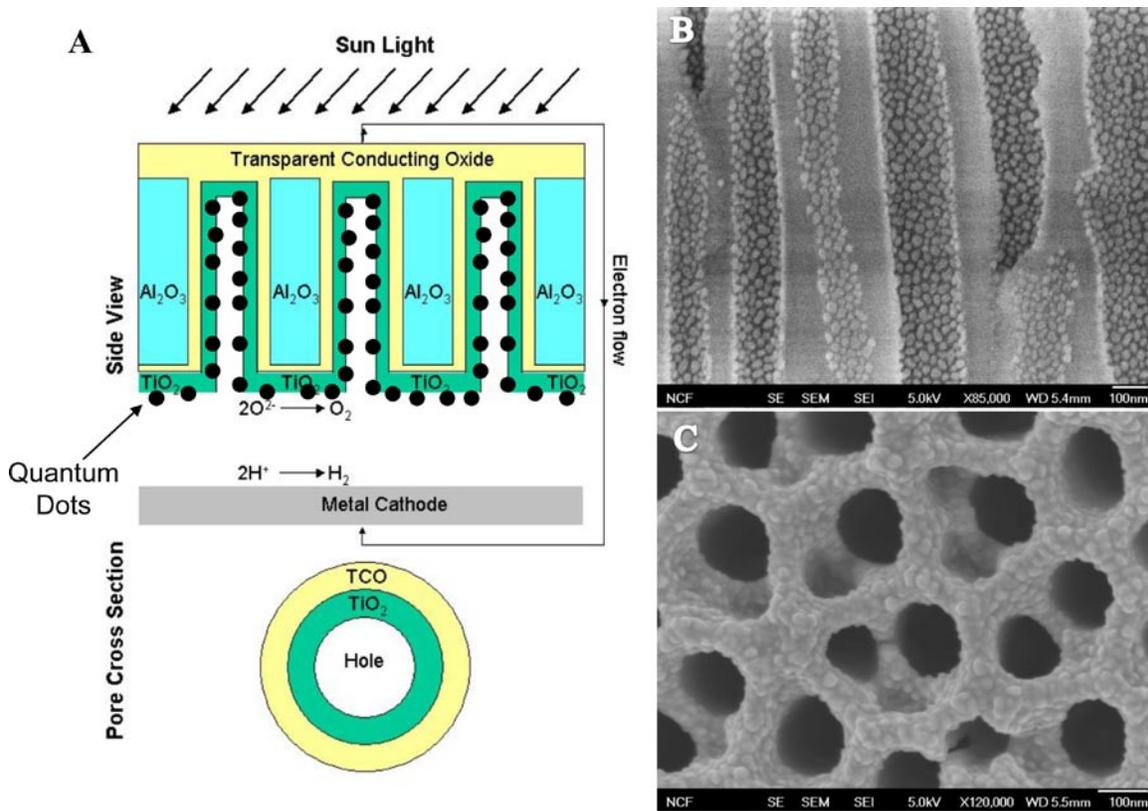

FIGURE 2. A: Conceptual drawing of PEC nanotube architecture with quantum dot catalyst. B: Side view of AAO after 100 cycles of Pt ALD. C: Top view of AAO after 100 cycles Pt ALD.

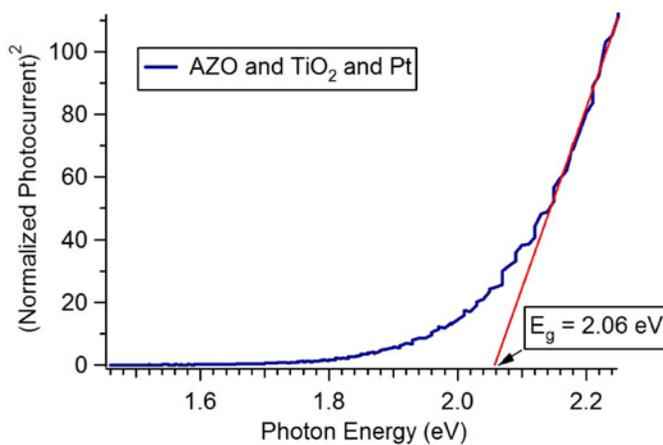

FIGURE 3. Photocurrent Spectroscopy Data Performed at NREL (Pt-coated PEC devices show a bandgap of 2.06 eV)

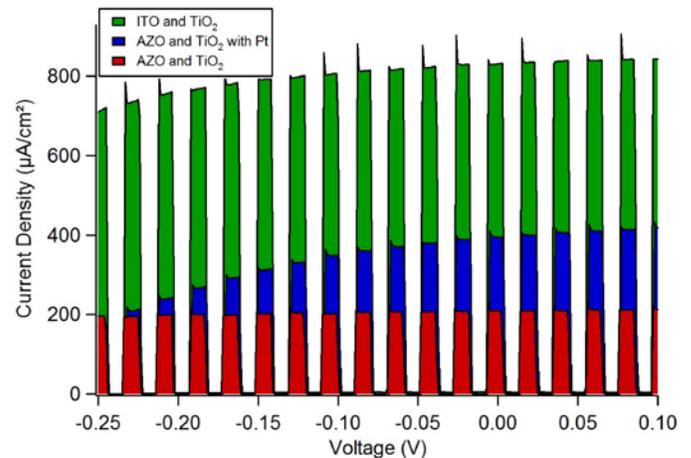

FIGURE 4. Photocurrent comparison in 0.1 M KOH (pH 13) on PEC samples with ITO/TiO₂, AZO/TiO₂/Pt, and AZO/TiO₂ as a function of applied potential (vs. Ag/AgCl electrode) under 1 sun illumination with chopped light.

Conclusions

We have developed a nanostructured PEC material that is manufactured using scalable techniques. We have successfully completed an intermediate scale up of the AAO scaffold for PEC applications. We have demonstrated a

visible light photoresponse in our PEC samples. We have also demonstrated significantly enhanced photocurrent by using ITO to replace the AZO in the device.

Future Directions

- Complete testing of WO₃ PEC samples.
- Fabricate samples of ITO/TiO₂/Pt.
- Measure long-term stability of best performing PEC sample.
- Manufacture large area PEC sample.

Patents Issued

1. On August 30th 2010 we resubmitted a U.S. Provisional Patent Application No. 61/174,577 entitled “ENERGY CONVERSION DEVICES AND METHODS FOR MAKING SAME.” This patent covers the architecture described in this project as well as related architectures for photovoltaics and other applications.

FY 2011 Publications/Presentations

1. We presented a poster on this work on May 10th 2011 at the DOE Hydrogen and Fuel Cells Program, and Vehicle Technologies Program Annual Merit Review and Peer Evaluation Meeting.

- Dr. Eric Johnson, Johns Hopkins University, Baltimore, MD
- Dr. Michael Flickinger, North Carolina State University, Raleigh, NC

Project Start Date: October 1, 2000

Project End Date: Project continuation and direction determined annually by DOE

- Integrate fermentative H₂ production using potato waste or sulfur-deprived, alginate-immobilized algal biomass as feedstock, with photosynthetic H₂ production by anaerobic, purple non-sulfur bacteria.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies (FCT) Program Multi-Year Research, Development and Demonstration Plan.

- (AH) Rate of H₂ Production
- (AI) Continuity of H₂ Production
- (AT) Feedstock Cost

Technical Targets

TABLE 1. Progress toward Meeting Technical Targets for Photobiological Hydrogen Production

Parameters	Current Status	2013 Targets	Maximum Potential
Duration of continuous photoproduction:			
• Aerobic, high STH (O ₂ -tolerant)	0	30 min.	12 hours daylight
• Anaerobic, low STH (S-deprivation)	90 days		Indefinite
• Aerobic, low STH (S-deprivation)	10 days		Indefinite
Cost ¹ (\$/kg H ₂)			
• Aerobic, high STH			\$2.99
• Anaerobic, low STH			\$6.02
• Integrated (photobiological and fermentative)			\$3.21

¹ Cost estimates based on B.D. James, G.N. Baum, J. Perez, K.N. Baum, 2009, <http://nrel.gov/docs/fy09osti/46674.pdf>

Fiscal Year (FY) 2011 Objectives

Primary Objectives

- Develop and optimize aerobic, high solar-to-hydrogen (STH) photobiological systems for the production of H₂ from water by:
 - Engineering a H₂-producing catalyst ([FeFe]-hydrogenase) that has an extended half-life following exposure to O₂.
 - Introducing a more O₂-tolerant hydrogenase into the green alga, *Chlamydomonas reinhardtii*.
- Design a fusion between hydrogenase Ca1 and ferredoxin to re-direct a larger portion of photosynthetic electron transport to hydrogenase rather than to CO₂ fixation under aerobic conditions; advise Massachusetts Institute of Technology (MIT) regarding *in vitro* testing of the fusion.
- Further optimize and utilize an anaerobic, limited STH working platform to study biochemical and engineering factors that affect H₂ photoproduction by biological organisms; focus on the effect of a leaky chloroplast adenosine triphosphate (ATP) synthase on the rates of H₂ photoproduction.

FY 2011 Accomplishments

- Used computational methods to identify differences in the geometries and energies of the gas diffusion barrier protecting the H-cluster in two [FeFe]-hydrogenases that display a 1,000-fold difference in the level of O₂ sensitivity.
- Used a previously-developed random mutagenesis technique to randomize the amino acid residues that comprise the areas identified above.
- Demonstrated the presence of double O₂-inactivation kinetics in green algal transformants expressing a clostridial hydrogenase, suggesting that the more O₂-tolerant clostridial enzyme Ca1 is active in wild-type green algae.

- Demonstrated an up to 2.6-fold increase in the H₂-photoproduction rates upon increases in the photobioreactor gas-to-liquid ratio, using either sulfur/phosphorus-deprived cell suspensions or alginate-immobilized, sulfur/phosphorus-deprived cultures. (The effect was shown to be due to inhibition of the reaction rates by H₂ that accumulated in the headspace.)
- Found that pre-treatment of alginate films with 0.1% polyethylenimine stabilized the films, resulting in a 14% increase in the H₂ yields but no significant increase in the period of performance.
- Showed a 40% improvement in the H₂ photoproduction rates by ATP synthase mutants due to dissipation of the proton gradient that limits photosynthetic electron transport in non-mutated cells.
- Demonstrated successful induction of a marker gene behind a chloroplast inducible promoter, a preliminary step for introduction of mutated ATP synthase subunits into *Chlamydomonas*.
- Obtained a 55% yield (based on 12 moles H₂/glucose) following fermentation of 2% starch (from potato waste), and subsequent utilization of the organic acid effluent using non-purple photosynthetic bacteria.

Introduction

Green algae can extract electrons from water and generate H₂ under illumination, using the concerted activities of the photosynthetic electron transport chain and the enzyme [FeFe]-hydrogenase. This pathway evolves O₂ as a by-product, which irreversibly inhibits the hydrogenase enzyme's catalytic center. The continuity of H₂ photoproduction is one of the major technical barriers to developing photobiological H₂-production systems that use water as the source of electrons (technical barrier AI).

A second major barrier to efficient algal H₂ photoproduction is the low rate of the reaction (technical barrier AH), which is dependent on many intracellular regulatory factors, including the competition for photosynthetic reductant between the H₂-production and the CO₂-fixation pathways; the down-regulation of photosynthetic electron transport from water under H₂-producing conditions; and the predominance of cyclic, unproductive electron transport over linear electron transfer under anaerobiosis.

Our current project addresses the O₂ sensitivity and low rates of algal H₂-production by using molecular engineering to alleviate these barriers and testing the results through the sulfur-deprivation platform. The latter allows us to measure the effects of molecular engineering on sustained hydrogen production, although at low STH conversion levels. Our project also addresses the performance of an integrated

fermentative/photobiological H₂-producing system that holds the potential for lowering the costs and increasing the yields of photobiological H₂.

Approach

Task 1. Molecular Engineering Approaches to Increase the O₂ Tolerance and the Rates of H₂ Photoproduction

This task has three major objectives: (a) the engineering of increased O₂ tolerance in [FeFe]-hydrogenases through random mutagenesis, targeted to regions that control O₂ access to the catalytic site; (b) the expression of a functional, more O₂-tolerant clostridial [FeFe]-hydrogenase in *Chlamydomonas reinhardtii*; and (c) the design and testing of bacterial hydrogenase-ferredoxin fusions for activity and interaction with Photosystem I (NREL acted as a consultant for MIT).

The targeted mutagenesis approach is being guided by extensive computational study of gas diffusion in the clostridial *Clostridium pasteurianum* CpI hydrogenase (that has a solved crystal structure). These studies previously identified a cavity, present next to the H-cluster of [FeFe]-hydrogenases, as a high-energy barrier for O₂ diffusion to the cluster. However, site-directed mutagenesis of residues that comprise the barrier have not yielded mutants with higher O₂-tolerance. Alternative computational and mutagenesis approaches have been devised and are being pursued.

Our studies aimed at expressing a more O₂-tolerant hydrogenase from *Clostridium acetobutylicum* (Ca1) in *C. reinhardtii*. Linking it functionally to photosynthetic electron transport involved: (i) designing genetic constructs for expression, activation and translocation of the hydrogenase into the stromal compartment of algal chloroplast; (ii) testing transformants for the presence of recombinant hydrogenase enzyme and activity; (iii) testing for O₂-tolerance of H₂ photoproduction under different physiological conditions. The availability of an algal strain expressing a more O₂-tolerant enzyme will provide us with the opportunity to examine physiological effects of such an enzyme in algal metabolism.

Sustained H₂ photoproduction, which is currently achieved through sulfur deprivation (see task 2), requires that the algal cultures be anaerobic, which, in turn, inactivates CO₂ fixation. However, once an O₂-tolerant enzyme becomes available, H₂ photoproduction will compete with the CO₂ fixation pathway (at the level of the electron transport mediator, ferredoxin) for photosynthetic reductant. In order to direct the flux of reductant towards the hydrogenase, we worked with Prof. Shuguang Zhang's research group at MIT to design (NREL), construct and test (MIT) the performance of bacterial hydrogenase-ferredoxin fusions. The collaboration produced some computational models but experimental work was not done due to limited funding.

Task 2. Use of the Sulfur-Deprivation Platform to Test Biochemical and Engineering Factors

To induce sustained H₂ photoproduction, we collaborated with the University of California in the development of a physiological switch that is based on removing sulfate from the algal growth medium. This procedure has become a platform for testing the performance of a variety of algal mutants, growth conditions, immobilization surfaces and other engineering factors that may affect the overall H₂ yield.

Task 3. Integrated H₂ Production System

The FCT Hydrogen Biological Production working group identified a system for biological H₂ production that depends on the integrated activity of photosynthetic (oxygenic and non-oxygenic) and fermentative organisms. The potential advantages of this system are (a) the wider absorption spectrum or oxygenic and non-oxygenic phototrophs, (b) the utilization of spent algal and bacterial biomass as feedstocks by fermentative organisms for increased H₂ production, and (c) the utilization of the fermentative effluent for improved growth of algae and photosynthetic bacteria.

NREL has been testing two integrated system configurations. The first one is based on using potato waste as the feedstock for H₂-producing fermentative organisms, which co-generate organic acids that are used to support subsequent H₂-photoproduction by photosynthetic bacteria. The second configuration takes advantage of spent algal biomass (harvested at the end of a photobiological H₂-production process) as feedstock for fermentative H₂-producing microbes.

Results

Task 1. Molecular Engineering Approaches to Increase the O₂ Tolerance and the Rates of H₂ Photoproduction

Computational simulations identified differences in the geometries and energies of the gas diffusion barriers protecting the H-cluster in two [FeFe]-hydrogenases with a 1,000-fold difference in the level of O₂ sensitivity. We randomized the regions around the diffusion barriers (not the barrier residues *per se*) to test the information provided by the simulations. The resulting mutants will be expressed and screened in a new high-throughput technique previously developed at our laboratory.

Concomitantly, we have proceeded with the expression of the more O₂-tolerant, clostridial [FeFe]-hydrogenase in wild-type *C. reinhardtii*. Plasmids for constitutive or inducible expression of Ca1 hydrogenase were constructed and used to transform wild-type *Chlamydomonas*. The presence of the codon-optimized Ca1 gene was confirmed by polymerase chain reaction (PCR), and its transcription was detected by reverse-transcriptase-PCR. Measurement of hydrogenase activity was initially inconsistent, perhaps due to differences in gene expression from sample to sample. However, O₂-

inhibition assays revealed double kinetics, suggesting that the more O₂-tolerant Ca1 gene was active. Optimization of the conditions for Ca1 expression will continue in order to unambiguously determine its contribution to overall hydrogenase activity in recombinant strains.

Our collaborative work with MIT helped to support the publication of a Proceedings of the National Academy of Sciences' manuscript, detailing the evidence for improved photosynthetic reductant flux to the hydrogenase *in vitro* using an algal hydrogenase-ferredoxin fusion. These results hold the promise to improve H₂ production rates *in vivo* as well.

Task 2. Use of the Sulfur-Deprivation Platform to Test Biochemical and Engineering Factors

Algal H₂-production is catalyzed by a reversible hydrogenase that is capable of H₂ production and H₂ oxidation, depending on the prevailing physiological conditions, such as the availability of photosynthetic reductant (favors H₂ production) and high headspace H₂ pressure (favors H₂ oxidation). We investigated the magnitude of the effect of different gas-to-liquid (or solid) ratios in the rates of H₂ production by suspension and immobilized algal cell reactors. The expectation is that, by diluting the H₂ produced by the cultures by increasing the headspace volume, it is possible to sustain high rates of H₂ production during the sulfur-deprivation process. Table 1 shows that increases in the gas-phase volume result in higher rates of H₂ photoproduction, with the highest reported rate of 12.5 μmoles mg Chl⁻¹ h⁻¹ being observed with a headspace volume of 925 mL. On the other hand, although the rates of H₂ photoproduction by cultures immobilized in alginate increase as the headspace volume is raised, they saturate at about 10 μmoles mg Chl⁻¹ h⁻¹, perhaps due to limited diffusion of released H₂ within the alginate matrix. Also, the inhibitory effect of H₂ was quantified by measuring the yields of H₂ photoproduction by suspension cultures in the presence of different concentrations of added H₂, as shown in Figure 1. These combined results imply that the added cost of gas purging and gas separation must be balanced with the added benefit of increased H₂ productivities in order to achieve the most economical system.

TABLE 1. Rates of H₂ Photoproduction and Total Yield of H₂ as a Function of Headspace Volume

Gas space volume	Rate of H ₂ production (mmoles x mg Chl ⁻² x h ⁻¹)	Total final yield of H ₂
Suspension cultures		
165 mL	4.8	250 mL/L
545 mL	7.3	400 mL/L
925 mL	12.5	560 mL/L
Immobilized cultures		
9 mL	6.1	0.20 mol/m ³
20 mL	9.6	0.24 mol/m ³
35 mL	10	0.33 mol/m ³
54 mL	10	0.36 mol/m ³
119 mL	10	0.35 mol/m ³

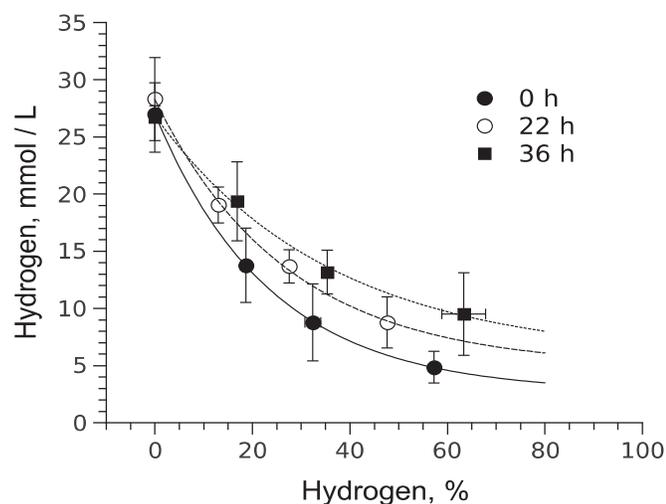

FIGURE 1. Final yield of H_2 as a function of the concentration of H_2 gas present in the bioreactor headspace at different time points (0, 22 and 36 hours) during the sulfur-deprivation process.

A second known limitation to the immobilized system is the low stability of alginate films over time. We examined the effect of treating the films with polyethyleneimine, a polymer that has been successfully used to increase the mechanical stability of a variety of films. We processed immobilized cultures through cycles of +S+P/-S-P and demonstrated that an increase in the polyetherimide (PEI) concentration up to 0.5% inhibits H_2 photoproduction but increases the mechanical stability of the film, allowing the cultures to undergo more cycles. The highest total H_2 yield was obtained in films pre-treated with 0.1% PEI, compared to untreated films. Our future studies will then be performed with cells immobilized in 0.1% PEI-treated films.

The sulfur-deprivation process was also used to test the performance of ATP synthase mutants designed to dissipate the proton gradient that is established during linear electron transfer (LEF) from H_2O to H_2 and that is known to down-regulate LEF (and thus H_2 production). Initial mutants, which were generated by Dr. Eric Johnson, Johns Hopkins University, had higher rates of H_2 photoproduction under high light but were affected in growth rates. New mutants were designed and are being tested to function under regulation of an inducible promoter, to allow the dissipation of the proton gradient to occur only under H_2 -producing conditions.

Task 3. Integrated H_2 Production System

The integrated H_2 -production system was tested, using a two-chamber reactor which separated the fermentative consortium from the photosynthetic bacteria. Unfortunately, many issues were found to affect the process, including (a) the low diffusion of volatile fatty acid feedstock; (b) the improper sealing of the membrane that did not prevent contamination; (c) inhibition of photosynthetic bacterial growth by factors present in the fermentative effluent; and

(d) the nitrogen sources for photosynthetic bacteria need to be tightly controlled. This process was replaced by independent, successive cultivations with pH correction and addition of N_2 gas. The latter was tested with different amounts of feedstock, different dilutions of fermentative effluent before transfer to photobioreactor, and a new strain of *Rhodobacter capsulatus*. Yields of 55% (based on 12 moles H_2 /glucose) were obtained with 2% starch (from potato waste), 75%–95% dilution of fermentative effluent before feeding the *R. capsulatus* strain N7. These yields are among the highest reported in the literature for an integrated system, and they serve as a baseline for our next step, where we will use spent algal biomass as the feedstock.

Conclusions and Future Direction

- **Task 1.** (a) continue the characterization of a wild-type *C. reinhardtii* transformant library harboring the Ca1 expression construct, and characterize new transformant library of Ca1 in a *C. reinhardtii* Hyd⁻ strain (developed under Basic Energy Sciences funding) that eliminates native hydrogenase activity; (b) express and screen a random mutant library of the bacterial hydrogenase Ca1 in *E. coli* to identify active mutants for O_2 tolerance characterization.
- **Task 2.** (a) design a more efficient immobilized H_2 -production system, suitable for long-term H_2 photoproduction (two months compared to 10 days using the current configuration); (b) finish the development and test the function of an inducible promoter that will turn the mutated ATP synthase ON only under certain environmental conditions, to allow us to control the expression of the proton channel dissipation trait; (c) revisit the use of photoautotrophic cultivation conditions for sulfur-deprived cultures, aimed at increasing H_2 yields and decreasing cost by eliminating organic carbon substrate.
- **Task 3.** Will be discontinued due to budget restrictions.

Technical Targets

TABLE 1. Progress toward Meeting DOE Technical Targets in Dark Fermentation

Characteristics	Units	2013 Target	2018 Target	2011 Status
Yield of H ₂ from glucose	mole H ₂ /mole glucose	4	6	3.2
Feedstock cost	cents/lb glucose	10	--	12

Yield of H₂ from glucose: DOE has a 2013 target of an H₂ molar yield of 4 using glucose as the feedstock. In FY 2010 we achieved a molar yield of 3.2, accomplished by *Clostridium thermocellum* fermenting avicel (commercial cellulose) via fermentation only.

Feedstock cost: The DOE Biomass Program is conducting research to meet its 2013 target of 10 cents/lb biomass-derived glucose. NREL's approach is to use cellulolytic microbes to ferment cellulose and hemicellulose directly, which will result in lower feedstock costs.

Fiscal Year (FY) 2011 Objectives

- Perform hydrogen fermentation using cellulolytic bacteria and lignocellulosic biomass to lower feedstock cost.
- Perform metabolic pathway engineering to improve hydrogen molar yield via fermentation.
- Develop microbial electrolysis cell to improve hydrogen molar yield using waste from the fermentation of lignocellulosic biomass.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section (3.1.4) of the Hydrogen, Fuel Cells and Infrastructure Technologies Program's Multi-Year Research, Development and Demonstration Plan:

(AR) H₂ Molar Yield

(AS) Waste Acid Accumulation

(AT) Feedstock Cost

FY 2011 Accomplishments

- Conducted sequencing fed-batch reactor experiments and determined hydraulic retention time and optimal amounts of solid feeding in bioreactor using the cellulose-degrading bacterium *C. thermocellum* fermenting avicel. We realized improved rates of H₂ production via retaining those microbes that were adapted to degrade cellulose.
- Using a custom-designed plasmid (University of Manitoba, Canada) and improved transformation protocols, we obtained two mutant lines of *C. thermocellum*, which serve as the foundation for future genetic engineering effort in this microbe.
- A prototype two-chamber microbial electrolysis cell (MEC) was designed, constructed, and tested to eliminate methane generation. The reactor was operated at three different hydraulic retention times (HRTs; 24 h, 16 h, and 10 h) and produced H₂ gas at a maximum rate of up to 191 ± 34 mL/d and a maximum volumetric current of 62 ± 1 A/m³ at HRT 10 h. Using this new reactor design, nearly pure hydrogen was obtained.

Introduction

Biomass-derived glucose feedstock is a major operating cost driver for economic H₂ production via fermentation. The DOE Fuel Cell Technologies Program is taking advantage of the DOE Biomass Program's investment in

developing less expensive glucose from biomass to meet its cost target of 10 cents/lb by 2013. Meanwhile, one alternative and valid approach to addressing the glucose feedstock technical barrier (AT) is to use certain cellulose-degrading microbes that can ferment cellulose directly for H₂ production. One such example is the cellulose-degrading bacterium *Clostridium thermocellum* 27405 (*C. thermocellum*), which was reported to exhibit one of the highest growth rates using crystalline cellulose [1]. Another technical barrier to fermentation is the relatively low molar yield of H₂ from glucose (mol H₂/mol sugar; Technical Barrier AR), which results from the simultaneous production of waste organic acids and solvents. Biological pathways maximally yield 4 mole of H₂ per 1 mole of glucose (the biological maximum) [2]. However, most laboratories have reported a molar yield of 2 or less [3,4]. Molecular engineering to block competing pathways is a viable option toward improving H₂ molar yield. This strategy had resulted in improved H₂ molar yield in *Enterobacter aerogenes* [5].

A promising parallel approach to move past the biological fermentation limit has been developed by a team of scientists led by Bruce Logan at Pennsylvania State University (PSU). In the absence of O₂, and by adding a slight amount of negative potential (-250 mV) to the circuit, Logan's group has produced H₂ from acetate (a fermentation byproduct) at a molar yield of 2.9-3.8 (versus a theoretical maximum of 4) in a modified microbial fuel cell called an MEC [6]. It demonstrates for the first time a potential route for producing eight or more mole of H₂ per mole glucose when coupled to a dark fermentation process. Indeed, in FY 2009 the team reported a combined molar yield of 9.95 when fermentation was coupled to MEC in an integrated system [7]. Combining fermentation with MEC could therefore address technical barriers AR and AS (waste acid accumulation) and improve the techno-economic feasibility of H₂ production via fermentation.

Approach

NREL's approach to addressing feedstock cost is to optimize the performance of the cellulose-degrading bacterium *C. thermocellum*. To achieve this goal, we are optimizing the various parameters in a sequencing fed-batch reactor to improve longevity, yield, and rate of H₂

production. To improve H₂ molar yield, we are selectively blocking competing metabolic pathways in this organism via developing genetic methods. Via a subcontract, PSU is testing the performance of a MEC using both a synthetic effluent and the real waste stream from lignocellulosic fermentation generated at NREL.

Results

Lignocellulose Fermentation

Cellulose is a solid substrate and continuous feeding will eventually suffer from clogging of feed lines and over-exhaustion of the feed pump. A more feasible strategy for cellulose fermentation is via feeding the substrate at a predetermined interval in lieu of continuous feeding. This strategy can be realized via the development of a sequencing fed-batch bioreactor. This method also simultaneously retains the acclimated microbes to increase rate of H₂ production. We carried out the experiment in an Electrolab bioreactor with a working volume of 1 L. The medium was continuously sparged with N₂ at a flow rate of 16 ccm and agitated at 100 rpm. The HRT tested was 48 h with a daily carbon loading of 2.5 or 5.0 g/L of avicel. The reactor was initiated by running the fermentation using avicel at 2.5 g/L for 24 h, turning off the agitation for 1 h during which the unfermented substrate along with the attached microbes settled, followed by removing 500 ml of the clear supernatant, and adding back 500 ml fresh medium replenished with avicel (2.5 or 5.0 g/L). We completed a total of eight cycles, four cycles for each carbon loading condition (Table 2).

Initial results indicate that 5.0 g/L loading works better than 2.5 g/L, the residual avicel from the former caused retention of the acclimated *C. thermocellum*, which displayed an intense yellow color. Higher substrate also leads to faster rate of H₂ production. One of the benefits of sequencing batch fermentation is the decrease in the lag phase upon subsequent substrate feedings, once adapted. This is shown as a dramatic decrease in "time to peak H₂ production" (Table 2). The t₁ in batch one was almost 19 h, yet by the fourth cycle, it has dropped to mere 4 h, providing compelling evidence as to feasibility of the sequencing fed-batch process in fermenting solid substrates.

TABLE 2. Rate of Hydrogen and Metabolite Production in Sequencing Fed-batch Bioreactor with *Clostridium thermocellum* Fermenting Avicel Substrate

Batch	Avicel Concentration	Time to peak H ₂ production (t, h)	Amount of H ₂ produced (mmoles)	Average H ₂ Production Rate (mmol L ⁻¹ h ⁻¹)	Lactate	Formate	Acetate	Ethanol
	(g/L)							
1	2.5	18:43	14.92	0.60	1.98	3.06	28.15	18.46
2-4		4:14	13.85					
5	5.0	8:09	17.57	0.92	13.07	5.02	40.79	32.12
6-8		5:27	22.11					

Metabolic Engineering

The ultimate goal of this approach is to develop tools to inactivate genes encoding competing metabolic pathways, thus redirecting more cellular flux to improve H_2 molar yield. Transformation in this organism has been challenging likely due to either an inefficiency of the plasmids used or an active restriction system in the host thus destroying the incoming plasmid. NREL established an active collaboration with the researchers from University of Manitoba, Canada. Using their proprietary plasmid along with optimized protocols, we successfully generated two mutant lines in *C. thermocellum* harboring the plasmid. The success is based on two lines of evidence: (a) growth in the antibiotic chloramphenicol (100 mg/L) (Figure 1A); and (b) polymerase chain reaction (PCR) of the chloramphenicol-encoding gene (cm^r) in the transformant (Figure 1B). For the latter, briefly, plasmid deoxyribonucleic acid (DNA) was isolated from *C. thermocellum* transformants using Qiagen mini prep kit protocol except 20 mg/ml lysozyme was added to the buffer for cells lysis. PCR was carried out using the primer for chloramphenicol-resistance gene. We obtained the anticipated 218 bp PCR product and confirmed the presence of plasmids in the two transformants tested (Figure 1B). Moreover, plasmid DNA was isolated from four *C. thermocellum* transformants and transformed to the *E. coli* elite electro-competent cells (Lucigen, WI, USA). Plasmid DNA was then isolated from the *E. coli* transformants and resulted in the restriction pattern with EcoRI (1.2 kb fragment) that is consistent with the presence of the correct proprietary plasmid in *C. thermocellum* (data not shown).

Microbial Electrolysis Cell

Previously, a 2.5 L-single chamber MEC equipped with eight electrode pairs was used to produce H_2 under continuous flow conditions. However, in this type of single-chamber MEC, all H_2 gas produced was converted to methane. In order to suppress methane production in single chamber MECs, anode potentials were set at different values (from -0.4 V to $+0.2$ V vs. Ag/AgCl) using a potentiostat. MEC performance with a potentiostat was compared to that obtained with an applied voltage of 0.6 V using a power supply. In batch tests the largest total gas production (46 ± 3 mL) and best overall energy recovery in terms of electrical energy used and substrate energy ($\eta_{E+S} = 58 \pm 6\%$) was achieved at a set anode potential of -0.2 V, and methane production was reduced at the higher set anode potentials (Figure 2). However, although the optimum set anode potential (-0.2 V) suppressed methane generation in batch tests, and stable H_2 was obtained at the beginning of the continuous flow operation, the gas composition became predominantly methane in continuous flow tests. Switching the anode to a new reactor immediately resulted in H_2 production and recovery with little methane production. This indicated that the methane originated primarily from non-anode associated microorganisms in the continuous flow tests.

A new type of tubular type MEC was designed and built for additional tests. In this new type of MEC the anode and the cathode chambers were separated by an anion exchange membrane. Although this increases costs, this greatly benefits gas purity and has minimal impact on production rates. The average volumetric current density (I_{vol}) was 59 ± 1 A/m³ at an HRT of 24 h using acetic acid as a substrate.

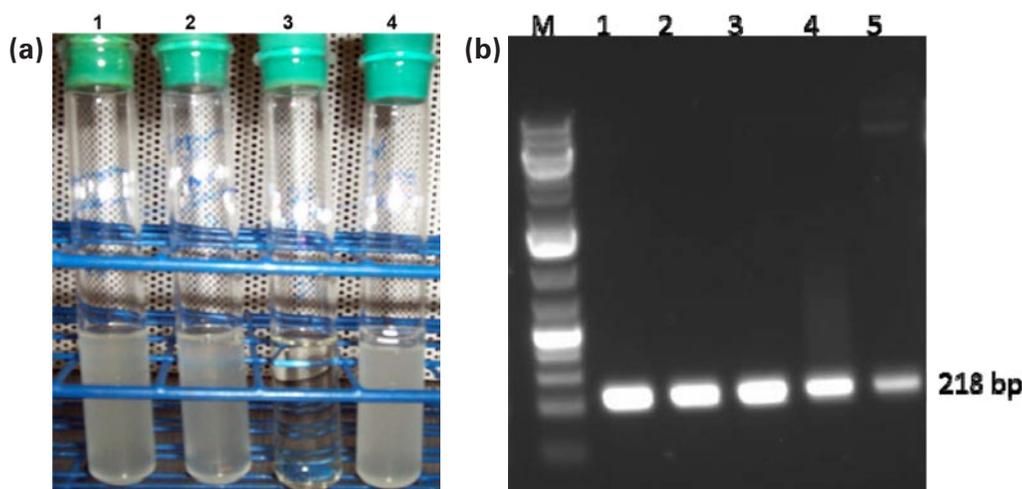

FIGURE 1. (A) Growth of *Clostridium thermocellum* transformants in liquid selection medium. 1. Transformants in 100 mg/L chloramphenicol, 2. Transformants without selection, 3. Control untransformed cells with 100mg/L chloramphenicol, 4. Control untransformed cells without antibiotic selection. (B) PCR amplification of chloramphenicol gene (cm^r) from plasmid DNA isolated directly from transformed *C. thermocellum*. Lanes 1, 2: colony # 1; lanes 3, 4: colony # 3, lane 5: plasmid positive control. M: molecular weight marker.

Shorter HRTs slightly increased the current, with average volumetric current densities of $60 \pm 1 \text{ A/m}^3$ (HRT 16 h) and $62 \pm 1 \text{ A/m}^3$ (HRT 10 h) (Figure 3). There were similar gas generation rates of $145 \pm 34 \text{ mL/d}$ at an HRT 16 h and $163 \pm 51 \text{ mL/d}$ at an HRT 24 h, but gas production increased to $191 \pm 34 \text{ mL/d}$ at HRT 10 h. This two-chamber MEC produced nearly pure H_2 in continuous mode as a result of the design that kept the cathode separated from the microorganisms on the anode and anode chamber.

Conclusions and Future Direction

- Using avicel cellulose as the substrate, we successfully conducted fermentation in the sequencing fed-batch mode. We determined that 5.0 g/L feeding was capable

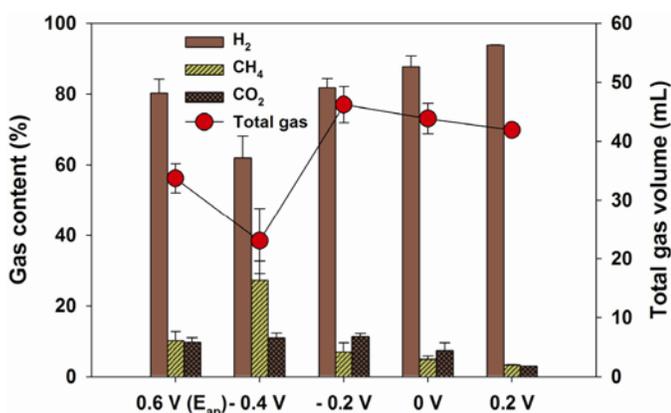

FIGURE 2. Hydrogen, methane, carbon dioxide contents and total gas volume at different set anode potentials and an added voltage of 0.6 V in batch tests.

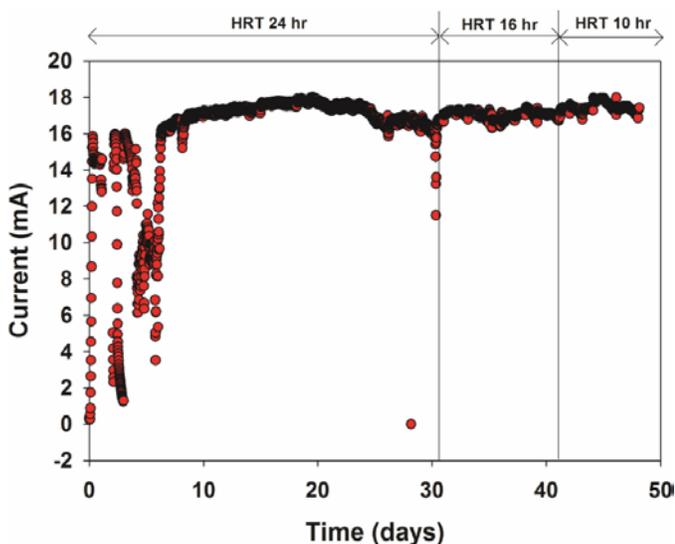

FIGURE 3. Current Generation at Different HRTs in a Two-Chamber MEC

of retaining more acclimated *C. thermocellum* which attached to the residual unfermented cellulose. The outcomes lead to higher rates and yield of H_2 . Retention of more acclimated microbes also significantly decreased lag time and led to a faster rate of H_2 production.

- We successfully developed genetic tools and produced two mutants in *C. thermocellum*. These tools will aid in the construction of targeted pathway mutants to improve yield of H_2 .
- In single chamber MECs, methanogenesis was suppressed by using higher anode potentials set by a potentiostat. However, it was revealed that methanogen proliferation could not be eliminated in this reactor because the methanogens were not primarily anode-associated.
- By separating the cathode from biological conditions in a new reactor design, nearly pure H_2 production was successful in a two-chamber continuous flow MEC with reasonable H_2 gas flow rates.

In the future, we will conduct sequencing fed-batch fermentation to further optimize hydraulic retention time, carbon substrate loading, and the volume of liquid replacement to improve rate and yield of H_2 production. We will continue to develop genetic tools for molecular engineering in *C. thermocellum* to alter its metabolic pathway to improve H_2 molar yield. In future MEC tests, following complete analysis of fermentation effluent, fermentation wastewater will be supplied to a two-chamber MEC in order to examine H_2 production from an actual fermentation effluent.

FY 2011 Accomplishments

JCVI

- We achieved higher hydrogenase activity from the environmentally derived hydrogenase expressed in cyanobacteria by adding additional transcriptional regulation to the gene cluster.
- The cyanobacterial ferredoxin was found to serve as an electron mediator to the environmentally derived hydrogenase.

NREL

- We developed genetic tools to manipulate the genome of *Rubrivivax gelatinosus* CBS and generated an affinity-tagged hydrogenase active in hydrogen production. This development will simplify hydrogenase purification for characterization in the long run.
- The *Rubrivivax* hydrogenase was expressed and purified from a *Synechocystis* host. The recombinant hydrogenase was shown to contain all four subunits (CooLXUH) forming a stable complex during aerobic growth of *Synechocystis*, albeit with no activity.
- Four *Rubrivivax* NiFe-hydrogenase maturation genes (*hypFCDE*) were transferred to *Synechocystis*, and HypE protein expression was confirmed. Expression of the maturation genes is a prerequisite for assembly of an active *Rubrivivax* NiFe-hydrogenase in *Synechocystis*.

Fiscal Year (FY) 2011 Objectives

Develop an O₂-tolerant cyanobacterial system for sustained and continuous light-driven H₂-production from water.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section (3.1.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (AH) Rate of Hydrogen Production
- (AI) Continuity of Photoproduction

Technical Targets

Characteristics	Current Status	2011 Target	2018 Target
Duration of continuous H ₂ photoproduction in air	Zero to 30 seconds in air	Produce a cyanobacterial recombinant evolving H ₂ through an O ₂ -tolerant hydrogenase	H ₂ production in air for 30 min

Introduction

Photobiological processes are attractive routes to renewable H₂ production. With the input of solar energy, photosynthetic microbes such as cyanobacteria and green algae carry out oxygenic photosynthesis, using sunlight energy to extract reducing equivalents from water. The resulting reducing equivalents can be fed to a hydrogenase system yielding H₂. However, one major difficulty is that most hydrogen-evolving hydrogenases are inhibited by O₂, which is an inherent byproduct of oxygenic photosynthesis. The rate of H₂ production is thus limited. Certain photosynthetic bacteria are reported to have an O₂-tolerant evolving hydrogenase, yet these microbes do not split water, and require other more expensive feedstocks.

To overcome these difficulties, we propose to construct novel microbial hybrids by genetically transferring O₂-tolerant hydrogenases from other bacteria into cyanobacteria. These hybrids will use the photosynthetic

machinery of the cyanobacterial hosts to perform the water-oxidation reaction with the input of solar energy, and couple the resulting reducing equivalents to the O₂-tolerant bacterial hydrogenase, all within the same microbe. By overcoming the sensitivity of the hydrogenase enzyme to O₂, we address one of the key technological hurdles to cost-effective photobiological H₂ production which currently limits the production of hydrogen in algal systems.

Approach

Our goal is to construct a novel microbial hybrid taking advantage of the most desirable properties of both cyanobacteria and other bacteria, to serve as the basis for technology to produce renewable H₂ from water. To achieve this goal, we use the following two approaches. The first approach is to transfer known O₂-tolerant hydrogenases from anoxygenic photosynthetic bacteria *Thiocapsa roseopersicina* and *Rubrivivax gelatinosus* to cyanobacteria. Since only a very limited number of O₂-tolerant hydrogenases are available, our second approach is to identify novel O₂-tolerant hydrogenases from environmental microbial communities and transfer them into cyanobacteria.

Results

JCVI

Previously, we reported the successful expression in cyanobacteria of active NiFe hydrogenases. These NiFe hydrogenases included the stable hydrogenase from *Thiocapsa roseopersicina* and a novel, environmentally-derived NiFe hydrogenase, HynSL, (previously named HyaAB). Although active hydrogenases were obtained indicating that all the required accessory proteins were expressed, the activity was low. We hypothesized that improved plasmid design may increase activity. The original expression plasmid, pRC41, expressed the environmentally-derived hydrogenase under the regulation of one promoter at the beginning of the 13 gene construct (Figure 1a). With such a long transcript (~13-kb), genes encoded at the end of the operon, such as the *hyp* genes, may not be expressed at sufficiently high levels to allow for maximal activity of the environmental hydrogenase in cyanobacteria. These genes at the end of the operon are required for maturation of the hydrogenase and must be transcribed at the optimal level.

In order to achieve higher expression throughout the gene cluster, we have re-engineered the expression plasmid to create pRC41-4 with an additional three promoters spaced throughout the operon (Figure 1a). The redesigned plasmid is also smaller after removing genes that we found did not contribute to hydrogenase maturation or function. Each new promoter sequence is preceded by a terminator sequence to create shorter transcripts that may be more stable.

When the plasmids were transferred to an *E. coli* strain lacking its native hydrogenases, strains containing

the redesigned plasmid, pRC41-4, and the single promoter control, pIY003, produced hydrogenase activity at similar levels in *E. coli* (Figure 1b). These plasmids were then successfully transferred to the cyanobacterium *S. elongatus* PCC 7942, and hydrogenase activity was measured (Figure 1c). Strain RC41-4 had approximately three-fold higher hydrogenase activity than the RC41 strain. We are currently working to increase this expression through further transcriptional modification.

To test whether HynSL could accept electrons from the native cyanobacterial ferredoxin, PetF, we obtained purified PetF from our collaborator at NREL and used it in place of methyl viologen in our *in vitro* hydrogenase assays. We tested extracts from our HynSL-expressing cyanobacterial strains in assays with PetF, but because of low HynSL expression levels, no hydrogen was detected (data not shown). However, when we used extracts from an *E. coli* strain expressing HynSL at a much higher level than the cyanobacterial strains, we were able to detect hydrogen produced via the PetF electron mediator (Table 1). This result provides evidence that the cyanobacterial ferredoxin can serve as an electron mediator for hydrogen production in strains over-expressing HynSL.

TABLE 1. Cyanobacterial Ferredoxin (PetF) can act as an electron mediator for the novel environmental hydrogenase, HynSL, expressed in *E. coli*.

<i>E. coli</i> Strain	Treatment	nmole H ₂ /mg protein/ h
Empty Vector	Dithionite + PetF	0.00
pRC41	Dithionite	0.04
pRC41	Dithionite + PetF	0.16

NREL

The overarching goal for the NREL work is to construct a cyanobacterial recombinant harboring the O₂-tolerant hydrogenase from *Rubrivivax gelatinosus*, using *Synechocystis* sp. PCC 6803 as a model host. A prerequisite for success is to gain better understanding of the *Rubrivivax* hydrogenase and its underlying maturation machinery to ensure transfer of the correct genes into *Synechocystis*. As such, we successfully developed genetic tools to manipulate the genome of *Rubrivivax*. We generated an affinity-tagged *Rubrivivax* hydrogenase with hydrogen production activity similar to the wild type enzyme (Figure 2a), and protein immunoblot confirmed expression (Figure 2b). This outcome could simplify hydrogenase purification for characterization and for comparison to the heterologously expressed *Rubrivivax* hydrogenase in *Synechocystis*. Using these genetic tools, we also successfully generated a *Rubrivivax* mutant lacking the *hypE* gene, which is putatively involved in the assembly of the *Rubrivivax* hydrogenase. However, the mutant displayed a wild-type level of hydrogenase activity, suggesting the presence of

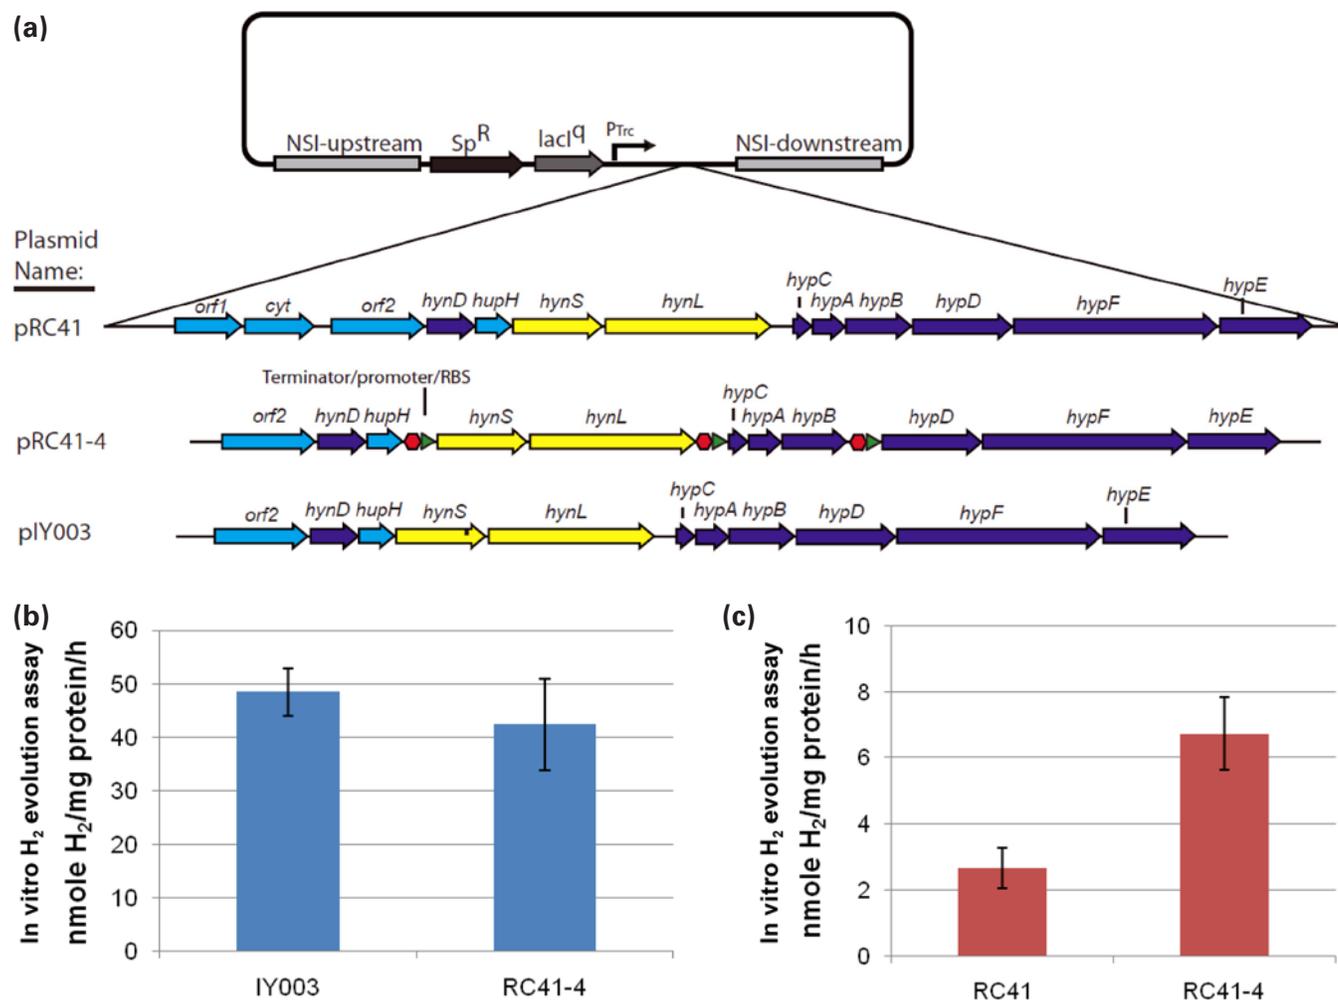

FIGURE 1. Re-engineered plasmids to express the environmentally derived hydrogenase HynSL. (a) The map of the original expression plasmids, pRC41, and modified plasmids, pLY003 and pRC41-4. Colors depict hydrogenase structural genes, HynSL (yellow), genes encoding essential maturation factors (dark blue), non-essential factors (light blue). Plasmids pLY003 and pRC41-4 are similar to pRC41 but is shortened by two genes. Plasmid pRC41-4 also has three additional terminators (red octagons) and promoters (green arrows). (b) *In vitro* H₂ evolution assay from *E. coli* strains expressing the environmental hydrogenase from strains containing plasmid pLY003 and pRC41-4. (c) *In vitro* H₂ evolution assay from cyanobacterial strains expressing the environmental hydrogenase from strains RC41 and RC41-4.

multiple copies of the *hypE* gene (data not shown). Work is underway to sequence the genome of *Rubrivivax*, which will guide construction of the recombinant *Synechocystis*.

Working toward building the cyanobacterial recombinant, four genes (*coolXUH*) encoding the multi-subunit *Rubrivivax* O₂-tolerant hydrogenase have been transformed in *Synechocystis*. The recombinant hydrogenase was purified, and protein immunoblot confirmed that all four subunits were expressed and formed a complex during aerobic growth of *Synechocystis*, albeit with no activity (Figure 3). This finding prompted us to additionally express the hydrogenase maturation genes,

hypABCDE, which are likely involved in the assembly and maturation of the *Rubrivivax* hydrogenase. We generated a construct containing the *Rubrivivax hypFCDE* genes and demonstrated integration of *hypFCDE* into the genome of *Synechocystis*. Protein immunoblot confirmed the expression of the HypE protein, suggesting the upstream HypFCD proteins are also expressed. However, no hydrogenase activity was detected in the *Synechocystis* recombinant line (already harboring the *coolXUH*) lacking its native hydrogenase. The expression of *hypAB* is underway.

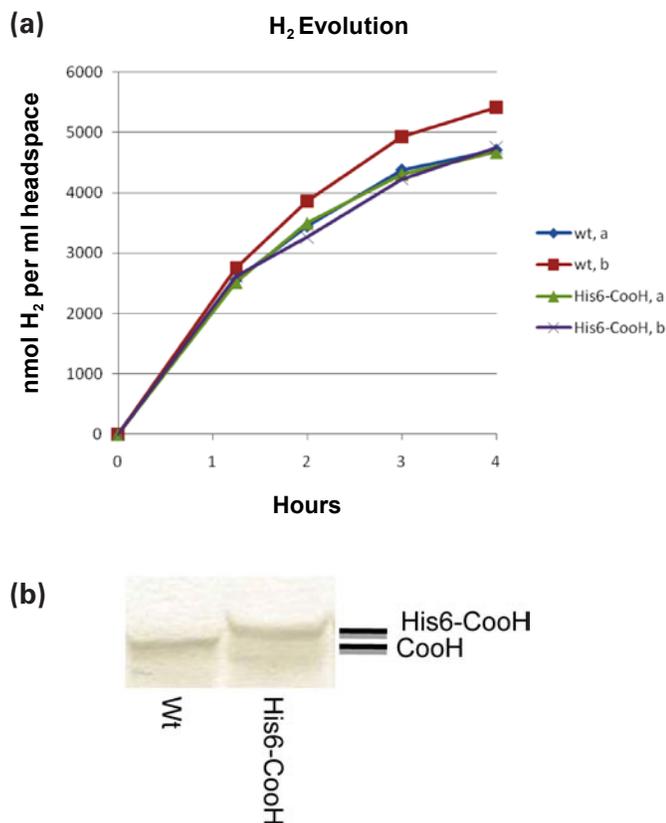

FIGURE 2. Hydrogen production in wild-type and affinity-tagged hydrogenase in *Rubrivivax gelatinosus* CBS. (a) wild-type and mutant *Rubrivivax* expressing His6-CooH were incubated with CO at time zero, and hydrogen evolution was monitored over time. (b) Protein immunoblot revealed that only the affinity-tagged version of the hydrogenase (His6-CooH) was expressed in the mutant cell line.

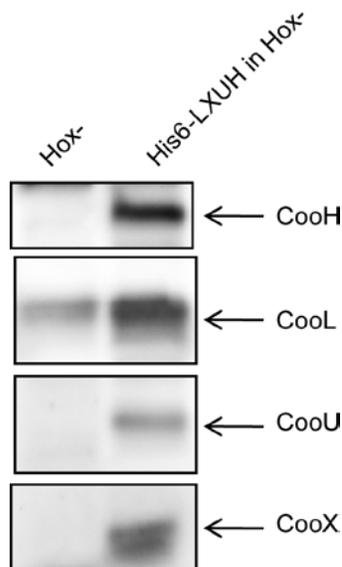

FIGURE 3. Protein immunoblot reveals expression of *Rubrivivax gelatinosus* CBS hydrogenase structural genes in a *Synechocystis* host.

Conclusions and Future Directions

Conclusions

JCVI

- Increased activity of the environmentally-derived hydrogenase can be achieved by modifying the transcriptional regulation of the gene operon.
- Cyanobacterial ferredoxin can act as an electron mediator to the environmentally derived hydrogenase.

NREL

- Using the genetic tools developed in *Rubrivivax*, we generated an active affinity-tagged hydrogenase to facilitate purification for characterization. Using these tools, we also successfully generated a *hypE* knock-out mutant in *Rubrivivax* to probe HypE function. However, the mutant displayed a wild-type level of hydrogenase activity, suggesting the presence of multiple copies of this maturation gene.
- Four *Rubrivivax* hydrogenase maturation genes (*hypFCDE*) were incorporated into the genome of a transgenic line of *Synechocystis* already harboring the *Rubrivivax* hydrogenase *cooLXUH* genes. We confirmed expression of HypE protein, albeit with no hydrogenase activity. Nevertheless, this *Synechocystis* strain will serve as the platform to express additional *Rubrivivax* hydrogenase maturation genes.

Future Directions

- We will continue to modify the environmentally-derived hydrogenase cluster to increase hydrogenase activity in cyanobacteria (JCVI).
- We will identify additional hydrogenase maturation genes using the sequenced genome of *Rubrivivax*. Once confirmed, these maturation genes of *Rubrivivax* will be transferred to express a functional O₂-tolerant hydrogenase in *Synechocystis* (NREL).
- We will optimize growth conditions to maximize the expression of the heterologous hydrogenase in *Synechocystis* (NREL).

Contract Number: DE-FG36-05GO15041

Start Date: December 1, 2004
 End Date: November 30, 2011

Fiscal Year (FY) 2011 Objectives

- Minimize, or truncate, the chlorophyll antenna size in green algae to maximize photobiological solar conversion efficiency and H₂-production.
- Demonstrate that a truncated chlorophyll (Chl) antenna size would minimize absorption and wasteful dissipation of sunlight by individual cells, resulting in better light utilization efficiency and greater photosynthetic productivity by the green alga mass culture (Table 1).

Technical Barriers

This project addresses the following technical barriers from the Biological Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (AG) Light Utilization Efficiency: Low light utilization efficiency in photobiological hydrogen production due to a large photosystem chlorophyll antenna size.

Technical Targets

The Fuel Cell Technologies Program Multi-Year Plan technical target for 2005 for this project was to reach a 10% utilization efficiency of absorbed light energy (out of a theoretical maximum of 30% possible) in unicellular green. Progress has currently achieved a green alga utilization efficiency of absorbed light energy of about 25% (Table 2).

Approach

- Employ deoxyribonucleic acid (DNA) insertional mutagenesis, screening, biochemical and molecular genetic analyses for the isolation of “truncated Chl antenna size” mutants in the green alga *Chlamydomonas reinhardtii*.
- Clone and characterize the gene(s) that affect the “Chl antenna size” property in *Chlamydomonas reinhardtii*.
- Apply such genes to generate a “truncated Chl antenna size” in this and other green algae.

FY 2011 Accomplishments

- Successfully cloned the *Tla2* gene and fully elucidated its function. Manuscript and disclosure in preparation.
- Successfully cloned the *Tla3* gene. Currently, conducting biochemical analyses and are in the process of elucidating the *Tla3* gene function.

TABLE 1. *Chlamydomonas reinhardtii* cellular chlorophyll content (Chl/cell), chlorophyll antenna size for photosystem-II (Chl-PSII) and photosystem-I (Chl-PSI), and energy utilization efficiency in wild type, *tla1*, *tla2* and *tla3* mutant strains, as determined by spectrophotometric kinetic analysis (n = 5, ± standard deviation).

Introduction

The goal of the research is to generate green algal strains with enhanced photosynthetic productivity and H_2 -production under mass culture conditions. To achieve this goal, it is necessary to optimize the light absorption and utilization properties of the cells [1-4]. A cost-effective way to achieve this goal is to reduce the number of Chl molecules that function in the photosystems of photosynthesis. Thus, efforts are under way to isolate microalga mutants with a truncated chlorophyll antenna size.

The rationale for this work is that a truncated light-harvesting Chl antenna size in green algae will prevent individual cells at the surface of the culture from over-absorbing sunlight and wastefully dissipating most of it (Figure 1). A truncated Chl antenna size will permit sunlight to penetrate deeper into the culture, thus enabling many more cells to contribute to useful photosynthesis and H_2 -production (Figure 2). It has been shown that a truncated Chl antenna size will enable about 3-4 times greater solar energy conversion efficiency and photosynthetic productivity than could be achieved with fully pigmented cells [5].

Approach

The focal objective of the research is to identify genes that control the Chl antenna size of photosynthesis and, further, to elucidate how such genes confer a truncated Chl antenna size in the model green alga *Chlamydomonas reinhardtii*. Identification of such genes in *Chlamydomonas* will permit a subsequent transfer of this property, i.e., “truncated Chl antenna size”, to other microalgae of interest

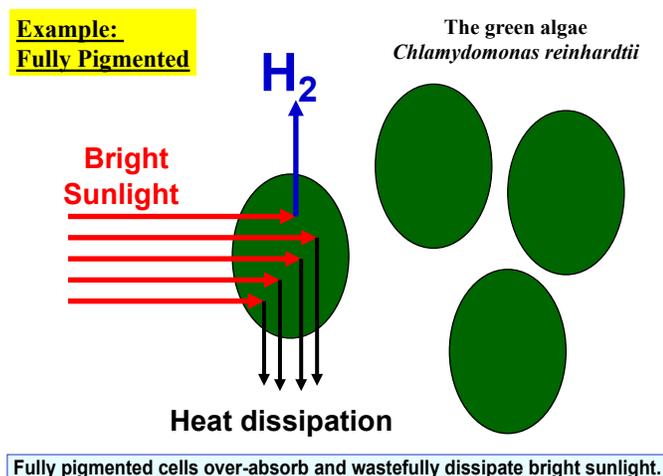

FIGURE 1. Schematic presentation of the fate of absorbed sunlight in fully pigmented (dark green) algae. Individual cells at the surface of the culture over-absorb incoming sunlight (i.e., they absorb more than can be utilized by photosynthesis), and ‘heat dissipate’ most of it. Note that a high probability of absorption by the first layer of cells would cause shading of cells deeper in the culture.

to the DOE Fuel Cell Technologies Program. This objective is currently being approached through DNA insertional mutagenesis/screening and biochemical/molecular/genetic analyses of *Chlamydomonas reinhardtii* cells.

Results

The *tla2* mutant plasmid insert site has been cloned and a gene of interest has been tentatively identified as causing the *tla2* mutation. This molecular and genetic analysis is currently in progress. Work further described the isolation and biochemical and physiological characterization of a new mutant of *Chlamydomonas reinhardtii*, termed *tla3*. Properties of the *tla* “truncated Chl antenna size” strains so far isolated are summarized in Tables 1 and 2, and Figure 3. The *tla3* mutant has the smallest yet Chl antenna size known in green algae.

Future efforts will be directed toward the cloning and characterizing the genes responsible for the *tla* phenotype in *tla2* and *tla3* mutants.

Conclusions

- Significant, ahead-of-schedule progress was achieved in terms of acquiring “truncated Chl antenna size” mutants. This demonstrates feasibility of the approach chosen and success of the methods employed.
- A truncated light-harvesting chlorophyll antenna size in the *tla*-type mutants enhanced solar conversion efficiencies and photosynthetic productivity under bright sunlight conditions.

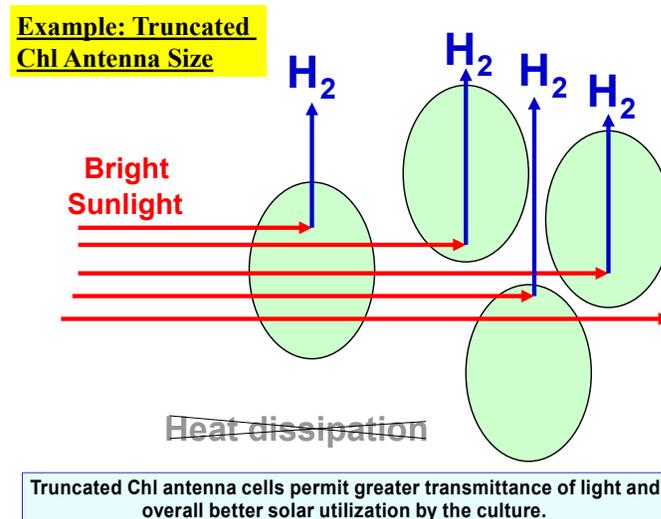

FIGURE 2. Schematic of sunlight penetration through cells with a truncated chlorophyll antenna size. Individual cells have a diminished probability of absorbing sunlight, thereby permitting penetration of irradiance and H_2 -production by cells deeper in the culture.

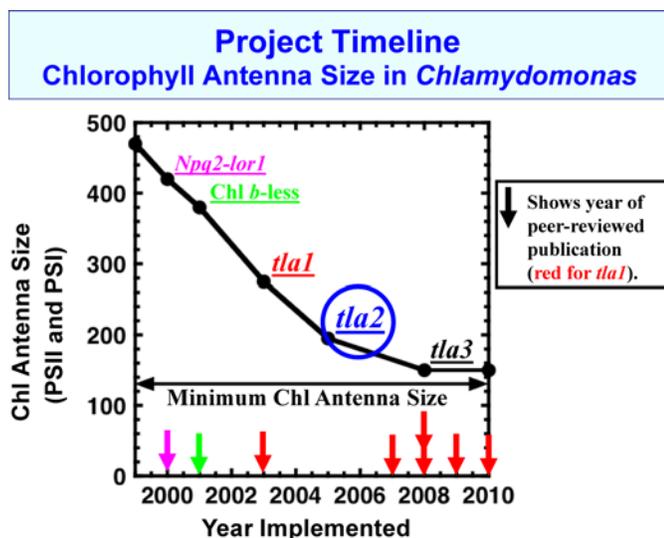

FIGURE 3. Project timeline and publications record on the truncated chlorophyll antenna size project. Arrows show publication year of peer-reviewed paper for each of the truncated Chl antenna size mutants. Note that work with the *tla2* and *tla3* strains is now reaching the stage of a peer-reviewed paper.

- Insights on the molecular mechanism for the regulation of the Chl antenna size by the *Tla1* gene were obtained (results not shown pending publication of these findings in a peer reviewed journal).

Future Directions

- Advance the biochemical and molecular characterization of the *tla2* and *tla3* strains.
- Publish results on the *tla2* and *tla3* phenotypes.
- Establish transformation (sense and antisense) protocols with *Tla*-type genes to enhance the down-regulation of the Chl antenna size in *Chlamydomonas reinhardtii*.

Technical Targets

Biological H ₂ Production	Units	2013/2018	Purdue 2010
Hydrogen Yield Percentage	%	20/30	utilizing organic wastes

FY 2011 Accomplishments

- Currently completing the fourth generation of the experimental test matrix and continue to test various combinations of waste material and inocula under various operating conditions. The developed optimized process has significantly increased hydrogen production. For the test matrix, gas volume is being measure by a calculation employing head space pressure. These values are correlated with gas molecular composition values from the gas chromatograph to give hydrogen production levels. The optimized values are used in the energy model and initial design the modular energy system. Measurements of pH are recorded during a portion of data runs.
- Homogeneity of feed stock is assured through the use of statistical sampling techniques. The water content of the substrate was preliminarily reduced from 98% to 60% with minimal decrease in hydrogen production. Methods to further decrease water content and ways to support substrate were tested. Distiller's dried grains (DDGS) are being tested as a substrate for hydrogen production. A new process has been developed that has greatly increased hydrogen yields for DDGS. This could significantly increase the efficiency of ethanol production from corn. A continuous fermentor (New Brunswick, BioFlo[®]/CelliGen[®] 115, 3 L) is being used to consider larger batch sizes and the influence of continuous feed of substrate on the values of optimal operating parameters. Currently DDGS is being tested in the fermentor. We are also exploring existing catalytic methods including nano catalysts for capture of CO₂ from the fermentation process. The vacuum tube solar pre and post process apparatus is fully operational and being used for pre and post processing of waste material.

Fiscal Year (FY) 2011 Objectives

- Investigate and evaluate initial processes for the production of hydrogen from various waste streams using microbial fermentation.
- Investigate paths for implementation of the research as a modular energy source initially for application in remote locations.

Technical Barriers

This project addresses the following technical barriers from the Biological Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(AR) H₂ Molar Yield

(AT) Feedstock Processing Cost

(AU) Systems Engineering

Introduction

This project allows the creation of a Hydrogen Research Laboratory in a unique partnership between Purdue University's main campus in West Lafayette and the Calumet campus. This laboratory is engaged in basic research in hydrogen production and storage and has initiated

engineering systems research with goals established as per the DOE Fuel Cell Technologies Program.

Bio-production of hydrogen is potentially an important renewable source of energy. Using organic wastes for bio-production of hydrogen not only has the potential to generate cost-effective and renewable energy but also can reduce pollution in the environment and provide a source of fertilizer for growing crops. The purpose of the current research effort is to investigate, obtain data, and evaluate initial processes for the production of hydrogen from various waste streams using microbial fermentation and investigate possible paths for implementation of the technology as a local electric and thermal energy source. This effort is targeted to assure that the developed technology will be applicable for integration into various current and future energy supply options including the Department of Energy Road Map. This effort is investigating ways to develop a modular anaerobic biological hydrogen production and energy system for applications initially in remote locations. It is realized that hydrogen production levels from conventional anaerobic processes are not as great as is desired in the long-term perspective for bulk production systems. This research is focusing on a process that has multiple products and associated values. Value streams include hydrogen, waste disposal function, heat for buildings, drinking water, and possibly a marketable chemical product produced from process carbon dioxide. After it is proven, it is anticipated that the technology will be leveraged to larger applications in continuing research

efforts. We have performed preliminary cost analysis studies, but factors such as the water content greatly influence the design and consequently the cost. It is also necessary to consider aspects such as the value of waste disposal, sanitized fertilizer, and ancillary energy. These aspects depend on the details of the process currently being developed. Preliminary estimates indicate that when all costs and benefits are considered, the technology has advantages over other alternatives for this application. The carbon dioxide capture portion of the process is intended principally for gas conditioning. Carbon dioxide is a co-product and H₂ purification is usually necessary. The potential for utilization of the captured CO₂ in the production of chemical products is under investigation as a part of maximizing the utility of the proposed self-contained system. Figure 1 shows an overview of major process inputs and products.

Approach

We have developed methods to optimize hydrogen production from waste through the use of a fermentation process. The optimization procedure forms the foundation for the subsequent development of a modular device that will use various waste streams, including garbage, animal or human waste, and DDGS for the production of hydrogen. This hydrogen will be separated from the bio-gas stream by use of nano catalyst or a membrane for use in a fuel cell or reciprocating engine to produce electricity locally. Methods

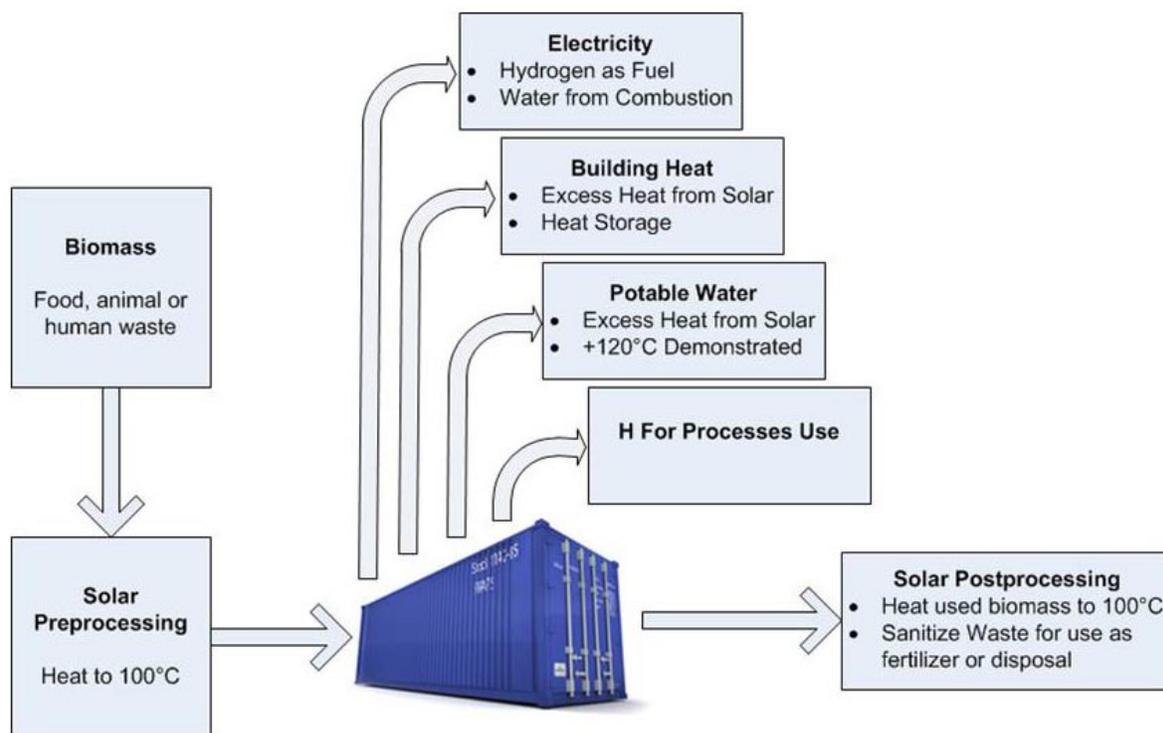

FIGURE 1. Modular System Major Inputs and Products

to sequester CO₂ as part of the process are also being considered. Energy for the pre- and post-processing of feed streams is being obtained from a solar collector system. A steam generator is attached to the solar system and is used to test production of potable water. Computer simulations of the process indicate that the system can be installed in a shipping container and used to provide local electric and thermal energy. Initial efforts have reduced the amount of water in the processed waste material from 98% to 75% with minimal decrease in hydrogen production. By reducing the fraction of water it will be possible to reduce the volume and weight of the bio reactor and increase the system efficiency and viability.

Results

Additional inocula have been tested and the concentration of hydrogen in the produced gas has been correlated with the experimental variables: pH, temperature, and substrate concentration. We have developed a new procedure for producing hydrogen with DDGS that shows considerably higher hydrogen production levels than any observed to date. We continue to investigate this approach. If verified, this may provide a new alternative for increasing hydrogen production levels with DDGS and provide a potential enhancement to the energy balance for ethanol production. Considerable interest in these results has been shown by the Industrial Advisory Board for the project since it could be of value for multiple industrial processes.

Test samples and data are being exchanged between Purdue Calumet and Lafayette and trials to test repeatability continue. A micro gas chromatograph (GC, CP-4900 Dual Channel Micro-GC; Varian Inc., equipped with a thermal conductivity detector and a 10 M-5A molecular sieve column with argon as the carrier gas for hydrogen and a 10 M Poraplot® [Varian, Inc.] column with helium as the carrier gas for CO₂). The testing program is based upon a central composite experimental design. We are currently completing the fourth iteration for the optimization of the hydrogen production levels. This process identifies combinations of operating variables that maximizes hydrogen production. Figure 2 shows a comparison of hydrogen production from the initial and optimized procedure for hydrogen production from DDGS for the multiple testing device. The multiple testing device that was developed as part of this research effort is fully operational and is being used to generate data. This device provides the capability to conduct multiple simultaneous tests with automated data processing and monitoring. Continuous production testing is currently being conducted at Purdue Lafayette. Testing of dry substrate designs are being investigated at Purdue Calumet and Lafayette. The model for the modular energy system was updated based upon new experimental values. Efforts using a catalyst process for capture of carbon dioxide have been initiated. The solar system testing for sanitizing waste material and production of potable water is ongoing.

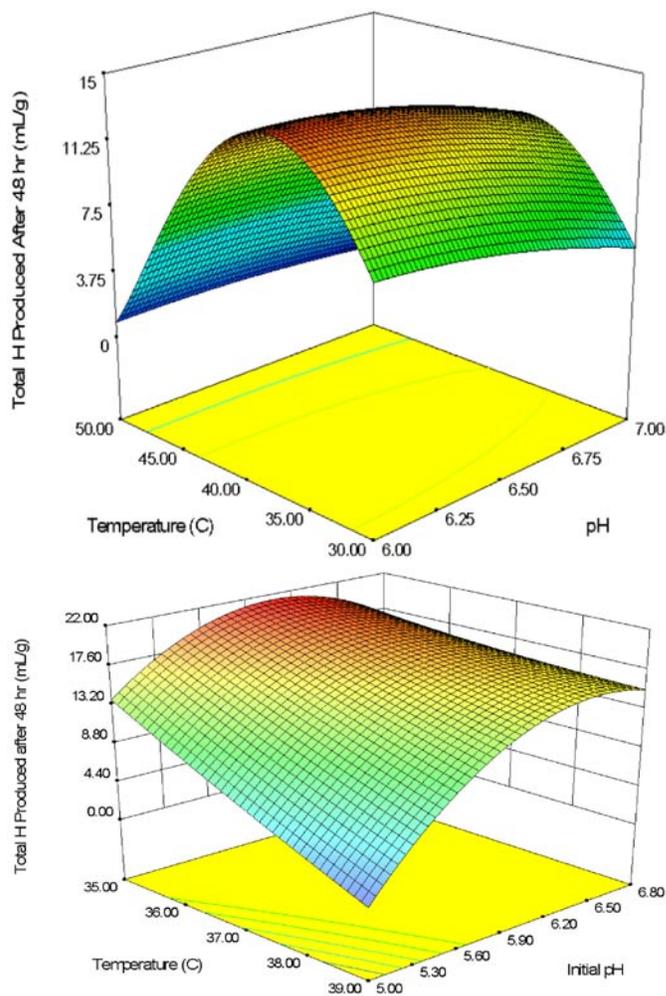

FIGURE 2. Comparison of H₂ Concentration for Previous (Top) and Optimized (Bottom) Method for DDGS

Conclusions and Future Directions

The biological hydrogen production work will include investigating optimal hydrogen production cultures for different substrates, reducing the water content in the substrate, and integrating results from the vacuum tube solar collector pre and post processing tests into an enhanced energy system model. The automated testing device will continue to be used to consider optimal hydrogen production conditions using statistical testing procedures. Testing with the continuous fermentor will be expanded to consider issues associated with continuous feed of substrate and scale up of the process. Gas flow from the fermentor is being measured with a mass flow meter. These flow values, combined with GC analysis data, are used to determine the concentration and volume of gas produced as a function of time. Values of pH are recorded continuously and are used to compare hydrogen, dissolved oxygen, and pH values as a function of time. We will also explore existing catalytic methods including nano catalysts for capture of CO₂ from

the fermentation process. The next phase of the research will involve the construction a bench top reactor based on the current test results and designs that will operate with dryer waste material and use solid material handling techniques. Funding is currently not available for the actual construction of the dry bench top test unit. This research considers hydrogen production, but also considers the leveraging of other value streams to overcome design issues that have arisen in the past. We consider this process to have significant value for waste processing and heat production as well as hydrogen production. The use of catalysis to condition the bio-gas stream also adds value to the process that has not been considered in the past for this application.

Subcontractor:
Directed Technologies, Inc., Arlington, VA

Project Start Date: 2010
Project End Date: Project continuation and
direction determined annually by DOE

Fiscal Year (FY) 2011 Objectives

Update the H2A central and forecourt models to:

- Incorporate new knowledge.
- Incorporate new Annual Energy Outlook (AEO) fuel cost projections.
- Update baseline year.
- Re-evaluate assumptions.

Technical Barriers

This project addresses the following technical barriers from the Systems Analysis section (4.5) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (B) Stove-piped/Siloed Analytical Capability
- (D) Suite of Models and Tools
- (E) Unplanned Studies and Analysis

Technical Targets

The update of the H2A models directly supports the following milestones from the Systems Analysis function from FY 2004 through FY 2016.

Milestone 26	Annual model update and validation. (4Q, 2008; 4Q, 2009; 4Q, 2010; 4Q, 2011; 4Q, 2012; 4Q, 2013; 4Q, 2014; 4Q, 2015)
Milestone 39	Annual update of Analysis Portfolio. (4Q, 2007; 4Q, 2008; 4Q, 2009; 4Q, 2010; 4Q, 2011; 4Q, 2012; 4Q, 2013; 4Q, 2014; 4Q, 2015)

FY 2011 Accomplishments

Three primary tasks were completed to update the H2A central and distributed case studies:

- Primary assumptions and values were reviewed and updated as needed.
 - Cost of land increased from \$5,000 to \$50,000 per acre.
 - Construction period increased from two to three years with little expenditure during the first year.
 - Compression, storage, and dispensing calculations were updated to reflect a new baseline of 10,000 psi onboard storage pressure.
- The reference year was updated to 2007.
 - Startup year changed from 2005 to 2010 current, 2020 future.
 - Feedstock prices were updated using the AEO 2009 reference case and program values.
 - Capital costs were updated to 2007 dollars using Chemical Engineering Progress Cost Indexes (CEPCI).
 - Operating and other material costs were updated using appropriate indexes (consumer price indexes, labor indexes, SRI chemical price indexes).
- Templates were developed for central and distributed case studies.

Introduction

In FY 2007 and FY 2008 the H2A hydrogen production discounted cash flow model was extensively revised and updated. The model was divided into separate forecourt and central versions and major new functionality including plant scaling, carbon sequestration, and new forecourt calculations were added. The model templates and 19 updated case studies were published in FY 2008. Version 2.1 of the H2A Hydrogen Production Model was uploaded to the H2A website on December 5, 2008. Version 2.1 incorporated minor fixes and improvements to the model. NREL, in consultation with researchers, is currently developing version 3 of the H2A hydrogen production models.

In Version 3, the reference year and costs have been updated to 2007 and major assumptions have been reviewed and updated as appropriate. Four new technologies have been added: solar thermo-chemical, photo-electrochemical and biological hydrogen production and reforming of bio-derived liquids.

Approach

Version 3 templates were developed for the H2A distributed and central hydrogen production models. The templates were reviewed for accuracy and completeness and the existing published H2A case studies were ported into the new templates. New case studies based on the templates, were developed for the four new technologies. All the completed case studies were reviewed for accuracy and completeness. The version 3 H2A case studies will be published on the DOE website (https://apps1.hydrogen.energy.gov/h2a_analysis.html). Case study reports outlining the changes to each technology case study were developed.

Results

The H2A production model central and forecourt primary assumptions were reviewed, and default values adjusted as necessary. New feedstock price tables were added to the model: AEO 2009 reference case, AEO 2009 high price case, and AEO 2010 reference case. CEPCI, consumer price index, labor index, and chemical price index tables were updated or added.

Nth plant assumptions were reviewed for the forecourt H2A models. The Nth plant assumption provides a context for estimating the effect of prior experience on capital and indirect costs for forecourt stations. At the technology readiness date, Nth plant assumptions apply; costs have decreased substantially because of learning, production

economies, and modularization. Figure 1 presents a hypothetical hydrogen production cost reduction plot for a technology with a technology readiness date of 2015. Nth plant also applies to stations. Station design is assumed to be modular, but each site also has unique features that affect layout and design and increase costs for some aspects of the facility.

Nth plant assumptions include:

- Moderate annual system production rate: 50–150 systems per year.
- Substantial reduction in system cost but not full automation.
- Corresponding markups: could be ~50% gross margin.

Several new calculations were added to the forecourt model to provide more flexibility in specifying the facility’s operating characteristics and to more accurately size equipment. New compression, storage, and dispensing calculations were added to model a new default refueling pressure of 700 bar (10,000 psi). The new calculations are based on the NREL H2A Delivery Components Model (NREL 2010, http://www.hydrogen.energy.gov/h2a_delivery.html). New calculations were also added to more accurately define the amount of onsite storage required to supply hydrogen during fluctuations in daily and weekly demand and during outages (see Figure 2) and to enable the user to define the weekly dispensing profile (Figure 3).

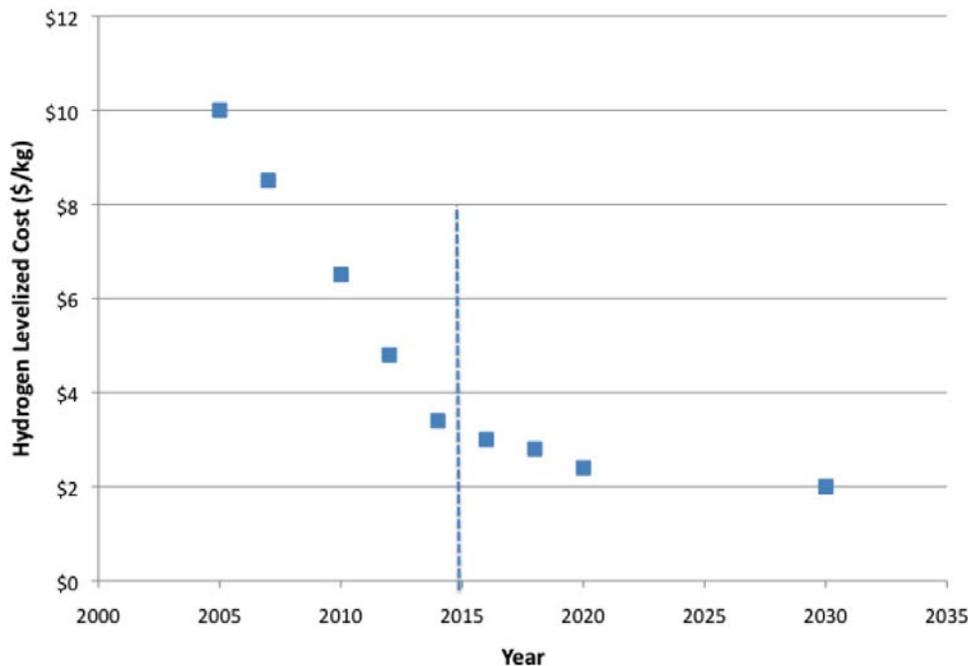

FIGURE 1. Hypothetical Hydrogen Cost Reduction Plot for a Technology with a Technology Readiness Date of 2015

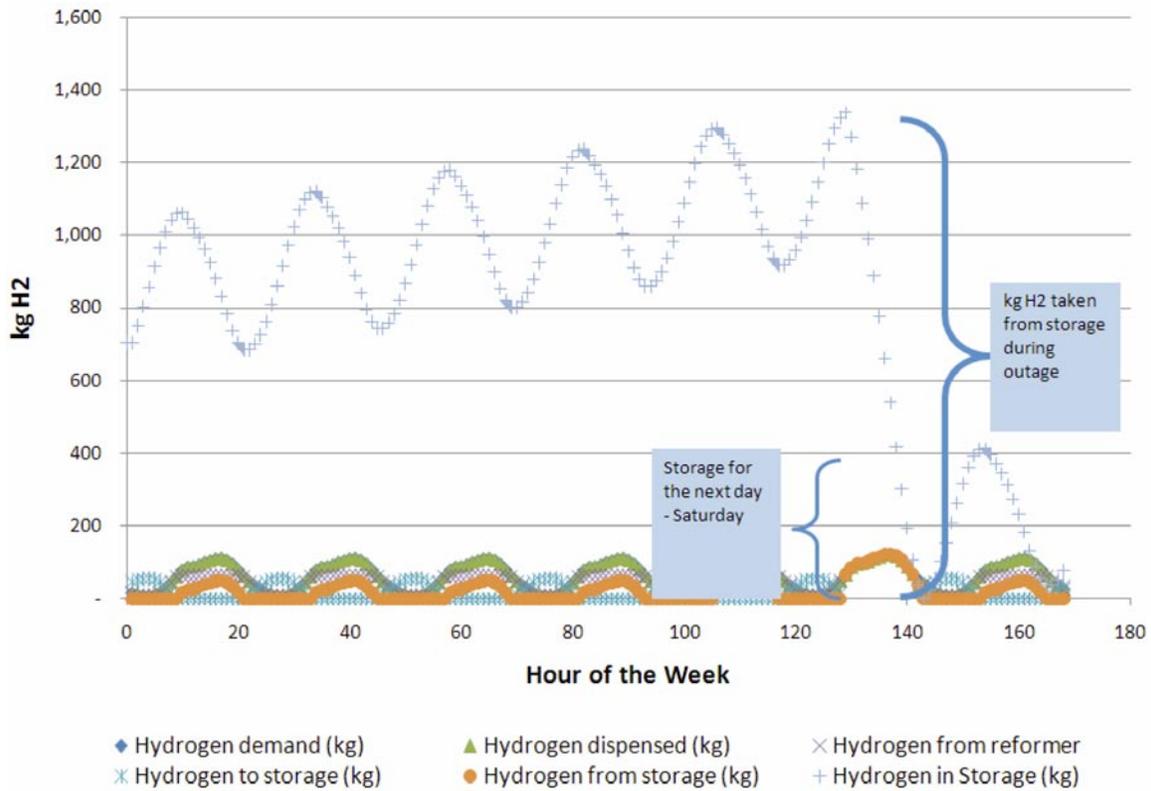

FIGURE 2. Hydrogen Dispensing and Storage Profile for a Week in the Summer – Worst Case Scenario Reformer Outage

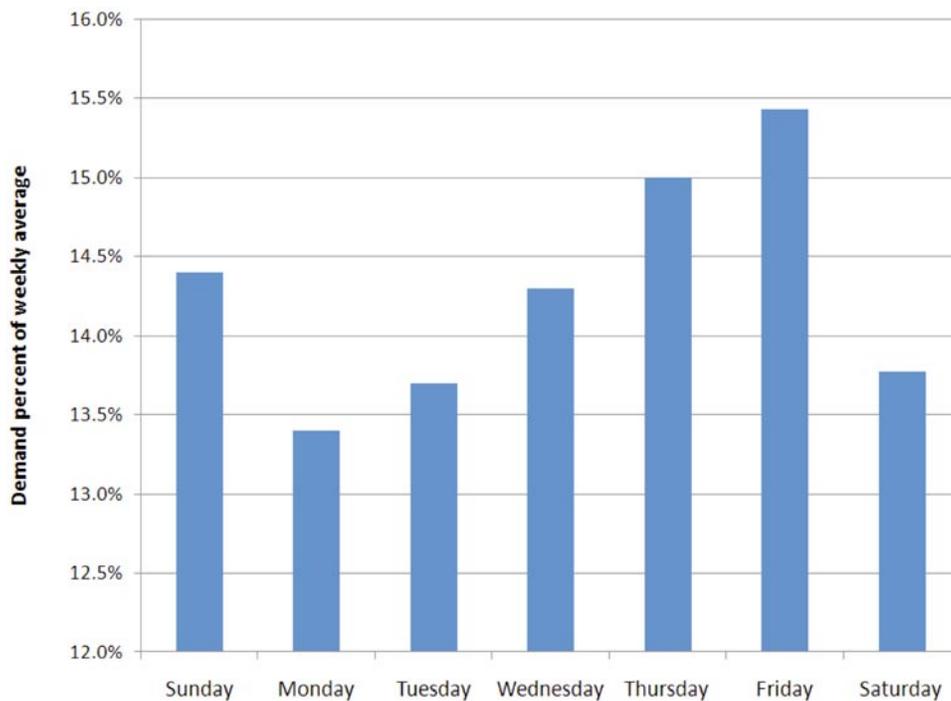

FIGURE 3. User-Defined Weekly Dispensing Profile

Conclusions and Future Directions

Development of Version 3 of the H2A hydrogen production models was necessary to maintain accuracy in the model and consistency with other DOE models. Updating to 2007 dollars and re-evaluation of Nth plant assumptions increased costs for all technologies. However, both top-down and bottom-up cost targets for all technologies are also being updated and will be using consistent assumptions.

FY 2011 Publications/Presentations

The following hydrogen production technology case studies will be published on the DOE website (https://apps1.hydrogen.energy.gov/h2a_analysis.html):

1. Current and Future Central Hydrogen Production via Biomass Gasification
2. Current and Future Central Hydrogen Production from Grid Electrolysis
3. Current and Future Central Hydrogen Production from Coal without CO₂ Sequestration
4. Current and Future Central Hydrogen Production from Coal with CO₂ Sequestration
5. Current and Future Central Hydrogen Production from Natural Gas without CO₂ Sequestration
6. Current and Future Central Hydrogen Production from Natural Gas with CO₂ Sequestration
7. Future Central Hydrogen Production from Nuclear Energy via High Temperature
8. Current and Future Forecourt Hydrogen Production from Grid Electrolysis (1,500 kg per day)
9. Current and Future Forecourt Hydrogen Production from Natural Gas (1,500 kg per day)
10. Current and Future Forecourt Hydrogen Production from Ethanol (1,500 kg per day)

Contract Number: DE-SC0001486

Project Start Date: August 15, 2010
Project End Date: August 14, 2012

FY 2011 Accomplishments

- Determined performance and operational limits of a cathode-feed electrolyzer that circulated water using a thermosiphon, rather than a circulating pump.
- Updated electrolyzer and compressed hydrogen safety codes and standards.
- Performed 50 cm² 2,000 psig (pumped cathode feed) electrolysis tests in a pressure dome.
- Tested Dimensionally Stable Membrane (DSM™) in balanced-pressure 17-cell 50 cm² 2,000 psig (pumped anode feed) stack in pressure dome.
- Completed first round of tests on protective coatings for pressure containment dome internals.
- Assembled pressure swing absorber dryer for sorbent testing.
- Began preliminary system layouts of proton exchange membrane (PEM) electrolyzer HRA breadboard system.

Fiscal Year (FY) 2011 Objectives

- Detail design and demonstrate subsystems for a unitized electrolyzer system for residential refueling at 5,000 psi to meet DOE targets for a home refueling appliance (HRA).
- Fabricate and demonstrate unitized 5,000 psi system (Year 2).
- Identify and team with commercialization partner(s).

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan [1]:

(G) Cost

(H) System Efficiency

Technical Targets

TABLE 1. Giner Electrochemical Systems, LLC (GES) Progress toward Meeting DOE Targets for Distributed Electrolysis Hydrogen Production [1]

Characteristics	Units	2017–2020 Targets	GES Status
Hydrogen Cost	\$/kg H ₂	2.00–4.00	2.99*
Electrolyzer Capital Cost	\$/kg H ₂	0.30	0.99
Electrolyzer Energy Efficiency	% (LHV)	74	73.6**

*Using H2A model rev 2.1.1; **5,000 psi operation; LHV = lower heating value

Introduction

U.S. automakers have invested significant resources in the research and development of hydrogen fuel cell vehicles. However, to enable the widespread use of fuel cell vehicles, an additional major investment will be required to construct an infrastructure for hydrogen production and delivery to fueling stations. In order to facilitate this transition, it has been recommended that high-pressure hydrogen, generated at 5,000 psig for home refueling of fuel cell vehicles, be implemented as an intermediary approach.

GES has matured a PEM-based electrolyzer technology for producing hydrogen at moderate to high pressure directly in the electrolyzer stack, while oxygen is evolved at near-atmospheric pressure. In this system, liquid water, which is a reactant as well as coolant, is introduced into the oxygen side at near atmospheric pressure; high-pressure hydrogen is removed from the product side. An improved, low-cost process for producing high-pressure hydrogen from water by electrolysis will significantly advance the development of the hydrogen economy, providing hydrogen for fuel cell vehicles at a price competitive with that of gasoline on a per-mile basis. The ability to produce hydrogen economically, the relatively low capital cost of the electrolyzer unit, and the low maintenance cost of the unit will allow widespread distribution of hydrogen home fueling appliances deemed necessary for the introduction of fuel cell vehicles.

Approach

GES is currently conducting a multi-year development project for DOE (Contract DE-FC36-08GO18065) that aims to reduce commercial electrolyzer costs while simultaneously raising the efficiencies of the PEM-based water electrolyzer units operating in the range of 400 psi. Future extension of this technology to pressures of 5,000 psig is feasible with modifications to the electrolyzer stack, providing the ability to safely operate in a balanced hydrogen/oxygen pressure mode. Based on an innovative electrolyzer stack concept and recent developments in high strength membrane, GES has designed a PEM-based water electrolyzer system for home refueling applications that will be able to deliver hydrogen at pressures of 5,000 psi. The design concept generates high-pressure hydrogen by means of “unitizing” the electrolyzer stack with a high-pressure hydrogen/water phase-separator and other subsystems. The combination of components eliminates the need for bulky and costly stack parts and facilitates a method for fabricating an electrolyzer system that can safely operate at a balanced hydrogen pressure of 5,000 psi. In addition, a reduction of major system components and system cost is realized.

Results

Electrolyzer Stack Design: The HRA has been designed for on-demand operation. The system is designed with a small 6-cell 2 kWe electrolyzer stack, providing a vehicle tank fill of 0.5 kg of hydrogen over a 12-hour period. This will provide 30 miles of driving range based on current fuel cell vehicle fuel economy estimates of 60 miles/kg-H₂. The electrolyzer stack is totally enclosed in a pressure

containment dome; the pressure in the pressure dome is matched to that of the electrolyzer’s hydrogen and oxygen product streams. This pressure dome-based design markedly simplifies many of the stack design requirements. Operating in the dome at pressures up to 5,000 psig, the 6-cell stack has a design pressure of 100 psid, and a proof pressure of 150 psid, meeting the requirements of the draft International Organization for Standardization (ISO) Standard ISO_DIS_22734-2 [2].

Preliminary Design of a 5,000 psi “Unitized” Electrolyzer System for Home Refueling: A block diagram outlining the process configuration for the 5,000 psi (34.6 MPa) PEM HRA is shown in Figure 1. The direct production of high-pressure hydrogen in the electrolyzer is shown via combining the water storage tank, electrolyzer stack and hydrogen/water phase-separators inside a pressure-containment dome, eliminating the need for a high-pressure mechanical hydrogen compressor, along with its ancillary equipments. The simplified major subsystems of the high-pressure electrolyzer system include the electrolyzer; the electricity feed sub-system; a user-accessible de-ionized (DI) water feed and DI water handling system. Note that the oxygen/water phase-separator is eliminated in this cathode-fed design; product oxygen that is free of liquid water will be promptly reduced from its high pressure and vented safely from the system.

Electrolyzer Operation Without a Circulation Pump: The most important project task involved verifying the catholyte circulation rate that can be supported in a thermosiphon-based cathode-feed electrolyzer. If insufficient water is circulated to meet the stoichiometric reaction needs of the electrolyzer, the membrane electrode

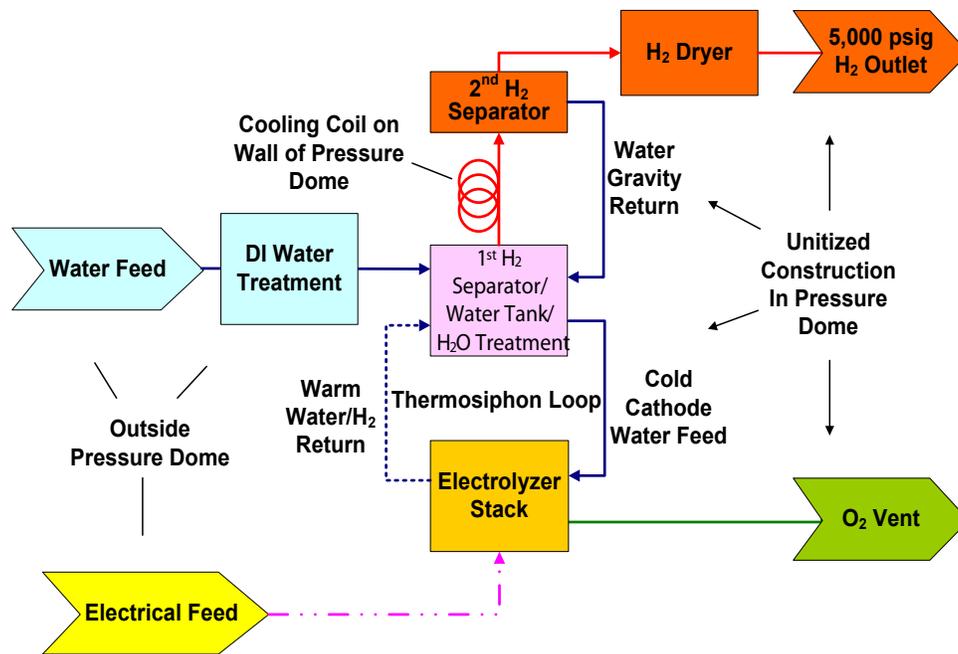

FIGURE 1. Cathode Feed Process Flow Diagram

assembly (MEA) can become water-starved, leading to membrane dry-out and inefficient electrolyzer operation, with eventual safety shutdown due to high voltage operation. Sufficient water circulation is also required for a second critical operational need: heat removal from the electrolysis reaction. As the electrolytic production of hydrogen and oxygen from water is not 100% efficient, byproduct waste heat is produced. The resultant waste heat must be removed from the electrolyzer. The standard GES electrolyzer design uses water circulation rates well in excess of the stoichiometric reaction requirements to remove the heat of reaction; the heat is then released to the surroundings through a separate heat exchange process.

Calculations during Phase I of this effort resulted in a thermosiphon water circulation rate prediction of 5.75 cc/min for a single 60-mil-thick, 160-cm² cathode-feed electrolyzer cell. Figure 2 illustrates the typical thermosiphon catholyte flow through a 90-mil cathode compartment. Flow measurements were quite consistent from ambient temperature up to 90°C. Thermosiphon flow ranged from a minimum of 36 cc/min. at 100 mA/cm², to a limit of 58 cc/min., reached over a range of 600–900 mA/cm². These flows are well in excess of the predicted flows: a factor of 6.3–10.1 times higher than the water circulation rate predicted in the project’s earlier Phase I effort. Consequently, one of the most important HRA operational requirements, adequate thermosiphon flow, was validated for the 90-mil cathode compartment thickness.

Thermosiphon Electrolyzer Voltage Performance:
After verifying the superior water circulation rates possible with the initial 90-mil thick, low-resistance cathode

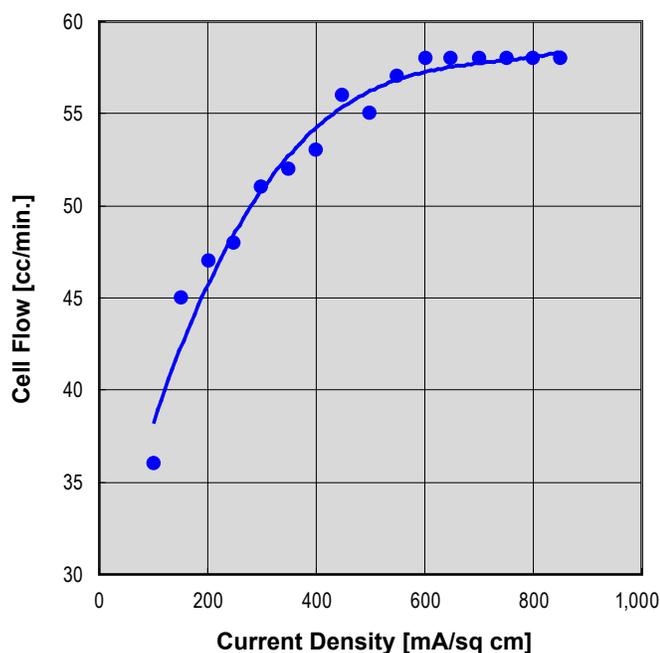

FIGURE 2. Cathode-Feed (Non-Pumped) 160 cm² Single-Cell Water Circulation Rate

design, voltage performance data was collected at ambient pressure and operating temperatures up to 90°C. Figure 3 illustrates the resultant polarization scans at 80 and 90°C. As expected, the higher temperature, 90°C operating data provides better performance (lower voltage), relative to operation at 80°C. The performance benefit of 90°C operation ranges from a 21 mV improvement at 100 mA/cm², up to an 82-mV improvement at 850 mA/cm². Obviously, if electrolyzer performance can be proven to be reliable and stable at 90°C, the energy efficiency of hydrogen production will be increased.

Cathode Feed (Pumped) Operation in Pressure Dome: On a separate National Aeronautics and Space Administration-funded project developing high-pressure oxygen electrolysis for life support, successful differential-pressure operation of a 50-cm² 1cell cathode-feed stack was conducted in a 2,000-psig pressure dome. Although not exactly in line with the goals of the HRA development project, this work demonstrated an advancement of state-of-the-art operations of high-pressure electrolyzers contained in pressure domes. Operation of both the 50-cm² 1cell cathode-feed and a 50-cm² 17cell anode-feed electrolyzer stacks was successful over a wide range of operating conditions. Figure 4 illustrates the resultant polarization scan from pumped anode-feed operation, for both 1,000- and 2,000-psig oxygen production pressures. (Cathode feed data is not shown.)

Data in Figure 4 illustrate the slight voltage penalty for producing oxygen gas at higher pressure, which occurs for all operating temperatures. At a constant 300 mA/cm², with

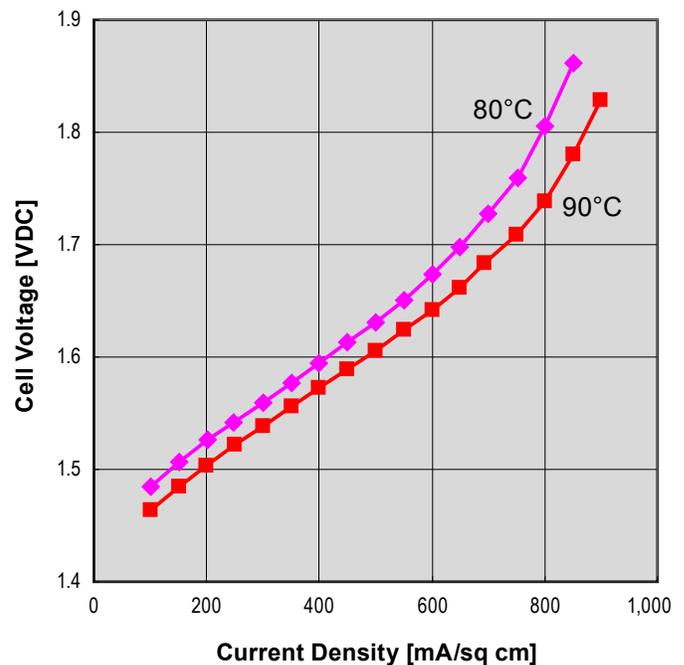

FIGURE 3. Cathode-Feed (Non-Pumped) 160 cm² Single-Cell Polarization Testing

40°C operation, raising the oxygen's production pressure from 1,000 to 2,000 psig requires an additional 42 mV. With 60°C operation, raising the oxygen pressure from 1,000 to 2,000 psig requires an additional 28 mV; at 80°C it requires an additional 20 mV.

Figure 4 also shows the advantages of raising the operating temperature from 40°C to 80°C. The primary advantage is to reduce the cell operating voltage, resulting in more efficient electrolyzer operation. For instance, at a constant 300 mA/cm² operation at 2,000 psig oxygen generation pressure, raising the cell temperature from 40 to 60°C reduces the voltage by 99 mV. In addition, further raising the cell temperature from 60 to 80°C reduces the voltage by an additional 57 mV. To summarize the cathode feed (pumped) tests in a pressure dome, the most efficient electrolyzer operation occurred at the highest temperature of 80°C.

Conclusions and Future Directions

The Phase II project is completing component tests that will lead to a practical design for a 5,000 psi “Unitized” breadboard system to be built and tested next year. The technology will be able to provide on-site residential hydrogen refueling at a cost that meets the DOE target of \$2.00–\$4.00/kg-H₂ in 2017–2020. In addition to unitizing the major components, the design incorporates numerous cost-saving (and reliability enhancing) simplifications, such as eliminating the need for any mechanical pumps, and

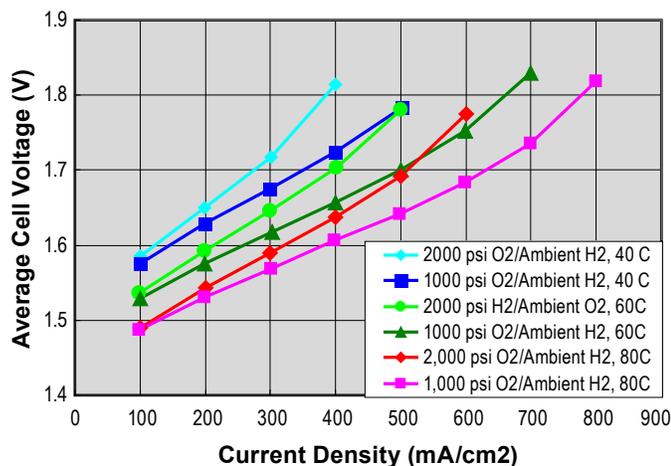

FIGURE 4. Cathode Feed (Pumped) Nafion® 117 Operation

utilizing passive cooling for low-cost, maintenance-free heat transfer. These design features eliminate the need for bulky and costly stack and system parts, and facilitate a method for producing a low-cost electrolyzer system that can safely operate at a hydrogen pressure of 5,000 psi in a residential setting. Future objectives are:

- Complete HRA component tests.
- Conduct a hazards and operational safety analysis/failure modes and effects analysis of the breadboard HRA system.
- Detail design and fabrication of a full-scale electrolyzer stack sized for a hydrogen production rate of 0.5 kg H₂ per 12-hour operational period.
- Detail design, component fabrication, and assembly of a “unitized” breadboard HRA electrolyzer system for 5,000 psi delivery pressure.
- Performance and durability testing of unitized breadboard system prototype.
- Complete a preliminary design and economic analysis of a future commercial HRA system.
- Develop marketing strategy and partnerships for wide scale adoption of technology.

Contract Number: DE-SC0001149

Project Start Date: August 15, 2010
 Project End Date: August 14, 2012

Fiscal Year (FY) 2011 Objectives

- Develop enabling technologies for 350-bar hydrogen home fueling.
- Design key electrolysis cell stack and system components.
- Fabricate, inspect and assemble prototype components.
- Demonstrate prototype 350-bar hydrogen generation.
- Demonstrate prototype 350-bar home fueling technologies.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (G) Capital Cost
- (H) System Efficiency

Technical Targets

TABLE 1. Progress towards Meeting Technical Targets for Hydrogen Production via Distributed Water Electrolysis

Characteristics	Units	2012 Target	2011 Status
Hydrogen Cost	\$/gge	3.70	5.99*
Electrolyzer Capital Cost	\$/gge	0.70	2.62*
Electrolyzer Energy Efficiency	% (LHV)	69	57**

*Based on H2A model modified for residential (non-commercial) application
 **Includes generation and compression to 350 bar with stack efficiency of 66% lower heating value (LHV)

FY 2011 Accomplishments

- Defined requirements for cell stack size.
- Completed cell stack concept designs.
- Initiated cell prototype component orders.
- Completed system plumbing and instrumentation diagram (P&ID).
- Drafted system electrical schematic and safety analysis.
- Specified and selected key system components (valves, etc.).
- Designed upgrades to pressure test apparatus.

Introduction

Based upon the results of the Phase 1 study, the fundamental requirements for a hydrogen home fueling appliance have been defined. The conclusion of the Phase 1 study indicated that an overnight-fill proton exchange membrane (PEM) electrolysis device that fills the vehicle directly to a maximum of 350 bar with no mechanical compressor or secondary hydrogen storage can cost effectively supply the daily hydrogen for a typical commuter operating a fuel cell vehicle. The case for including the hydrogen home fueling concept in the overall mix of fueling infrastructure is strong. The home fueler can grow in production volume and geographic distribution with individual vehicles as they are placed in the market with more flexibility than centralized fueling stations. Existing utility infrastructure (water, electricity) can be utilized within their existing capacities to cover the distribution aspect of the fueling infrastructure.

The goal of this Phase 2 project is to design and demonstrate the key hardware for 350-bar hydrogen home fueling based on PEM electrolysis. Proton Energy Systems has previously demonstrated durable PEM electrolysis equipment generating hydrogen at 165 bar. In addition, Proton has also demonstrated the ability of sub-scale prototypes to seal at the required proof pressure for 350-bar operation. Building upon this past work, designs have been initiated to utilize Proton's reliable PEM electrolysis cell stack and system technologies for hydrogen generation and vehicle fueling at 350-bar.

Approach

The approach to the Phase 2 project is threefold. First, utilize the data and modeling results from the Phase 1 project to provide approximate sizing for the hydrogen generation rate. Second, build upon Proton's proven cell stack design and development experience to undertake

the designs required for 350-bar operation. Third, utilize Proton's strong engineering processes that rely on a phased approach, with stage reviews, key written guidelines, and design output documentation to guide the successive levels of design refinement and demonstration. To that end, the project was organized into four main tasks: (1) Prototype System Design and Fabrication, (2) Prototype Stack Design, (3) Prototype Component Verification, and (4) Prototype System Testing. Task 1 utilizes engineering best practices to design and fabricate the prototype fueling system. This includes producing the P&ID, electrical schematics, bills of materials, control schemes and component specifications for the prototype system. In addition, Task 1 includes the procurement, fabrication, and acceptance testing of the prototype system. Task 2 includes producing the component designs and assembly models for the cell stack in three-dimensional (3-D) computer-aided design (CAD) format. Moreover, it includes completing design feasibility pressure testing using both sub-scale and full-scale active area components. Task 3 incorporates work on verifying the functionality of key components within the cell stack design and one or two custom components within the system design. Task 4 includes assembling and checking the first electrolysis-ready version of the new prototype stack design. Furthermore, it includes integrating the prototype stack into the prototype system and operating in electrolysis to generate hydrogen at 350 bar.

Results

During this first year, the team has made excellent progress toward the overall goals of the project. At the time of writing, the team has completed more than 40% of Task 1 and more than 70% of Task 2. At the end of year 1, we expect to be 50% complete with Task 1 and 100% complete with Task 2, which is on schedule to meet the deliverables at the end of Year 2.

Within Task 1, Prototype System Design and Fabrication, the initial conceptual designs of the major system components and system architecture were completed. This concept design effort culminated in an internal concept design review in December 2010. The design team then refined the concept design further through a prototype design stage. In this stage, the P&ID was modified to include more detail and finalize the piping architecture. The electrical schematic was completed, including the electrical safety circuit devices. The packaging of the mechanical components was completed in a 3-D CAD model (Figure 1). The actuated valves, piping, and fittings available for operation at 350 bar were evaluated and selections were made. The primary cell stack power supply was selected and a quote was requested. One key component, the hydrogen-water phase separator, required a higher level of detailed analysis because of the increases in system pressure, since the original phase separator had been designed for 165 bar operation. This part was re-designed and analyzed using finite element analysis (FEA) techniques to ensure that

the stresses in the part would be acceptable at the 350 bar operating pressures (Figure 2). The approach for controlling the system as a laboratory prototype was selected to utilize the flexible programmable logic controller (PLC) type of hardware. The key inputs to and outputs from the PLC were identified and listed to facilitate the selection of the PLC in-out cards. Finally, the system-level hazard analysis was initiated by defining the subsystem nodes within the overall system, identifying the hazards, and identifying hazard mitigation strategies. This prototype design stage culminated in a second internal design review. At the time of writing, the specification of the remaining components necessary to have a complete bill of materials (BOM) is underway. The system BOM will be completed allowing orders for all the major components to be placed by the conclusion of year 1.

Within Task 2, Prototype Stack Design, the design process started with a continuation of the feasibility testing previously started by Proton under internal research and development funding to demonstrate overboard sealing of a sub-scale test article. The previous testing was extended by doing short duration elevated temperature soaks to more closely simulate the operating temperature of a cell stack. Finally, an optimization of the sealing features

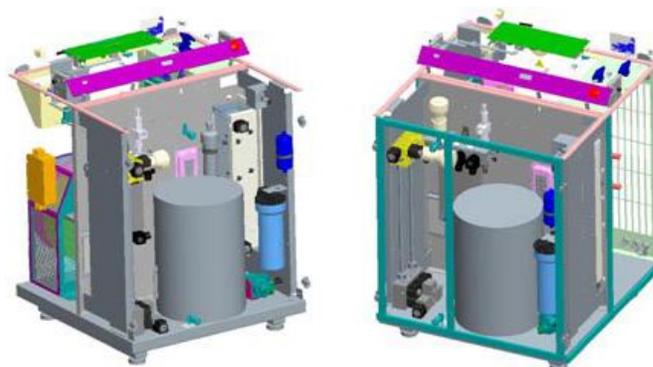

FIGURE 1. Prototype Test System 3-D Package Design

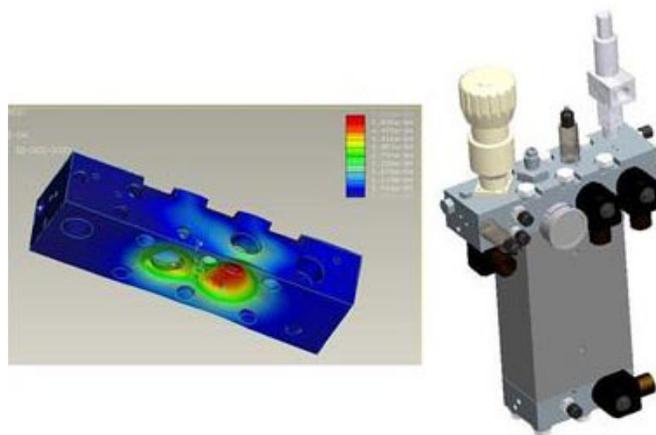

FIGURE 2. Phase Separator Design and Finite Element Analysis

was undertaken to permit more efficient sealing to the same proof pressure. The design of the full-scale stack started with rough sizing of the endplates and bolts for the required strength and stiffness of a 350-bar electrolysis cell stack (Figure 3). The design process continued with conceptual designs of the cell frames and the internal flow field components. As the design of the cell components firmed up, the initial rough designs of the endplate, fluid manifold, electrical bus plates, and tie rods were revised and refined (Figure 4). This iterative design effort included two intermediate design reviews and culminated with a concept stage design review. Based upon the approved designs, quotes were requested on the key components necessary for the first rounds of Task 3, Prototype Component Verification. Orders were placed for the key components to permit full-

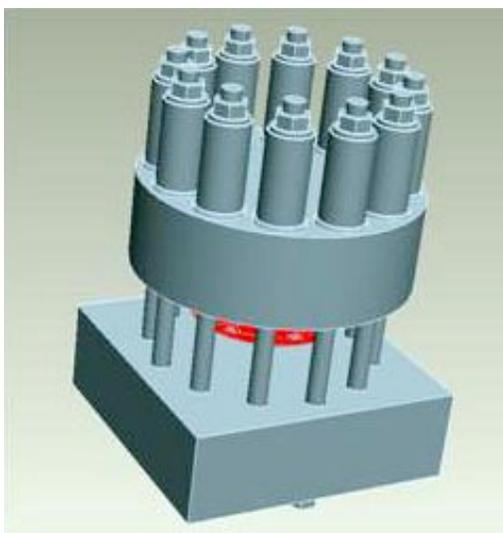

FIGURE 3. Initial Endplate and Tie Rod Sizing

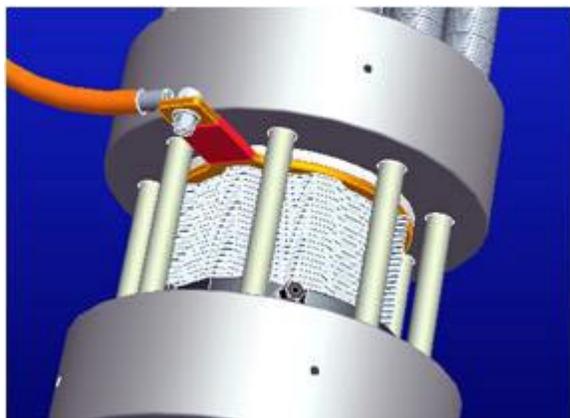

FIGURE 4. Initial Cell Component Design

scale active area pressure testing. At this time, we anticipate that Task 2 will be 100% complete at the end of year 1.

Conclusions and Future Directions

The project team is making excellent progress toward the culminating demonstration of 350-bar capable electrolysis technology. Moving into year 2 of the project, Task 1 will heavily involve the fabrication and assembly of the prototype system. This task will culminate with the basic sensor calibrations and acceptance tests including leak, ground continuity, and hi-pot testing. As Task 2 reaches completion, Task 3 will pick up with the detailed design verification inspections and tests of the components. Non-operational stacks will be built to verify sealing to proof pressure and proper distribution of load through the components. Flow tests will be conducted on single- and multiple-cell stacks. All of the tasks will culminate in the Prototype System Testing (Task 4). In this task, an operational electrolysis cell stack will be fabricated, assembled, and checked through standard acceptance criteria. The stack will then be integrated with the system and operated for a significant demonstration of 350-bar electrolysis technology.

In summary, the following tasks have been completed and next steps planned for the 350-bar electrolysis fueling system development effort and the parallel 350-bar electrolysis cell stack development:

- The prototype system design is complete, including P&ID, electrical schematic, and 3-D CAD layout.
- The component BOM list is complete with all components quoted for prototype purchase.
- Key prototype system components have been ordered.
- Feasibility cell sealing tests were completed favorably, demonstrating overboard sealing at full proof pressure.
- Differential pressure cross-cell capability feasibility tests were completed at greater than operating pressure.
- Preliminary design calculations have been completed for a full-size cell stack.
- All cell components have been modeled in 3-D CAD and detailed engineering drawings have been drafted for the preliminary design.
- Key prototype cell stack components have been ordered.
- Initial rounds of component verification testing will begin at the end of year 1 and the start of year 2.

- (E) Greenhouse Gas Emissions

Task 2: Technical Barriers Addressed

- (Y) Materials Efficiency
- (Z) Materials Durability
- (AA) PEC Device and System Auxiliary Material
- (AB) Bulk Material Synthesis

Technical Targets

Progress towards meeting Technical Targets for CO₂ Use as a Feedstock and Greenhouse Gas Remission

Task 1

- Synthesis of three ruthenium polypyridyl complexes.
- Proof-of-concept demonstration of CO₂ reduction to methanol using electrochemical and photochemical methods.

Task 2

- Combustion Synthesis of BiVO₄, Bi₂WO₆, and AgBiW₂O₆ nanoparticles.
- Photodeposition of Pt on AgBiW₂O₆ nanoparticles to enhance electron-hole separation under irradiation.
- Photocatalytic reduction of CO₂ using Pt-modified AgBiW₂O₆

Fiscal Year (FY) 2011 Objectives

TASK 1: Develop Homogeneous Ruthenium Photocatalysts for H₂ Production and CO₂ Reduction

- Synthesis of ruthenium-polyridyl complexes (RPCs) as photocatalysts.
- Screen RPCs for electrocatalytic activity.
- Evaluate the photophysical properties of the RPCs.
- Demonstrate photocatalytic CO₂ reduction with RPCs.
- Optimize photocatalytic reaction.

TASK 2: Develop Heterogeneous Oxide Photocatalysts for H₂ Production and CO₂ Reduction

- Develop new oxide semiconductors for photocatalysis and photoelectrochemical catalysis.
- Demonstrate combustion synthesis of BiVO₄, Bi₂WO₆, and AgBiW₂O₆ nanoparticles.
- Demonstrate photoreduction of CO₂ using BiVO₄ nanoparticles.
- Develop method for photodeposition of Pt on AgBiW₂O₆.
- Optimizing Bi₂WO₆ and AgBiW₂O₆ for CO₂ photoreduction.

This project addresses the following technical barriers from the Production section (3.1) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

FY 2011 Accomplishments

Task 1

- Prepared two photocatalysts containing a ruthenium chromophore linked to pyridyl moiety.
- Demonstrated that these photocatalysts are competent for CO₂ electroreduction to methanol with an optimum performance at pH of 2.0.
- Demonstrated that the two new photocatalysts are capable of CO₂ photoreduction to methanol but that they require a mixed MeCN-water solvent to function.

Task 2

- Prepared BiVO₄, Bi₂WO₆, and AgBiW₂O₆ nanoparticles by Combustion Synthesis.
- Demonstrated that the combustion synthesized nanoparticles possess higher photocatalytic performance

and larger surface area than those obtained by solid state reaction.

- Demonstrated the photocatalytic generation of H₂ and reduction of CO₂ using Pt-modified AgBiW₂O₆ nanoparticles.

Introduction

Given the current environmental concerns over CO₂ as a greenhouse gas and the need for fuels derived from renewable energy sources, the capture and reduction of CO₂ into fuels could help alleviate the environmental issue and turn this cheap and common feedstock into valuable fuels. The combustion of these fuels would regenerate CO₂ which could, in theory, be ‘recycled’ into fuel, leading to a closed carbon-cycle. Of course, there is a required energy input for this carbon-based fuel cycle, and ideally this would be based on solar-energy. Task 1 of this project describes the development of molecular photocatalysts, based on the discovery of Bocarsly and co-workers that pyridine is an excellent electrocatalyst for the reduction of CO₂ to methanol [1-3]. In this work, we covalently link a ruthenium chromophore to a pyridine co-catalyst to develop a homogeneous CO₂ reduction photocatalyst. The project involves the design, synthesis, characterization and testing of these photocatalysts for CO₂ reduction to methanol. Task 2 describes the preparation of BiVO₄, Bi₂WO₆ and AgBiW₂O₆ semiconductor nanoparticles by a “mild” (low-temperature) combustion synthesis. This method is both energy- and time-efficient because the exothermicity of the combustion reaction provides the energy for the synthesis and the reaction times are just few minutes. The resulting combustion synthesized nanoparticles are tested as photocatalysts for H₂ generation and CO₂ reduction. Sample characterization involves several techniques such as high resolution transmission electron microscopy, thermogravimetric analysis, Brunauer-Emmett-Teller (BET) surface area, diffuse reflectance spectroscopy, X-ray diffraction (XRD) and X-ray photoelectron spectroscopy (XPS).

Approach

Task 1

We designed and prepared complexes in which the well-established photochemistry of ruthenium-polypyridyl coordination complexes is used to generate a reduced pyridine functional group. These complexes are characterized electrochemically and photochemically to determine optimum reaction conditions. Excitation of each Ru(II) complex with visible light in the region of 400-500 nm forms an excited ¹MLCT (metal-to-ligand charge-transfer) state in which the pyridine-containing

ligand is reduced by one electron. This excited state quickly relaxes to a second, long-lived, triplet excited state, ³MLCT. Reductive quenching of the Ru³⁺ center traps the electron on the pyridyl ligand and thus has ‘photogenerated’ an analogue of the pyridine radical. Reaction of this radical anion with CO₂ at the proper pH leads to a sequence of photoreductions that ultimately produce methanol. We used electrochemistry to screen the photocatalysts for electrocatalytic CO₂ reduction activity under various pH conditions. Gas chromatography coupled with mass spectrometry was used to look for the reduced CO₂ products, specifically for methanol. The complexes ability function as photocatalysts was examined in a custom designed photoreactor with 470 nm ultrabright diode lamp. Reaction conditions included the presence of a sacrificial donor, triethanolamine (TEOA) to reductively quench the photoexcited complexes.

Task 2

We used solution combustion synthesis (SCS) to prepare BiVO₄, Bi₂WO₆ and AgBiW₂O₆ semiconductor nanoparticles. The selection of these three materials was based on their respective band gap energy overlapping the solar spectrum and thus making them able to perform heterogeneous photoreactions using solar light. Using SCS is very convenient as compared with the traditional solid-state reaction method for nanoparticles preparation. The combustion synthesis uses a fuel (i.e. urea) that in contact with the metal precursors promotes the combustion reaction in few minutes instead of the high energy consumption associated with the solid state reaction that normally takes several hours of heating at high temperatures. Furthermore, SCS generates much smaller nanoparticles because of the gases generated during the combustion reaction. The synthesized powders were characterized in their physical shape and size (high-resolution transmission electron microscopy [HRTEM], BET), composition, crystalline structure (XRD, energy dispersive X-ray spectroscopy, XPS), and light absorption (diffuse reflectance ultraviolet-visible spectroscopy [UV-Vis]). The ability of these nanoparticles as heterogeneous photocatalysts was examined in a 200 mL photoreactor containing 0.5 g of semiconductor nanoparticles in aqueous media irradiated from a light source (xenon or tungsten halogen lamp) placed in an inner Pyrex glass compartment.

Results

Task 1

We prepared the three photocatalysts shown in Figure 1 in 90% yield and have characterized them by nuclear magnetic resonance and elemental analysis. They are isolated as the hexafluorophosphate salt for solubility in acetonitrile or as chloride salt for solubility in water.

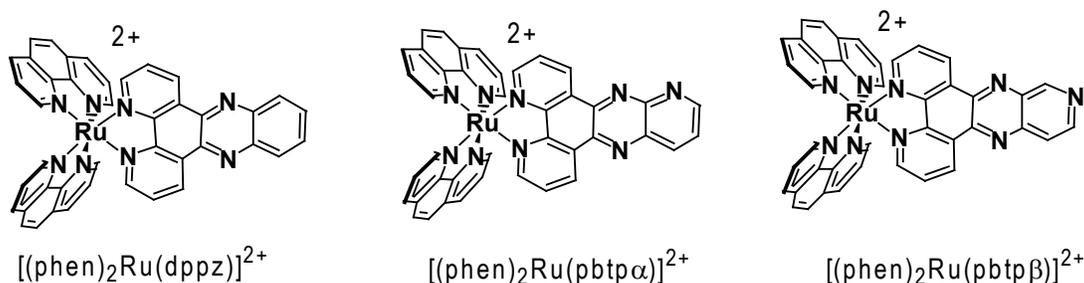

FIGURE 1. Structures of RPCs Described in Task 1

Electrochemistry

The voltammetric behavior of $[(\text{bpy})_2\text{Ru}(\text{ptpb}\alpha)]^{2+}$ and $[(\text{bpy})_2\text{Ru}(\text{ptpb}\beta)]^{2+}$ complexes in the presence of CO_2 is compared in Figure 2. It is worth noticing that both profiles are similar in shape although $[(\text{bpy})_2\text{Ru}(\text{ptpb}\beta)]^{2+}$ is peaking at less negative potentials than its analog $[(\text{bpy})_2\text{Ru}(\text{ptpb}\alpha)]^{2+}$ indicating a more facile interaction with CO_2 for the first complex. In both cases, the formation of a reactive nitrogen site in the ptpb (either α or β) ligand for CO_2 adduct formation in the form of a carbamate is expected. Figure 2 also shows that a neat increase of current is occurring at potentials more negative than -1.1 V for both complexes indicating that a next electron uptake is also a possible center for photocatalytic CO_2 reduction. This point is important in the view of the photochemical reduction of CO_2 as the $^1\text{MLCT}$ excitation of the Ru $\pi \rightarrow \text{ptpb}$ $d\pi$ band in any of the complexes and reductive quenching of the $^3\text{MLCT}$ excited state by triethylamine could trap the electron on the ptpb ligand to form $[(\text{bpy})_2\text{Ru}^{\text{II}}(\text{ptpb}^-)]^+$ either in the bpy structure of the ptpb or at the farther N of the structure. The two different locations in the ptpb ligand might work properly in the photochemical reaction. In relation to the returning positive-going scan in Figure 2, it is clear that anodic currents are much smaller than those shown in the absence of CO_2 and pointing out to a chemical reaction of CO_2 with the reduced product of any of the complexes.

For the mechanistic aspects of the electrochemical reaction, the pH dependence of the electrocatalysis was examined. As shown in Figure 3, the reduction potential shifts positive as the pH is lowered as expected for a proton-coupled process. A 60 mV shift positive for every pH unit is in agreement with a one proton-one electron process. A separate measurement of the pK_a of the pyridine acid in $[(\text{bpy})_2\text{Ru}(\text{ptpb}\beta)]^{2+}$ revealed a pK_a near 2.0 which corresponds nicely with the peak potential shift observed for the cathodic peak. Using this data and the findings by Bocarsly that pyridine electrocatalysis of CO_2 reduction works best at the pK_a of the pyridine acid, we ran all subsequent photoreductions at pH 2 for complexes $[(\text{bpy})_2\text{Ru}(\text{ptpb}\alpha)]^{2+}$ and $[(\text{bpy})_2\text{Ru}(\text{ptpb}\beta)]^{2+}$ [3].

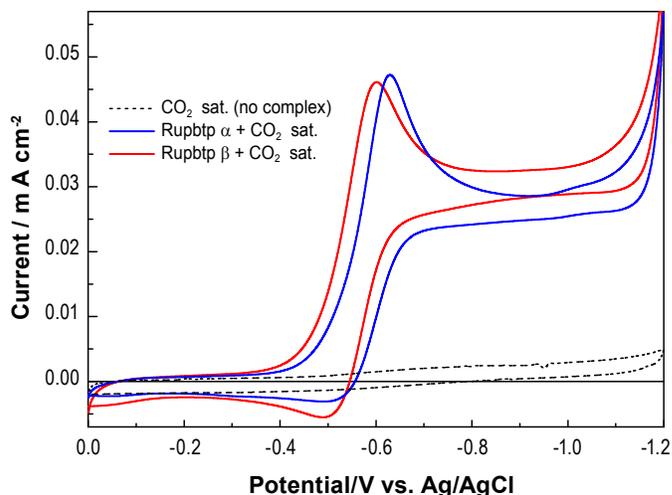

FIGURE 2. Comparison of the voltammetric behavior of $[(\text{bpy})_2\text{Ru}(\text{ptpb}\alpha)]^{2+}$ and $[(\text{bpy})_2\text{Ru}(\text{ptpb}\beta)]^{2+}$ in CO_2 saturated solution. Scan rate = 5 mV/s. The voltammogram of CO_2 in the absence of any complex is shown in black dot line.

Photochemistry and Photocatalysis

We examined the ability of $[(\text{bpy})_2\text{Ru}(\text{ptpb}\alpha)]^{2+}$ and $[(\text{bpy})_2\text{Ru}(\text{ptpb}\beta)]^{2+}$ to serve as photocatalysts for CO_2 reduction under a variety of conditions. As expected from the literature, pure water solutions were not practical as the excited state lifetime is too short for photoreactions [4]. Solvent mixtures of dimethylformamide (DMF)/water and acetonitrile (MeCN)/water resulted in suitable excited-state lifetimes for the photocatalysts. In a typical experiment, a water jacketed reaction vessel of 50 mL total volume was filled with ~ 25 mL MeCN that is 1.0 M H_2O , 0.20 M TEOA, and 100 μM Ru complex. The solutions are degassed and then placed in a homemade photochemical reactor in which blue light irradiation of wavelength 470 nm is provided by ultra bright diode array setup. Samples of both the headspace and solution are collected at various time periods and subjected to gas chromatographic (GC) analysis for product detection.

GC data was collected using a Haysep DB packed column with a length of 3 m and used N_2 as a carrier gas (starting at 110°C, a temperature ramp of 1°C/minute

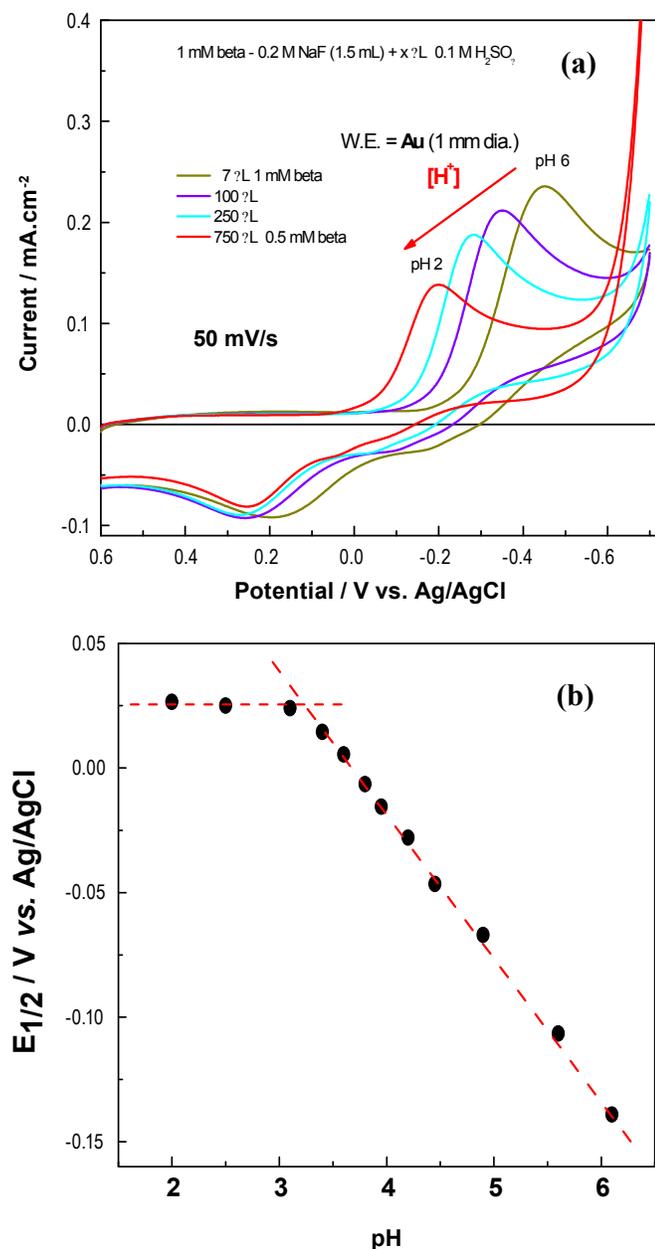

FIGURE 3. a) Selected voltammograms of $[(bpy)_2Ru(pbtpp)]^{2+}$ (1 mM) in aqueous media showing the effect of pH on the peak potential associated to the first electroreduction process. b) Linear shift of the half-wave potential ($E_{1/2}$) as a function of the solution pH.

temperature was done immediately after sample injection to a final temperature of 150°C). Retention times were as follows: carbon monoxide, 0.80 min.; methane, 0.88 min.; methanol, 5.8 min.; formaldehyde and formic acid, 8 min.

Methanol was detected under electrolytic and photolytic conditions. Methanol production increased with electrolysis time as expected. In the electrolysis experiment, conditions were 5 mM $[(bpy)_2Ru(pbtpp)]^{2+}$, 0.1 M KCl electrolyte, pH 2.0, constant CO_2 bubbling. Constant current at -0.45 mA was applied to a Pt working electrode using a Pt counter

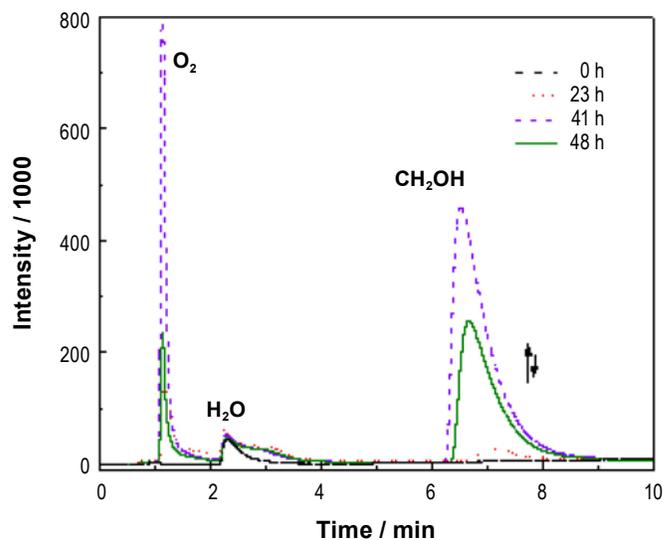

FIGURE 4. Selected GC runs of samples (liquid phase) taken during the $Ru(phen)_2pbtp^{2+} + CO_2$ electrolysis.

electrode in a separate compartment, and Ag/AgCl reference electrode in the working electrode compartment. These results are only semi-quantitative due to peak overlap in the gas chromatogram and need further refinement for yields and turnover numbers. Similarly, methanol was detected in a photochemical experiment. In a typical experiment, a water jacketed reaction vessel of 50 mL total volume was filled with ~25 mL MeCN or DMF that is 1.0 M H_2O (pH 2), 0.20 M ascorbic acid, and 100 mM Ru complex. The solutions are degassed, saturated with CO_2 , and then placed in the photochemical reactor for irradiation at 470 nm. Samples of both the headspace and solution were collected at various time periods and subjected to GC analysis for product detection. Methanol was detected by GC of the solution phase (Figure 4) and its identity confirmed by mass spectrometry. As with the electrolysis result, the results are not quantitative as overlap of the MeOH peak with another species prevents accurate quantification. Work is in progress to find conditions for clear resolution of the MeOH peak by GC.

Task 2

$BiVO_4$, Bi_2WO_6 and $AgBiW_2O_6$ nanoparticles were prepared by SCS [5]. The band edges of these three semiconductor materials are shown in Figure 5 comparatively to other materials and also the redox potentials for CO_2 electroreduction and water splitting are shown there. The three selected materials have band gaps in the 2.4-2.7 eV range thus overlapping the solar spectrum and in contrast with TiO_2 which has served as a model workhorse for a stable and inert inorganic semiconductor although its 3.2 eV band gap is too high to be used as solar absorber.

All samples were fully characterized (by HRTEM, XPS, XRD, BET, UV-Vis and Raman spectroscopy) to ascertain

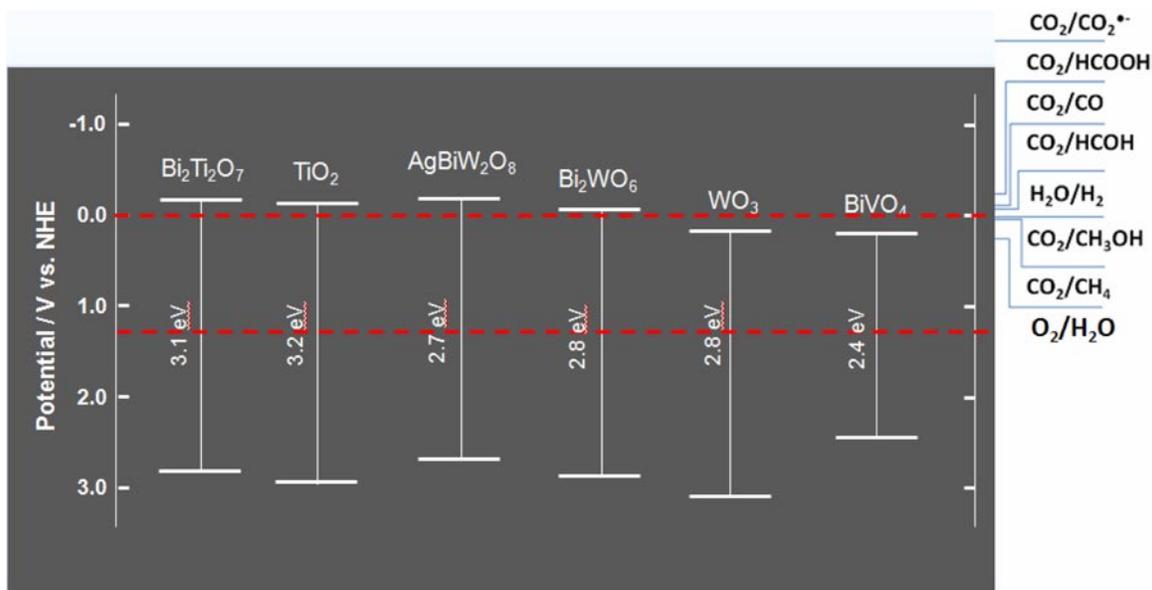

FIGURE 5. Comparison between the band edges of selected semiconductors (at pH 1) and the redox potentials for CO₂ reduction and water splitting.

particle size, composition, crystalline structure and absence of impurities [6]. Figure 6 shows the UV-visible diffuse reflectance data on a SCS-synthesized AgBiW₂O₈ sample processed in the form of Tauc plot of the square root of the Kubelka–Munk function vs. the photon energy. The band gap value estimated from this plot is 2.73 eV and in very good agreement with the value (2.75 eV) reported for this ternary oxide in a previous study on solid-state reaction

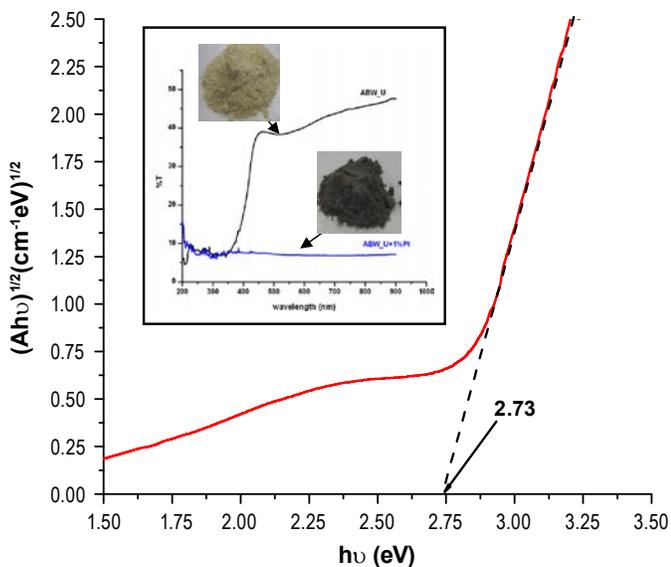

FIGURE 6. Tauc plot for combustion synthesized AgBiW₂O₈. The inset shows the percent transmittance data of the sample before (black line) and after photodeposition of 1wt% Pt (blue line), along with the corresponding sample photographs.

(SSR) [7]. Much higher surface areas (as determined by BET isotherm, see Table 1) are found for the SCS samples than for those prepared by SSR, thus pointing out to a better quality product obtained in a time- and energy-efficient manner by SCS.

TABLE 1.

Photocatalyst	Micropore Area (cm ²)	External Surface Area (cm ²)	BET Surface Area (m ² g ⁻¹)
SCS AgBiW ₂ O ₈	5.488	28.938	34.44 (our work)
SSR AgBiW ₂ O ₈	0.136	0.406	0.54 (our work)
SSR AgBiW ₂ O ₈	-	-	0.29 (ref. 7)

A newly designed sealed photoreactor was then used to perform heterogeneous photocatalysis with the semiconductor particles suspended in CO₂ saturated water. The lamp (400 W medium-pressure Hg arc encased in Pyrex glass, photon flux: 235 mW/cm²) was turned on and the gaseous products evolved were analyzed by gas chromatography (GC SRI 310) as a function of the illumination time using a Shin Carbon column and a thermal conductivity detector.

Best samples for photoreduction of CO₂ are the SCS-derived AgBiW₂O₈ powders which are able to perform the photocatalytic generation of syngas followed the principle outlined in Figure 7a. The rationale for using formate ions as the in situ precursor for CO₂ was two-fold. The direct electroreduction of CO₂ in aqueous media is beset both by the low partial pressure of CO₂ in the atmosphere (3.9 x 10⁻⁴ atm) and by its low solubility in water (1.5 g/L at

298 K) [8]. On the other hand, formate species have high solubility in water (945 g/L at 298 K) [9]; they have high proclivity for being adsorbed on oxide surfaces and are easily photoconverted to CO_2 (Figure 7a). The in situ generated CO_2 can be subsequently reduced by the photogenerated electrons in the oxide particle. For the simultaneous photogeneration of H_2 , the photogenerated electrons must be stored on the oxide surface in noble metal catalyst (e.g., Pt) islands [10]. Thus, the AgBiW_2O_8 particles were loaded with 1 mass% Pt using a photocatalytic procedure described elsewhere [11]. After surface modification with Pt, the color of the oxide particles changed significantly from light yellow to a grayish hue as illustrated in Figure 6 (insert). The diffuse reflectance spectra also changed consequently as also shown in Figure 6 (insert). Thus, we envision that the portion of the photogenerated electrons channeled toward the Pt catalyst islands would reduce protons to hydrogen while those that diffuse to the (naked) oxide surface would be utilized for the reduction of CO_2 to CO (Figure 7a).

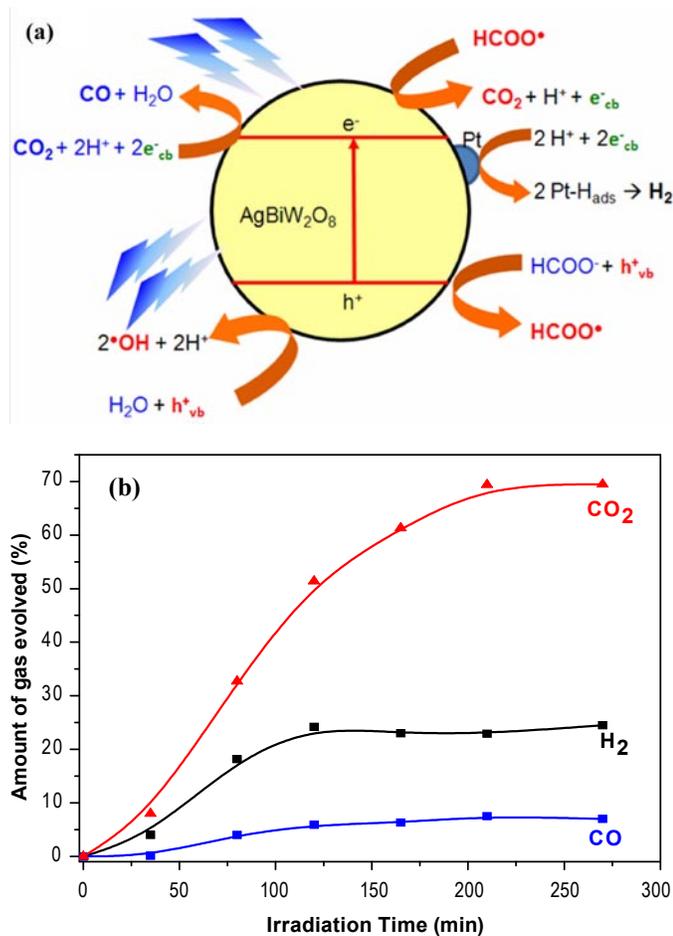

FIGURE 7. a) Diagram of heterogeneous photocatalytic formation of syngas on an illuminated AgBiW_2O_8 -Pt nanoparticle. b) Amount of gas evolved (H_2 and CO) as a function of irradiation time using in situ CO_2 generation from 0.1 M HCOOH .

The Pt-modified AgBiW_2O_8 particles were loaded into the photoreactor containing a de-aerated solution of 0.1 M HCOOH at a dose of 2 g/L. Figure 7b illustrates the temporal profiles of the three products of the overall photocatalytic reaction, namely, H_2 , CO and CO_2 . It is worth noting that the first products to be seen are the generation of CO_2 and H_2 from the oxidation of HCOOH using the photogenerated holes from the semiconductor valence band and the reduction of H^+ through photogenerated electrons in the conduction band of AgBiW_2O_8 respectively. The (subsequent) formation of CO tracks the in situ photogeneration of CO_2 at or near the particle surfaces. The run was terminated at 225 min at which time the gases accumulated were as follows: $\text{H}_2 = 1.0 \times 10^{-2}$ mol/gL, $\text{CO} = 3.0 \times 10^{-3}$ mol/gL and $\text{CO}_2 = 2.8 \times 10^{-2}$ mol/gL. These data are reported as the number of moles of product divided by the photocatalyst mass and liquid volume in the photoreactor. Quantum yields for the formation of syngas ($\text{H}_2 + \text{CO}$) and CO_2 in the formic acid solution amount to $\text{H}_2 = 3.0\%$, $\text{CO} = 0.8\%$ and $\text{CO}_2 = 4.5\%$.

Conclusions and Future Directions

Our findings in Task 1 show that properly designed RPCs can act as a homogeneous photocatalyst or electrocatalyst for CO_2 reduction to methanol. This proof of concept now needs to be refined and optimized to determine the efficiency of the process. Ultimately, we would need to couple the reductive process with a more practical oxidative process, for example water oxidation, to construct a practical system for solar fuel generation.

Our findings in Task 2 show that among the three heterogeneous photocatalysts, the Pt-modified AgBiW_2O_8 is capable of performing CO_2 photoreduction. The data described is a useful proof-of-concept for the following: (a) AgBiW_2O_8 can be simply and quickly prepared by SCS; (b) A mild photocatalytic procedure for syngas generation can be developed based on the use of formate ions as an in situ precursor for CO_2 , and (c) The SCS-derived AgBiW_2O_8 powder, after Pt surface modification, can generate syngas via this procedure. Ultimately, better performances can be expected by optimizing the amount of Pt on the semiconductor nanoparticles and by using solvent mixtures of DMF/water and MeCN/water to enhance CO_2 solubility in the liquid phase.

Contract Number: DE-FG02-07ER84869

Project Start Date: June 20, 2007

Project End Date: May 15, 2011

FY 2011 Accomplishments

- Fabricated A2B6 photoelectrodes using solution deposition to produce CdS/ZnS bilayer (n-type) films.
- Designed, fabricated, and tested a third generation PEC reactor cell panel and mechanical framework (0.5 m x 0.5 m).
- Conducted techno-economic analysis for PEC reactor system.

Introduction

Sunlight is an abundant, renewable and domestically available energy source that can provide a significant proportion of carbon-free energy in the future, particularly if sunlight can be harnessed to generate hydrogen fuel for transportation. PEC hydrogen generation is an approach to generate hydrogen fuel directly from water by using sunlight to drive a water-splitting reaction on the surface of novel semiconductor materials. The primary technical barriers to the development of these semiconductor materials are that they absorb a sufficient amount of the incoming solar energy, efficiently transfer that energy to drive the water-splitting reaction, and remain durable and efficient for long operational times while remaining cost-competitive with other hydrogen generation approaches. In this project, Physical Optics Corporation is developing an approach for the low-cost fabrication of A2B6 semiconductor photoelectrode architectures and building a prototype PEC reactor cell for testing and demonstration.

Approach

The approach of this project is to increase the solar-to-hydrogen efficiency by using lower band gap A2B6 semiconductor materials (addressing the Materials Efficiency technical barrier). Using a lower band gap enables increased solar absorption due to capturing the abundant lower energy photons inaccessible to traditional high band gap PEC materials. Previously we selected a CdS/ZnS bilayer and also ZnTe as promising A2B6 material combinations with band gaps in the 2.2-2.4 eV range. Recently, we concentrated on the CdS/ZnS architecture and explored and evaluated different processes for producing the films. These processes included an electrodeposition approach for co-depositing CdS with the ZnS capping layer from a single solution and a sequential deposition of CdS followed by ZnS via chemical solution deposition. We concluded our investigation of the ZnTe film, based on additional testing which revealed that the durability of the electrodeposited ZnTe films was insufficient for system integration.

Fiscal Year (FY) 2011 Objectives

- Fabrication of components of scaled-up prototype photoelectrochemical (PEC) reactor cell.
- Integration of scaled-up prototype of a PEC reactor cell.
- Demonstration of the scaled-up prototype reactor cell with photoelectrodes and performance evaluation.

Technical Barriers

This project addresses the following technical barriers from the Production section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (Y) Materials Efficiency
- (AC) Device Configuration Designs
- (AD) Systems Design and Evaluation

Technical Targets

TABLE 1. Progress towards Meeting Technical Targets for PEC Hydrogen Production

Characteristic	Units	2013 Target	2011 Status
Usable Band Gap	eV	2.3	2.2
Chemical Efficiency	%	10	To be determined
Solar-to-Hydrogen Efficiency	%	8	~5% - to be verified
Durability	hr	1,000	0.5 - to be verified

In addition to fabricating photoelectrode materials, we developed and assembled the third generation in a series of prototype reactor cell systems to house the photoelectrodes and capture the generated hydrogen. This PEC reactor housing is the final prototype for this project and will be used for testing and demonstration purposes. Technoeconomic evaluations of the hydrogen production cost have been made based on the prototype fabrication costs, the material costs, and the projected photoelectrode efficiency and lifetime of the mature system. This work directly addresses the Systems Design and Evaluation technical barrier.

Results

Our efforts on this project have focused on the development of the two major cell components: the semiconductor photoelectrode structure and the PEC reactor cell housing.

Electrodeposited A2B6 Photoelectrode Development

Previously we had developed a process for co-deposition of an *n-n* CdS/ZnS bilayer film using electrochemical deposition. Recently we have refined the deposition process to increase the thickness of the films as shown in Figure 1. The thicker films have higher overall durability, however the uniformity of the coating, particularly of the ZnS window layer requires further improvement. The co-deposition process utilizes both zinc and cadmium salts simultaneously in the reaction vessel along with a single organic sulfur source. Due to the electrodeposition of CdS proceeding more rapidly than the solution-deposited ZnS, as well as the lack of stirring during the electrodeposition, local concentration effects may be among those contributing to the poor uniformity.

To improve the ZnS coating uniformity, a solution deposition process was developed for coating previously electrodeposited CdS samples with a ZnS window layer. First, single layer ZnS films were developed and characterized. These samples bandgap around 3.5 eV which is consistent with zincblende ZnS. Next the coating process was applied to the electrodeposited CdS films immediately upon their removal from the CdS bath. These two fabrication step samples were tested and compared to the co-deposited samples, and test results indicated that while the two-step samples were more durable, the co-deposited films provided superior PEC performance. This is attributed to the continuous variation in stoichiometry that results from the co-deposited films allowing carriers to transfer between layers more efficiently, when compared to the abrupt interface present in the two-step samples. In the future, the next step would be to apply a hybrid procedure where the thickness of the ZnS layer of a co-deposited is incrementally increased through a second deposition in a fresh bath. This hybrid process may provide both a gradual stoichiometry

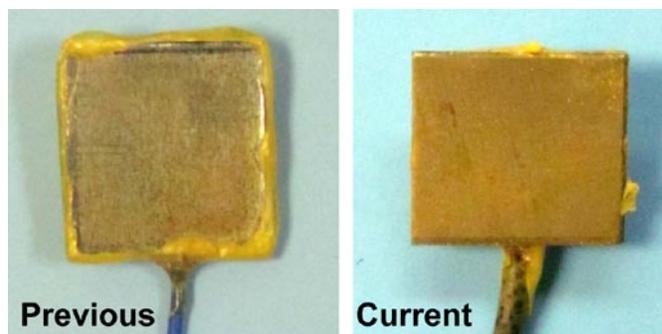

FIGURE 1. CdS/ZnS bilayer films showing increased thickness through two-step process as compared to previously deposited samples through the optimization of the coating process.

change from CdS to ZnS along with an increased total ZnS coating thickness.

PEC Reactor Cell Development

After the successful testing of the second generation prototype for the PEC reactor cell which houses the photoelectrode, counterelectrode, water and evolved H₂ and O₂ gases, we scaled up the design and fabricated a third generation prototype as shown in Figure 2. The prototype takes advantage of the scalable and modular design to increase the total size of the system area to 65 cm x 50 cm with an available harvesting area of approximately 20 cm x 20 cm (due to excess area allocated to the counterelectrode and for gas capture). The system is designed to allow simple and flexible integration of photoelectrodes for loading and maintenance, as well as autonomous extraction of the hydrogen gas and refilling of the aqueous electrolyte. The prototype system has recently been evaluated for system cost and durability based on testing and projected performance parameters.

Conclusions and Future Directions

Physical Optics Corporation has explored a novel electrodeposition and chemical solution deposition approaches to fabricating CdS/ZnS bilayer films for PEC hydrogen generation. In addition, a third generation prototype of the reactor cell mechanical framework has been designed, assembled, and is being evaluated. Future work would work to improve the film uniformity and durability by optimizing the deposition process. We plan to continue to investigate opportunities for verification of PEC test results through collaboration with other members of the PEC workgroup. The results of the system development and economic analysis will provide a strong basis for further commercial development of PEC hydrogen production components or systems in the future while working to overcome DOE technical barriers.

Objectives

With this project, we seek increased understanding of the mechanisms for assembly and activation of [FeFe] hydrogenases as well as the structural role that the polypeptide scaffolding plays in forming and stabilizing this complex enzyme's active site. We are developing *in vitro* maturation methods to enable detailed study of the biochemical reactions required to provide precursors and to assemble the catalytic H-cluster as well as to install it into the apoenzyme. We are also searching for enzyme mutations that will reveal the role of the polypeptide structure. To accomplish these objectives and to help advance this important field of research, we are also developing improved methods for producing these complex enzymes and for evaluating various functional characteristics.

Technical Barriers

This project is designed to provide information relative to the maturation and structure function relationships of [FeFe] hydrogenases. Since these are nature's most prolific hydrogen producers, this information will facilitate the design, assembly and cost-effective production of improved biological and biomimetic catalysts for the production of hydrogen and for hydrogen based fuel cells. The project will also deliver improved methods for the evolution, evaluation, and production of improved hydrogen producing catalysts. Since the most plentiful proton source for producing hydrogen is water and oxygen is a side product, the project will also search for oxygen tolerant hydrogenase mutants

and seek to understand the structure function relationships relative to oxygen tolerance.

Abstract

The first project objective is to elucidate the substrates and mechanisms for assembly and maturation of the 6Fe-6S active site of [FeFe] hydrogenases. An early *in vitro* maturation method was developed using an *E.coli* cell extract in which the three required maturases had been expressed and activated. The extract was also dialyzed to remove small molecules. We showed, for the first time, that activation of the purified apoenzyme was significantly enhanced by incubating this extract in the presence of S-adenosyl methionine, Fe(II), sulfide, and 20 amino acids. A design of experiment (DOE) investigation then showed that tyrosine was required and cysteine was beneficial for maturation. Further investigation showed that the para-hydroxyl substituent of tyrosine was required for efficient activation. An improved maturation procedure was then developed in which the three maturase proteins were expressed separately to avoid *in vivo* maturase interactions. Such interactions were thought to be important for function, and we sought to gain control over this portion of the maturation mechanism. In contrast to previous inferences, efficient apoenzyme activation was observed using the separately produced maturases. This new system enabled the production of much larger quantities of *in vitro* activated [FeFe] hydrogenase. This, in turn, enabled high resolution FTIR (Fourier transform infrared spectroscopy) analysis of the C-O and C-N stretches associated with the cyanide and carbon monoxide adducts in the 6Fe-6S active site. Isotopic labeling of tyrosine then conclusively showed that all three of the CO and both of the CN moieties in the active site are derived from tyrosine.

The second project objective is to gain better understanding of the impact of the polypeptide scaffolding on hydrogenase activity. The expression gene for the CpI [FeFe] hydrogenase from *Clostridium pasteurianum* was extensively mutated using nucleotide analogs, and isolates were identified that retained at least partial activity and also displayed increased stability during oxygen exposure. The most interesting isolate contained 13 mutations and was extensively analyzed. When two of the amino acid changes were reversed, full activity was restored. Three different mutations increased oxygen tolerance. Unexpectedly, none of these mutations are near the active site 6Fe-6S H-cluster, but four of the five mutations are close to the proximal 4Fe-4S center that either donates electrons to the active site H-cluster or receives them, depending on the direction of catalysis. These results suggest that the function of this ancillary iron-sulfur center has a stronger than expected

influence on enzyme function. During this work, we also observed that oxygen inactivation of [FeFe] hydrogenases can be substantially reversed in contrast to general belief. The reversibility also appears to be influenced by the ancillary Fe-S center. Future work will now seek to assess the function of the amino acids surrounding this ancillary center as well as those that support the active site.

During the course of these investigations, a number of methods were developed of general utility to this field of research. These include: the *in vitro* hydrogenase maturation protocols, a procedure for producing high levels of maturases and hydrogenases in *E.coli* cultures, improved methods for producing and screening hydrogenase mutants, and a new method for assessing sustained hydrogen production activity while using a reduced ferredoxin protein as the electron donor. In particular, the last method is very important as it will now allow us to screen for mutants with increased oxygen stability while they are actively making hydrogen. In addition, this method suggests the feasibility for cost-effectively producing hydrogen from biomass hydrolysates. A new research program has now been initiated to develop technology for the large scale production of hydrogen from biomass hydrolysates.

Progress Report

Taking our lessons from the investigation of another important and complex enzyme, nitrogenase, we first sought to develop methods for the *in vitro* maturation of the [FeFe] hydrogenases. Although early work from the Peters lab at U. of Montana had achieved *in vitro* activation (although with very low yields), that system was not suitable for investigating the effects of small molecular weight substrates. Based on our success with cell-free protein synthesis of the hydrogenases (Boyer et al, 2008), we developed an *in vitro* maturation protocol that achieved substantial activation of the *C. reinhardtii* HydA1 [FeFe] hydrogenase using cell extracts in which the three maturases, HydE, HydF, and HydG, had been expressed. These maturases were expressed from the relevant genes taken from *Shewanella oneidensis* and were produced under anaerobic conditions at 20°C to encourage proper folding. For convenience, the extracts were then prepared under aerobic conditions and were frozen for storage. The extracts were then dialyzed just before use to remove small molecules, and the maturases were reconstituted (reactivated) by anaerobic incubation with Fe(II) and S²⁻. The apoenzyme was produced in *E.coli* cultures lacking the maturases and had no activity after purification. As expected, S-adenosyl methionine, Fe(II), and S²⁻ were necessary for activation. However, full activation was only achieved with the additional presence of a mixture of the 20 natural amino acids. A design of experiment (DOE) protocol then indicated that tyrosine was essential and cysteine was beneficial (see Figure 1) for hydrogenase activation.

A previous report had suggested that co-expression of the maturases was necessary for their activation. However, we reasoned that more information about hydrogenase

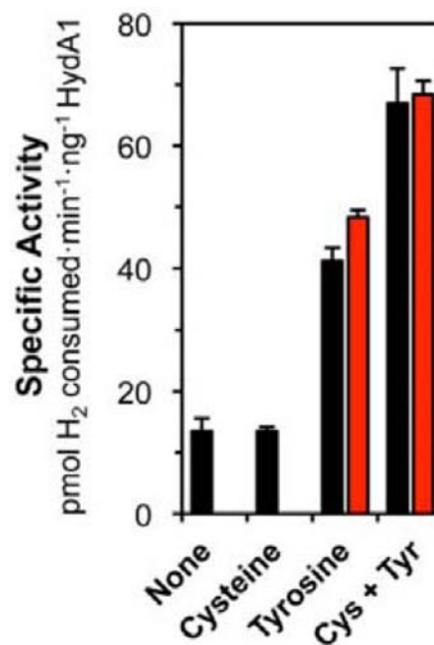

FIGURE 1.

maturation could be gained if the maturases could be expressed in separate *E.coli* cultures. This would then require that nearly all maturation related reactions take place during the *in vitro* activation. This protocol would also have a higher likelihood of enabling complete incorporation of isotopically labeled precursors into the H-cluster active site. Again, the apoenzyme was produced in cultures lacking the maturases and had no activity. At this point in the project, we had discovered that an *E. coli* strain with a Δ *iscR* deletion (Akhtar & Jones, 2008) produced more of the maturases as well as more apoenzyme. By mixing three extracts, each containing high levels of an individual maturase, effective apoenzyme activation was achieved. This protocol also efficiently matured the more complex CpI hydrogenase from *Clostridium pasteurianum*. After isotopically labeled tyrosine was added to the maturation reactions, the activated and purified hydrogenase samples were analyzed by FTIR. Distinctive shifts in the C-O and C-N stretches were observed as shown in Figure 2. These shifts indicated that all of the CN⁻ adducts in the active site H-cluster derived from the alpha carbon and amino nitrogen of tyrosine and all of the CO adducts derived from the carboxylate group of tyrosine. Recent work had shown that CO and CN could be extracted from the HydG maturase and that these species derived from tyrosine, but these recent publications had not shown that all of the adducts in the active enzyme derived from tyrosine.

The work to characterize the role of the polypeptide structure began with a mutant of the *C. pasteurianum* CpI hydrogenase that was isolated with 13 amino acid changes that conferred lower activity and improved oxygen tolerance. When the wild type amino acids were restored at positions 186 and 188, full activity was also restored. (See Figure 3)

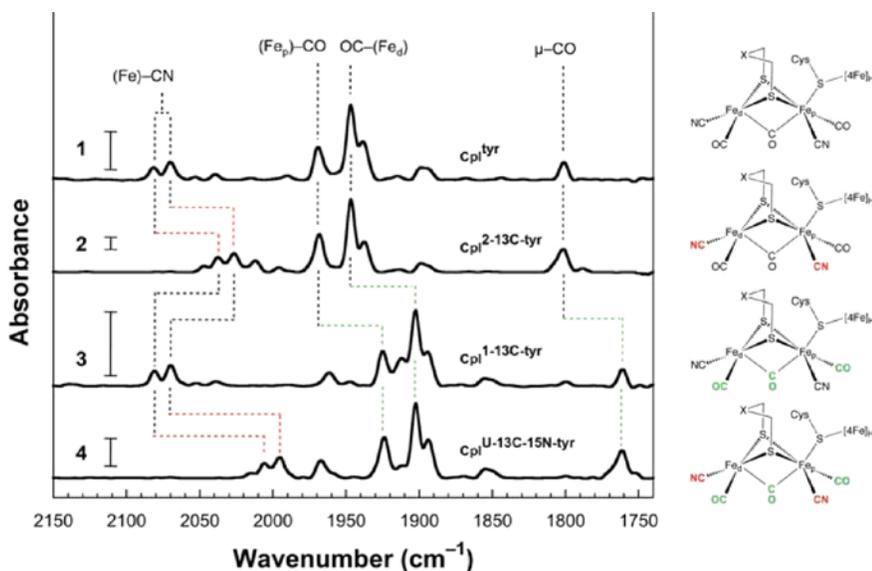

FIGURE 2.

Interestingly, these mutations were not near the active site, but rather adjacent to the electron conducting 4Fe-4S center proximal to the active site. It also turned out that the most influential mutation for conferring oxygen tolerance was at position 197, an amino acid that is adjacent to the same 4Fe-4S center. Amino acid position 160 was also influential for oxygen tolerance and was adjacent to the same cluster.

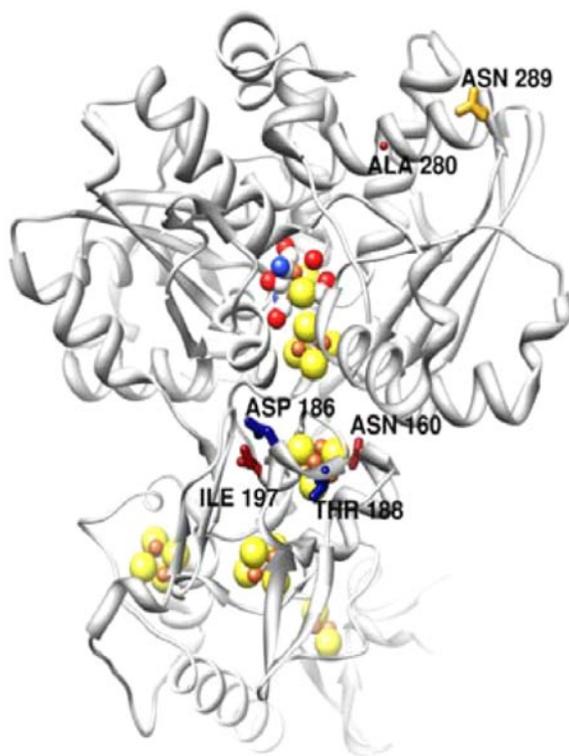

FIGURE 3.

It thus became clear that this 4Fe-4S cluster proximal to the catalytic center has strong influences on functional properties. The influences of the other amino acids surrounding this cluster will now be further characterized in addition to those surrounding the catalytic center.

Perhaps even more important than these specific discoveries is the collection of methods that have been developed. For example, paper no. 2 in our publication list describes a new production protocol that increases volumetric hydrogenase yields by 10 to 30 fold when produced by an rDNA *E.coli* culture. We have also established the ability to continually transfer electrons from NADPH to the hydrogenase to assess oxygen tolerance while the enzyme is making hydrogen. Unfortunately, this new technique showed that our oxygen tolerant

mutant was only tolerant when in the resting state and not when it is producing hydrogen. This is a totally unexpected observation. It will be investigated further, but it also suggests that we need to adjust our screening assays. The new pathway from NADPH will form the basis for a high throughput screening assay that assesses oxygen tolerance for the active enzyme. This new method also forms the basis for a new pathway to convert biomass hydrolysates to hydrogen and this is now being pursued by a new project.

Future Directions

We now have accumulated a large variety of enzyme production and assessment methods and we can now enter a more active period to generate many new mutants that differ in functional characteristics. We will continue to work with our spectroscopy experts to gain a fuller understanding of the relationship between structural and functional changes and will most likely also begin a collaboration with X-ray structural experts to gain more detailed information about the impact of individual mutations. To better understand maturation, we will also work to establish catalytic maturation; i.e., the ability to catalyze multiple turnovers of the maturases when working to activate the hydrogenase.

of electrons towards H₂ involved transcriptional control of Calvin cycle gene expression. These observations pointed to the Calvin cycle as a convenient single target to disrupt to force more electrons towards H₂ production. Blocking Calvin cycle flux by mutation in the H₂-producing strain resulted in higher H₂ yields for all substrates. The increase in H₂ yield was proportional to the Calvin cycle flux in the parent strain for most substrates. These results demonstrate how systems level approaches, such as ¹³C-metabolic flux analysis, can lead to effective strategies to improve product yield. Furthermore, our results underscore that the Calvin cycle and nitrogenase have important electron-accepting roles separate from their better known roles in biomass generation and ammonia production.

Objectives

The objectives of this project are (i) to use ¹³C-metabolic flux analysis and other approaches to identify metabolic factors that influence the phototrophic production of H₂ from organic compounds by *Rhodospseudomonas palustris* and (ii) to use the resulting information to guide the engineering of *R. palustris* for improved H₂ production.

Technical Barriers

A technical barrier to engineering bacterial strains for enhanced H₂ production is a limited ability to follow electron flow through metabolism. Here we used ¹³C-metabolic flux analysis, in combination with physiological and other 'omics' analyses, to overcome this barrier by tracking fluxes through redox reactions.

Abstract

Although most manufactured H₂ comes from fossil fuels, H₂ can also be produced biologically. The bacterium *Rhodospseudomonas palustris* uses energy from sunlight and electrons from organic waste to produce H₂ via nitrogenase. In order to understand and improve this process we used ¹³C-substrates having various oxidation states to track and compare central metabolic fluxes in non-H₂ producing wild-type *R. palustris* and an H₂-producing mutant. The pathways by which substrates were oxidized generated excessive amounts of reducing power such that only 40-60% could be used for biosynthesis, depending on the growth substrate. Wild-type cells relied heavily on the CO₂-fixing Calvin cycle to oxidize the excess reduced electron carriers, using CO₂ produced from the organic substrates by other metabolic reactions. The H₂-producing mutant used a combination of CO₂ fixation and H₂ production to oxidize excess reduced electron carriers. The majority of electrons for H₂ production were diverted away from CO₂ fixation for all substrates. Microarray and qRT-PCR analyses indicated that this shift

Progress Report

We established ¹³C-labeling techniques to determine metabolic fluxes in batch cultures of *R. palustris*. This information provided key insights into the physiology of *R. palustris*, some of which provide a better understanding of its genome sequence (e.g., an additional isoleucine pathway was identified by the labeling studies that was missed during genome annotation), or could not have been predicted from the genome sequence (e.g., 80-90% of the NADPH needed for biosynthesis comes from a transhydrogenase-like reaction and not from canonical sources such as the pentose phosphate pathway and isocitrate dehydrogenase). Our data also quantitatively answered a long-standing question of why an electron accepting process (e.g., CO₂ fixation or H₂ production) is needed during photoheterotrophic growth on relatively oxidized organic compounds. Additionally, we identified the Calvin cycle as the primary competing pathway for electrons against H₂ production during growth on multiple substrates. We show that the Calvin cycle is a convenient, non-essential, single target for disruption that leads to higher H₂ yields during growth on all substrates tested.

Future Directions

Even in our Calvin cycle mutants, the majority of substrate electrons are incorporated into cellular biomass. For example, 15% of the electrons in acetate are used for H₂ production while 85% are used for biosynthesis. Thus, using non-growing cells should result in much higher H₂ yields. Indeed, *R. palustris* produces H₂ from acetate at 60% of the theoretical maximum yield when completely starved of nitrogen. *R. palustris* is potentially well suited for use as a non-growing biocatalyst since it can remain metabolically active for months in a non-growing state using light energy and cyclic photophosphorylation to satisfy maintenance

energy demands. By the same token, *R. palustris* can serve as a model bacterium for studying the physiology of non-growing cells. We are now determining the fate consumed electrons in nitrogen-starved *R. palustris* by quantifying excreted products and changes to its biomass composition. Additionally, we are adapting our ^{13}C -labeling protocols to determine metabolic flux distributions in non-growing *R. palustris*. The resulting information will be used to engineer *R. palustris* to improve the H_2 yield under non-growing conditions.

Objectives

The Hydrogen Fuel Initiative Workshop report (www.science.doe.gov/bes/hydrogen.pdf) sponsored by DOE stated that a fundamental understanding is needed of the structure and chemical mechanism of the enzyme complexes, known as hydrogenases, that support hydrogen generation, and that we need to understand how these catalysts are assembled with their cofactors into integrated systems. The proposed research specifically addresses the issues of understanding the assembly and organization of hydrogenases. This is the first step to ultimately reducing their size and complexity and of determining structure/function relationships, including energy conservation via charge separation across membranes.

Technical Barriers

Remarkably, in spite of the large amount of research that has been carried out on hydrogenases, it is not possible to readily manipulate or engineer the enzyme using molecular biology approaches since a recombinant form produced in suitable amounts in a suitable host is not available. Such resources are essential if we are to understand what constitutes a “minimal” hydrogenase, and to design such catalysts with desired properties, such as resistance to oxygen, extreme stability and specificity for a given electron donor. However, this is very challenging from a technical perspective as numerous gene products are required to synthesize the catalytic nickel-iron (NiFe) catalytic site of the protein and to assemble the mature, active hydrogenase enzyme.

Abstract

As a model system we are using the NADP-dependent, cytoplasmic NiFe-hydrogenase I (SHI) of *Pyrococcus furiosus*, a hyperthermophile that grows optimally at 100°C. We made two breakthrough discoveries during the funding period. First, we have generated the catalytically-active form

of the heterotetrameric SHI by heterologous gene expression in the mesophilic bacterium, *Escherichia coli*. Second, a genetic system is now available in *P. furiosus* and this allows us to generate modified forms of the SHI by homologous gene expression. Specifically, we have overexpressed SHI in *P. furiosus* such that the organism produces an order of magnitude more of the native enzyme, increasing the amount purified from native biomass by up to 50-fold. We have also taken the first step toward generating a ‘minimal’ hydrogenase by homologous expression of an affinity-tagged heterodimeric form of the heterotetrameric enzyme and by so doing we have also changed its electron carrier specificity. In contrast to the native form, the heterodimer does not use NADP/H as an electron carrier and directly interacts with the pyruvate-oxidizing enzyme, pyruvate ferredoxin oxidoreductase, thereby enabling direct hydrogen production from pyruvate by an as yet unknown mechanism.

Progress Report

1. Production of the Native Tetrameric Form of *P. furiosus* hydrogenase I (SHI) in *E. coli*.

Hydrogenases are extremely complex, air-sensitive enzymes that achieve catalysis using a binuclear nickel-iron cluster that contain cyanide and carbon monoxide ligands to the iron atom (see **Figure 1**). This cluster is covalently bound to the protein and receives electrons for proton reduction via multiple iron-sulfur (FeS) clusters. A very complicated maturation process is required to synthesize the [NiFe]-catalytic center and insert it into the apoenzyme (see **Figure 1**). We successfully produced in *Escherichia coli* the recombinant form of *P. furiosus* SHI using novel expression vectors for the co-expression of thirteen *P. furiosus* genes (four structural genes encoding the hydrogenase and nine encoding maturation proteins). Remarkably, the native *E. coli* maturation machinery will also generate a functional *P. furiosus* hydrogenase when provided with only the genes encoding the hydrogenase subunits and a single protease (frxA) from *P. furiosus*. Another novel feature is that its expression was induced by anaerobic conditions, whereby *E. coli* was grown aerobically and production of recombinant hydrogenase was achieved by simply changing the gas feed from air to an inert gas (N₂). The recombinant enzyme was purified and shown to be functionally similar to the native enzyme purified from *P. furiosus*, including its high stability towards oxygen ($t_{1/2} > 20$ hr in air) and the use of NADP(H) as an electron carrier. An enzyme that evolves hydrogen from NADPH holds promise for large-scale harvesting of molecular hydrogen from renewable biomass, and the methodology to produce the key hydrogen-producing enzyme has now been established.

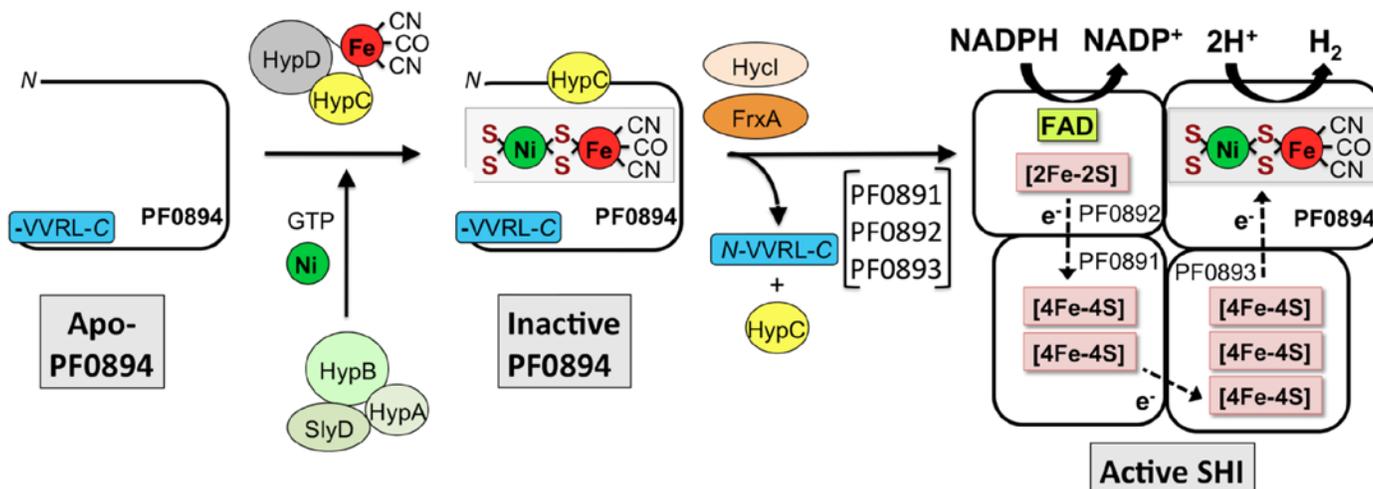

FIGURE 1. Biosynthesis of *P. furiosus* hydrogenase I (SHI) in *E. coli*.

2. Over-Production of the Native Tetrameric Form of *P. furiosus* Hydrogenase I (SHI) in *P. furiosus*.

A major breakthrough in the past year has been the development of a genetics system in *P. furiosus* in another on-going project in the PI's laboratory. We are utilizing this to develop expression systems for the hydrogenase I. This gives us the capability for both heterologous (in *E. coli*) and homologous (in *P. furiosus*) systems to engineer *P. furiosus* hydrogenases. Our first objective was to obtain a *P. furiosus* strain in which SHI was significantly over-expressed and where the protein contained an affinity tag for rapid purification. To achieve this we utilized a parental strain that had a deletion in a gene (*pyrF*) required for uracil biosynthesis in *P. furiosus*. This requires uracil for growth and is resistance to the uracil biosynthetic pathway inhibitor, 5-fluoroorotate (5-FOA). A 'knock-in' cassette was constructed containing the upstream (UFR) and downstream (DFR) flanking regions of the promoter region for SHI (P_{SHI}), together with *pyrF* (driven by the promoter for glutamate dehydrogenase, P_{GDH}), a terminator sequence (T1) and replacing P_{SHI} with P_{SLP} the promoter for the S-layer protein (PF1399), and the strep-II tag (8 amino-acids) at the N-terminus of the PF0891 subunit of SHI. P_{SLP} is one of the most highly expressed genes in *P. furiosus* based on our DNA microarray data.

The specific hydrogenase activity of cytoplasmic extracts of wild type *P. furiosus* cells and the $\Delta pyrF$ strain were 0.77 ± 0.5 units/mg. The two strains in which SHI was over-expressed (OE-SHI) by P_{SLP} showed no obvious phenotype but their specific activities were 8.2 ± 0.2 units/mg, representing an increase of more than an order of magnitude in hydrogenase activity. The dramatic overexpression of SHI protein in the OE-SHI strains was confirmed by immunoanalysis using antibodies to PF0894 (the catalytic subunit of SHI). Given the extremely complex maturation process that is involved in synthesizing the

hydrogenase, the results show that the wild-type level of the maturation machinery is able to process >10-fold more SHI than it usually does. This was somewhat surprising since no attempt was made to up-regulate these processing genes. Unfortunately, the Strep-II tag on PF0891 appeared to be partially buried as OE-SHI bound weakly to the streptactin column. Nevertheless, while five chromatography steps are normally needed to purify native SHI yielding 2-10 mg /500 g of cells, the OE-SHI strain yielded 11 mg/50 g of cells. The native and OE-forms had similar thermal stabilities and oxygen sensitivities.

3. Over-Production of a Heterodimeric form of *P. furiosus* Hydrogenase I (SHI) in *P. furiosus*.

As a first step towards making a 'minimal' hydrogenase, we produced the heterodimeric form of SHI containing only the large catalytic (LSU; PF0894) and the small FeS-cluster containing subunit (SSU, PF0894), as shown in Figure 2. The SSU contained an N-terminal His₅-tag and expression was driven by the P_{SLP} promoter. Recombinant Pf cells had no significant phenotype and a total of ~6 mg of the pure protein (148 U/mg) was obtained from the Ni-NTA column using 50 g of cells. The OE-dimer was less thermostable ($t_{1/2}$ 1 hr at 90°C) and more oxygen sensitive ($t_{1/2}$ 1 hr in air) than native heterotetrameric form of SHI. The dimer did not evolve H₂ from NADPH (since it lacked FAD-containing PF0892) nor did it evolve H₂ from reduced ferredoxin of *P. furiosus*. However, in contrast to the native form, the heterodimer directly interacted with the pyruvate-oxidizing enzyme, pyruvate ferredoxin oxidoreductase (POR) from *P. furiosus*, thereby enabling direct hydrogen production from pyruvate. It therefore appears that the novel heterodimeric hydrogenase is able to accept electrons by a direct enzyme-enzyme (hydrogenase-POR) interaction although the mechanism is unknown.

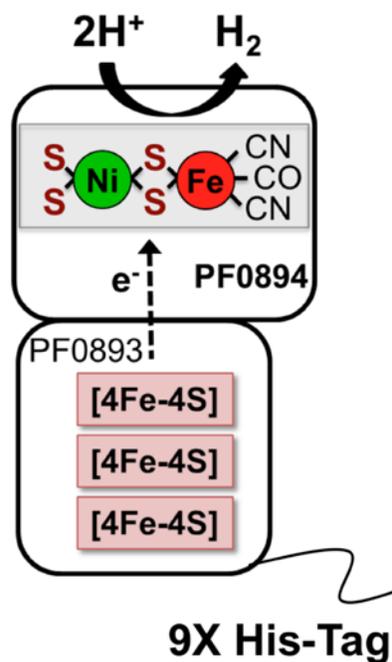

FIGURE 2. Structure of the heterodimeric form of SHI.

Future Directions

The longer term objectives of our research are to capitalize on the breakthroughs made in the current funding period and to a) optimize production of tagged recombinant forms of the cytoplasmic hydrogenase of *P. furiosus*, b) to obtain soluble and membrane-bound tagged recombinant forms of the ferredoxin-dependent, membrane-bound hydrogenase that is also present in *P. furiosus*, an enzyme that we have shown simultaneously evolves H₂ and pumps protons, c) to design ‘minimal’ hydrogenases with tailored catalytic activity, oxygen sensitivity and electron donor specificity, and d) to design membrane-bound hydrogenases in artificial membranes that generate ion gradients and evolve hydrogen. Such enzymes have potential utility in various biotechnological applications.

Progress Report

Protein complexing suggests electron bifurcation and electron delivery from formate to heterodisulfide reductase. By purifying Hdr from *M. maripaludis*, we discovered a protein complex that contains not only Hdr but a hydrogenase (Vhu), a formate dehydrogenase (Fdh), and formylmethanofuran dehydrogenase (Fwd) (5). The existence of the complex supports a model of electron flow in which either hydrogen or formate directly reduce the flavin of Hdr, and electron bifurcation leads to the reduction of heterodisulfide and of CO₂ to formylmethanofuran (formyl-MFR). In addition, in a mutant deleted for Vhu, growth on hydrogen was poor but growth on formate was as good as wild type.

Genetic analysis reveals three pathways of hydrogen utilization for methanogenesis and an independent pathway of formate utilization. We have generated numerous deletion mutants in genes for hydrogenases. Only in a mutant deficient in three hydrogenases could we eliminate the ability of hydrogen to support methanogenesis. Thus, we eliminated F₄₂₀-reducing hydrogenase (Fru), Hdr-associated hydrogenase (Vhu), and the hydrogenase Hmd that can act in concert with Mtd to reduce F₄₂₀ (6). This mutant required formate for growth even when hydrogen was present. It also required hydrogen, and evidence to be presented suggests that the hydrogen requirement is restricted to biosynthesis. This result alters the previous view in which methanogenesis from formate required production of hydrogen from formate. Instead, it now appears that formate can support methanogenesis directly (5, 7). In addition, the multiple-hydrogenase mutant should be unable to re-utilize for methanogenesis any hydrogen that is produced

Uncoupling of methanogenesis from growth does not depend on the energy-conserving hydrogenase Ehb. Growth yields (cell mass produced per methane produced) of *M. maripaludis* were three-fold higher under hydrogen limitation (in chemostats) compared to hydrogen excess. Thus, under hydrogen excess conditions metabolism partially uncouples from growth, enhancing prospects for growth-independent hydrogen production. Uncoupling could occur by several mechanisms, including depletion of chemiosmotic membrane potential by the energy-conserving hydrogenase Ehb (8). However, uncoupling still occurred in a *ehb* mutant.

Future Directions

Our strategy for hydrogen production from formate involves the derepression of nitrogenase in a mutant that is deficient in hydrogen re-uptake. Based on the above results, we are now ready to construct a strain that fulfills these criteria. In addition, using the purified Hdr complex we will test in vitro whether formate is indeed a direct electron donor and whether the complete pathway of electron bifurcation occurs. Finally, to maximize hydrogen production we seek to optimize the uncoupling of methanogenesis from growth, in order to direct maximal

ATP to nitrogenase. To this end, we will test several hypotheses for the basis of uncoupling.

Objectives

The overall goals of the project are to develop an understanding of [FeFe]-hydrogenases (H₂ase) as model hydrogen (H₂) activation catalysts, and to elucidate the parameters that control hydrogen production by H₂ases in photoelectrochemical cells and molecular photocatalytic complexes. The research objectives include: (i) developing theoretical models of H₂ase to understand electron/proton-transfer (ET and PT) and catalysis; (ii) characterizing redox-induced changes in H₂ase catalytic site structures using mutagenesis and infra-red (FTIR) spectroscopy; (iii) optical and electronic studies of H₂ase-carbon nanotube and nanoparticle complexes; and (iv) electrochemical characterization of native and structurally minimized H₂ases on Au-SAM electrodes using electrochemical STM. These efforts will provide fundamental knowledge how H₂, and how to functionally integrate them as components of artificial hydrogen production schemes.

Technical Barriers

Developing efficient solar hydrogen production requires robust and efficient catalysts, and the understanding of how to integrate them with photoactive materials into efficient artificial systems. The H₂ases possess many characteristics of an ideal catalyst, and elucidation their basic structure-function properties can help to guide efforts to develop synthetic catalysts. A fundamental challenge is to resolve how the metallo-clusters, essential ligands and the surrounding peptide function together to achieve an overall efficient catalytic process. Another is how to control molecular interactions between H₂ases and photoactive molecules to achieve self-assembly into bio-hybrid photocatalytic complexes for hydrogen production.

Abstract

We seek to advance the understanding of [FeFe]-hydrogenases (H₂ase) structure-function, and the parameters that control assembly, charge-transfer and catalytic efficiencies of H₂ases as model catalysts in bio-hybrid, solar H₂-production systems. The knowledge that is gained will help to elucidate the biochemistry of H₂ activation, and support design and development of more efficient solar-to-H₂ conversion by artificial photosynthetic schemes. H₂ases are expressed using a recombinant expression system, and purified enzymes are characterized using a combination of biochemical, electrochemical (electrochemical Scanning Tunneling Microscopy, STM) and spectroscopic (FTIR) techniques. The assembly and characterization of purified H₂ases in bio-hybrids is being studied using solution-phase, photoactive nanoparticles, and as an electrocatalyst in photoelectrochemical cells. Together with the experimental studies, theoretical models are being developed to investigate the H₂ase catalytic site, electron-transfer [FeS]-clusters, substrate transfer pathways, and bio-hybrid complexes. The latest progress in these respective research areas will be summarized.

Progress Report

- (i) Computational chemistry studies of H-cluster models with perturbed diatomic ligands have revealed a potential role of the bridging ligand in buffering charge upon enzyme reduction during catalysis.
- (ii) A quantum chemical H₂ase model encompassing the H-cluster, accessory [4Fe-4S]-clusters and surrounding protein was constructed. Custom computational methods allow for breaking the spin symmetry within accessory [4Fe-4S]-clusters, and integration of the initial gas-phase calculation into a QM/MM model of the complete H₂ase. The free energies along PT pathways were investigated using QM/MM and umbrella sampling techniques. Several important residues were identified and *pK_a* values estimated by thermodynamics integration method.
- (iii) Brownian dynamics and molecular dynamics simulation techniques predicted the binding structures between H₂ase and SWNTs or bulk carbon surfaces, and ET rates. ET appears to be at least a 100-fold faster for SWNTs than for a bulk carbon surface, and independent of SWNT diameter.
- (iv) The native H₂ase has been successfully adsorbed to Au electrodes bearing self-assembled thiol-based monolayers (SAMs) and retains activity. Binding is via interactions between positively charged patches on the enzyme and carboxylate groups on the SAM.

Single-molecule images have been obtained in an electrochemical STM and suggest tunneling currents increase under an applied bias. Removal of adsorbed H₂ase from the STM surface helped confirm that the features observed with the STM are H₂ase.

- (v) Electrostatically guided assemblies of H₂ase with mercaptopropionic acid capped CdTe nanocrystals (NC) and CdS nanorods have been successfully formed in solution. Both types of complexes were isolated by gel electrophoresis and showed evidence of compositional heterogeneity. Photoluminescence and hydrogen evolution studies suggest that competition of electron transfer with internal relaxation pathways is favored for 1:1 molecular ratios. We have preliminary Transient Absorption kinetics for H₂ase:CdS complexes that shows the estimated electron-transfer step from CdS to H₂ase occurs at a timescale of ~10² nsec, whereas internal relaxation of CdS occurs at ~10 nsec.

Future Directions

- Tunneling currents will be examined between accessory [4Fe-4S]-clusters and the H-cluster in the H₂ase model. Dynamics trajectories will also be analyzed to determine protein conformational features correlating with large couplings, as approximated by empirical pathways analysis. The free energies along the PT pathways will be further refined based on the *pKa* calculation results.
- We will continue to investigate the binding free energies for H₂ase with SWNTs and bulk carbon surfaces using MD simulation techniques, and develop these models to predict binding modes, orientations and ET processes.
- We will continue to characterize redox-induced changes in catalytic site structures of H₂ases using FTIR spectroscopy to define ligand conformations of oxidized and reduced states, and use mutagenesis to characterize the role of the peptide environment.
- Single-molecule electrochemistry of immobilized H₂ase on Au-electrodes will continue to be developed to characterize the binding interaction, tunneling currents and the operating potentials of the enzyme. Mutated H₂ases lacking individual accessory iron-sulfur clusters functioning in electron-transfer will be studied in order to learn more about the conductive path through the protein.
- We will develop and apply FTIR spectroscopy to characterize the binding and charge-transfer reactions between H₂ases and SWNTs both in solution and in films, to identify how the SWNT intrinsic electronic properties affect redox active modes of H₂ase.
- Characterize redox-induced changes in H₂ase-NC complexes under photoexcitation using steady-state and time-resolved optical and FTIR techniques.

Objectives

Research objectives are to study genes and proteins within *Desulfovibrio* strain G20 that are involved in syntrophic interactions in coculture with a Syntrophic butyrate degrading bacterium and a during lactate oxidation in coculture with a hydrogenotrophic methanogen. Specifically, this has involved screening mutants for loss of ability to grow in coculture in order to identify genes in *Desulfovibrio* needed for syntrophic growth. Mutants, mutated genes and the proteins encoded by these genes are being characterized to determine their specific function during syntrophic growth. Characterization involves a determination of the effect of the mutation on growth characteristics as well as the properties of the protein encoded by that gene.

Technical Barriers

- Identify key enzymes involved in H₂ production by *Desulfovibrio*.
- Characterize these enzymes to determine their role in H₂ production.

Abstract

In order to identify proteins involved in H₂ metabolism in *Desulfovibrio desulfuricans* G20, transposon insertion mutants deficient in syntrophic growth were identified and are being characterized. A screening done with G20 in a hydrogen uptake role in coculture with *Syntrophomonas wolfeii* found that mutants for the *flhA* flagellar biosynthesis gene, the *fliF* flagellar ring gene, and the *pilA* pilus assembly gene were unable to grow, suggesting a role for chemotaxis or other flagellar function in syntrophy. Microscopy showed the *flhA* mutant to lack flagella and both flagella mutants and the pilus mutant produced considerably less biofilm than the parent strain. Recent experiments suggest that the flagella mutants grow more slowly on H₂, perhaps indicating a need to motility during H₂ growth in laboratory

cultures. We have also recently identified mutants in a membrane protein annotated as Rnf. This protein appears to be involved in H₂ uptake as G20 mutants will not grow on H₂ or formate. We are currently identifying the specific mechanisms by which the above proteins allow the cell to grow with H₂.

The membranes of several mutants of *Desulfovibrio vulgaris* including a *qmo* (quinone membrane oxidoreductase) mutant were extracted and separated on Blue Native gels to identify large protein complexes. The *qmo* mutant was found to be missing several bands compared to the parental strain. These bands were identified to be the *qmo* protein complex as well as a complex of the *qmo* and APS reductase, suggesting that these two proteins operate as a multiprotein complex during H₂ oxidation. Affinity tagged genes are being used to verify this phenomenon as well as to identify other proteins that may be involved in this electron transport complex.

Progress Report

Genes involved in syntrophic growth. A number of genes have been identified which appear to be required for syntrophic growth of *Desulfovibrio* as the H₂ user with *Syntrophomonas wolfeii*. Some characterization experiments have been done and results are presented below (table 1). Results show that both the presence of flagella as well as the Rnf protein play a role in H₂ uptake. Rnf has been characterized in *Rhodobacter capsulatus* and shown to be involved in nitrogen fixation (1). It is a large membrane spanning protein with homology to energy conserving oxidoreductases in many other bacteria. Although some species of *Desulfovibrio* contain genes for nitrogen fixation, strain G20 does not, suggesting that Rnf plays a different role. The mechanisms for disruption of H₂ metabolism will be investigated.

Membrane Protein Complexes in *Desulfovibrio*.

Several mutants were grown in culture and their membranes were isolated and run on Blue Native gels to determine whether they formed large complexes. Gels run with a mutant in the QMO complex had three absent bands in comparison to the parental strain (Fig. 1). Bands were excised and proteins were identified by mass spectroscopy. One of the bands (C) appears to be the *qmo* complex while another band (B) appears to be a complex containing both QMO and APS reductase. This complex has been speculated to operate together for the reduction of sulfate (APS) to sulfite as both QMO genes and APS reductase genes are located adjacent to each other on the chromosome (2). As well, the QMO mutant will grow on sulfite but not on sulfate (3). This is the first evidence showing a physical interaction between these proteins. Affinity tagged strains have been produced and in

TABLE 1. Growth and biofilm formation by pure cultures of some syntrophy mutants. Results shown that mutations in flagellar function and pilus function affect both biofilm formation and growth on H₂. As well, rnf mutants do not grow on H₂. ND-not determined.

the presence of detergent, both QMO and APS reductase have been purified to homogeneity from cell extracts of strain G20. These enzymes are expected to be present in complexes with each other as shown in figure 1. SDS gel banding patterns of each of the purified enzymes are identical suggesting that they all contain the same set of proteins as a complex. However, to be certain we are in the process of identifying protein bands from SDS gels using mass spectroscopy. This will prove the association of QMO reductase and determine whether any other proteins are associated with this complex.

Future Directions

Determination of the role of syntrophy genes. RNF appears to play a role in the syntrophic interaction. The inability of G20 rnf mutants to grow in the presence of H₂ may be the reason for its inability to grow syntrophically. Rnf is a large membrane spanning protein complex that couples electron transfer to energy transduction (1). It is thought to also involve quinone reduction. The growth of rnf mutants will be further investigated to determine whether Rnf may interact with QMO or with DSR directly

of perhaps whether it plays a more indirect role in H₂ uptake. This is the first study that I am aware of that implicates Rnf in H₂ metabolism by *Desulfovibrio*. A group of three flagella and pilus genes have also been shown to be involved in syntrophy. The specific role that these genes play will be investigated. Through growth experiments, chemotaxis studies as well as experiments looking at the physical interaction between the two members of the syntrophic consortium

Membrane Protein Complexes in Desulfovibrio. This work will build on the above results showing the presence of respiratory membrane complexes in strain G20. Our recent work has demonstrated a role for a protein now referred to as Qrc (Mop) in the uptake of H₂ by *Desulfovibrio* G20. Qrc has recently also been purified and shown to interact with both tetraheme cytochrome C3 in the periplasm and menaquinone (most likely in the membrane) (4). It is therefore possible that Qrc interacts directly with QMO for the oxidation of H₂ coupled to the reduction of adenosine phosphosulfate (APS). We will test this hypothesis by reconstituting purified enzymes tetraheme cytochrome C3, Qrc, QMO, APS reductase available with affinity tags along with menaquinone to determine whether this process can occur in vitro.

Transcriptomic Analysis of Syntrophic Cocultures. A number of genes have been identified that are involved in syntrophic interactions, based on growth assays. In the original proposal, we described experiments using microarrays to validate the role of these genes in syntrophy. New and more powerful technologies are available and the most promising of these is RNA-seq. This technique involves extracting mRNA from active cultures and sequencing the RNA using Illumina technology. This technique is advantageous over microarrays in that there is no up front cost and effort and information is not only obtained on the amount of each transcript present, but the complete sequence of each transcript is also obtained providing information on operon structure, etc. Pure cultures and syntrophic co-cultures will be grown to log phase, cells will be harvested and transcript abundance will be determined. We will compare cocultures of *Syntrophomonas wolfei*, *Syntrophus aciditrophicus* and *Desulfovibrio* G20 grown with *Methanospirillum hungatei*. Pure cultures will also be tested. In this way, comparisons can be made and genes expressed only in co-cultures can be compared between cocultures to identify those with a direct role in coculture interaction.

Objectives

The energy transduction systems of the anaerobic sulfate-reducing bacteria of the genus *Desulfovibrio* are to be elucidated. The target strain is *D. alaskensis* G20 because of its robust fermentative growth on pyruvate that should allow mutant analysis of sulfate respiration. Mutations of various transmembrane complexes are to be analyzed to determine their role in the energy budget of the cell. The development of genetic transfer systems for manipulation of the G20 strain is necessary for this analysis.

Technical Barriers

The assumption that pyruvate fermentation generates ATP only through substrate-level phosphorylation may be inaccurate. Thus learning the pathway(s) of reoxidation of the reduced ferredoxin produced in pyruvate oxidation is likely to reveal electron transfer complexes pumping protons that contribute to a proton gradient used for ATP synthesis. The gene transfer capacity of the G20 strain through transformation has proven recalcitrant. Gene transfer by conjugation is more time consuming but it allows the generation of mutants to proceed.

Abstract

Energy generation by the strictly anaerobic sulfate-reducing bacteria has been a controversial topic because of the unique feature that sulfate is the only inorganic electron acceptor that requires an energy-consuming activation before reduction. During the initial stages of growth of batch cultures that are respiring sulfate with organic acids as electron donors, hydrogen is both produced and then consumed. This observation led to the interesting hydrogen-cycling hypothesis (Odom and Peck, 1981) as a mechanism for contributing to the energy budget of the cells. We seek

to elucidate the role of hydrogen in the energy budget of these bacteria through genetic approaches. Exploration of electron flow in the *cycA* mutant of the G20 strain, I2, that lacks the type 1 tetraheme cytochrome c_3 (Tp1- c_3) has revealed an apparent minor role for fumarate as a terminal electron acceptor even during sulfate respiration. Further growth results with this mutant have shown that high pyruvate concentrations transiently inhibit sulfate respiration. In studies to determine the enzymes and compartments for hydrogen production during the hydrogen transient observed, it has been observed that putative cytoplasmic hydrogenases are not conserved among species of *Desulfovibrio*. Examination of our library of nearly 7000 random transposon mutants of the *D. vulgaris* Hildenborough strain constructed in cells grown on lactate/sulfate medium revealed that the cytoplasmic CO-associated hydrogenase complex was not interrupted by transposons. This result was interpreted to mean that this enzyme complex plays an important role in the metabolism of cells grown on these substrates. Interestingly this hydrogenase has been shown to be among a family of transmembrane hydrogenases that oxidize reduced ferredoxin generating hydrogen and pumping a proton. We will continue to generate mutations in genes encoding transmembrane complexes to elucidate their role(s) in energy generation in the sulfate-reducing bacteria.

Progress Report

1. Studies with the *Desulfovibrio* G20 tetraheme cytochrome c_3 (Tp1- c_3) mutant, CycA-, showed that sulfate respiration was transiently inhibited with electrons from pyruvate (Giles et al. under revision).
2. The alternative respiration of fumarate by G20 is robust (Fig. 1A) and analyses of excreted metabolites showed that some electrons are diverted to produce succinate even during sulfate reduction or pyruvate fermentation by the wild type G20 strain. CycA- mutant and a fumarate reductase transposon mutant are unable to respire fumarate (Fig. 1A).
3. Microarray and proteomics (Fig. 2) analysis of G20 and I2 revealed the surprising result that genes for fumarate respiration and, therefore, the enzymes were significantly decreased in the I2 mutant regardless of the growth mode. This suggests a redox control on transcription of these genes affected by the absence of the periplasmic cytochrome.
4. A putative two component regulatory operon was found upstream of the fumarate reductase operon (Fig. 3). A transposon mutation in the histidine kinase gene in that operon was tested for growth on fumarate and found to be unable to disproportionate fumarate

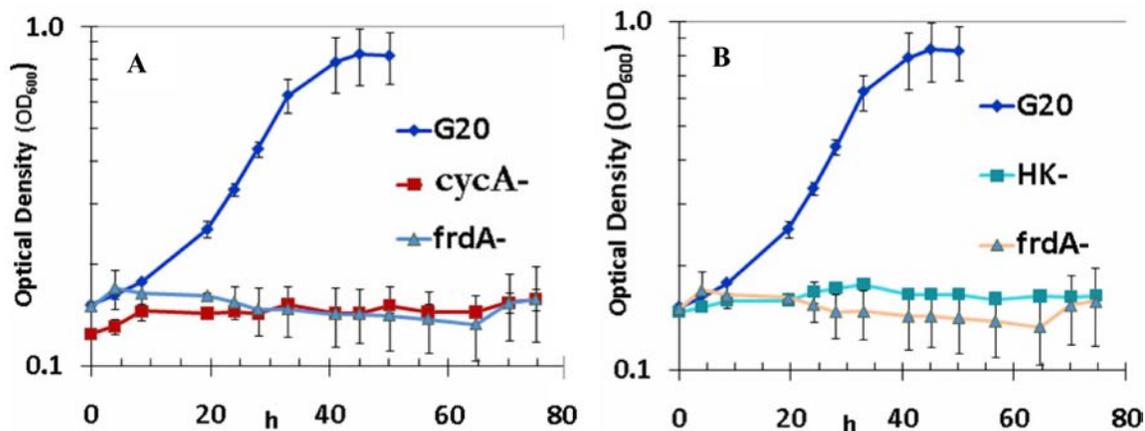

FIGURE 1. Growth by disproportionation of 60 mM Fumarate by *D. alaskensis* G20, a fumarate reductase (*frdA*) transposon mutant, the I2 mutant (*cycA*), and a transposon mutation in the histidine kinase (HK) upstream of the fumarate reductase operon.

HK, histidine kinase; RR, response regulator; HP, hypothetical protein. *frdCAB* encode a putative fumarate reductase, *ttdA*/*fumA* encode the two subunits of a putative fumarase, and *sfcA*, a malic enzyme.

(Fig 1B). We will test to determine whether this is a redox sensing regulator affected by the redox changes occurring when the periplasmic tetraheme cytochrome is missing.

- Over 7000 transposon mutations of *D. vulgaris* Hildenborough have been located through sequencing in collaboration with Adam Deutschbauer at LBNL.

All selections have been performed with respiration of sulfur oxides and lactate as carbon source and electron donor. If randomly positioned, we would expect nearly two insertions per kb. When the insertion positions were examined, it was surprising that the genes encoding the CO-associated hydrogenase, covering about 7.5 kb, (but not the CO dehydrogenase enzyme) lacked transposons

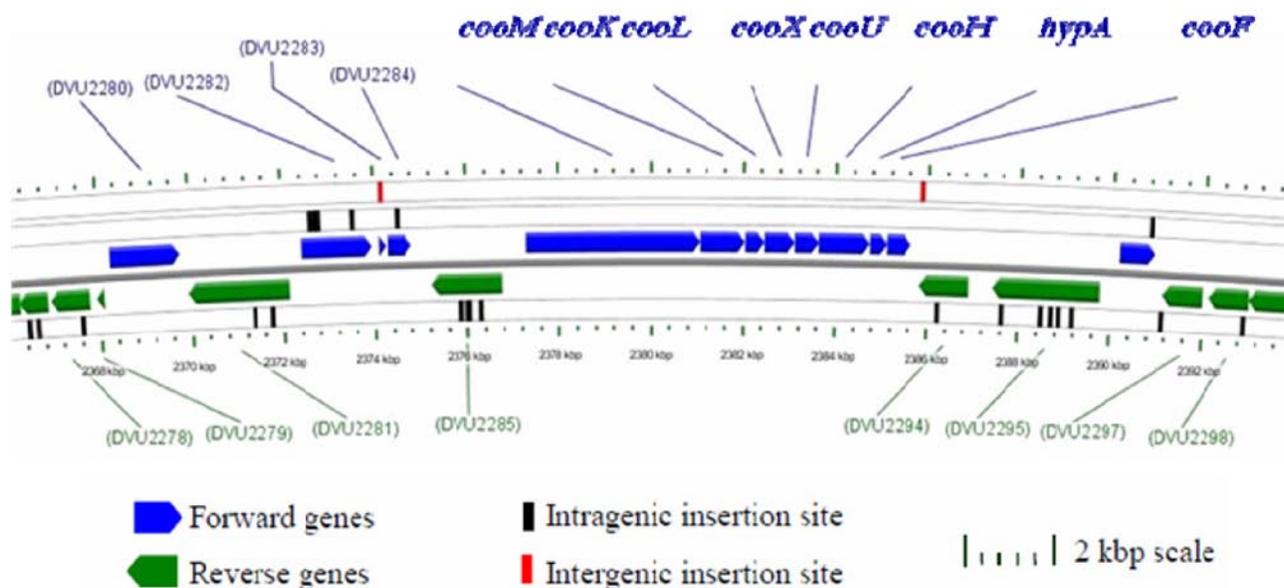

FIGURE 4. *D. vulgaris* chromosomal map in the region of the CO-associated cytoplasmic hydrogenase. Generated with CGView. *CooMKLXUHhypAcooF* had no transposon mutations.

(Fig. 4). We interpret this result as suggesting that strains with interruptions in these genes are not readily recovered in our procedures or that this enzyme complex is needed for growth under the conditions of selection. This hydrogenase has been predicted to be involved in energy conservation, acting as a primary proton pump in a ferredoxin-dependent electron transport system (Welte et al., 2010).

Future Directions

1. In *D. vulgaris*, we can construct multiple mutations in a single strain and propose to delete both the CO-associated as well as the Ech hydrogenase because these are the two candidates for cytoplasmic hydrogenases. The results of this experiment may allow us to resolve the debate about the hydrogen cycling contribution to the energy budget.
2. Candidates for energy conserving, ferredoxin-dependent complexes in G20 are not as obvious. There are now over 12,000 transposon mutants and no predicted cytoplasmic hydrogenase that lacks mutations. We will explore the heterodisulfide reductase complex mutants for growth rate comparisons with wild type cells to determine whether the mutants appear to be impaired because of an energy defect.

Objectives

The overall objective of this project is to develop fundamental understanding about the regulation of the partitioning of photosynthetic reductant between the H₂-production and the CO₂-fixation pathways. Specific objectives are to: (a) identify protein factors whose expression may be required for optimal hydrogenase expression; (b) identify active promoter regions and transcriptional elements for the two algal hydrogenases; and (c) determine whether the recently identified FIXL homologs in *C. reinhardtii* play a role in O₂-sensing mechanism and mediate components of the anoxic regulatory response that leads to hydrogenase expression.

Abstract

Photobiological H₂ production from water is a clean, non-polluting and renewable technology that could play a significant role in a future hydrogen economy. The potential light conversion efficiency to H₂ by biological organisms is theoretically about 10%. One of the limitations to meeting this efficiency is the low availability of reductant to the hydrogenase, due to the existence of competing metabolic pathways, such as CO₂ fixation. This project aims at understanding how photosynthetic reductant is partitioned between different metabolic pathways at the level of ferredoxin. In particular, the project continues to investigate the mechanism that underlies the anoxic regulation of hydrogenase in *C. reinhardtii* at the transcriptional and post-transcriptional levels. These goals are being pursued by (a) using high-quality sensors developed by Dr. Mathew Posewitz at Colorado School of Mines to identify and characterize candidate mutants displaying altered hydrogen production from insertional libraries; (b) fusing the truncated promoters of HYDA1 and HYDA2 to the SNAP reporter gene lacking its own promoter, to identify the DNA region required for anaerobic gene expression; (c) investigating the O₂ and CO-binding affinities of the truncated FXL1

and FXL5 homologues from *C. reinhardtii* expressed in *E. coli* and further studying their role in hydrogenase signal transduction; (c) probing the physiological and metabolic differences between structurally different algal [FeFe]-hydrogenases.

Progress Report

- To define the role of individual hydrogenases in green algae, we screened a *Chlamydomonas hyda2* mutant background (generated under DOE's BER funding) for mutants lacking all hydrogenase activity. A double *hyda2hyda1* mutant has been identified; it is being further characterized and is being used as the background strain for expression of recombinant [FeFe]-hydrogenases in *Chlamydomonas* by DOE's FCT Program.
- To identify active promoter regions for the two algal hydrogenases, we fused the truncated promoters of HYDA1 and HYDA2 to the SNAP reporter gene. Transformants expressing the SNAP protein with truncated promoters were shown to be transcribed only under anaerobic condition. The results indicate that region between position -144 and -1 for HYDA1 and -149 to -1 for HYDA2 with respect to the transcription start site is required for anaerobic specific gene expression.
- To determine whether the recently identified FIXL homologs in *C. reinhardtii* play a role in O₂-sensing mechanism and mediate components of the anoxic regulatory response that leads to hydrogenase expression, we cloned the PAS domains of FXL1 and FXL5 from *C. reinhardtii*, overexpressed them in *Escherichia coli* and purified the ~13 kDa proteins. The recombinant FXL1 and FXL5 domain polypeptides both stained positively for heme, while ΔFXL1 and ΔFXL5, mutated in the conserved, ligand binding histidine residue resulted in loss of heme binding. Met-FXL1 and Met-FXL5 had their Soret absorption maximum around 415 nm followed by several weaker absorptions at longer wavelengths, 530/560 nm, which are characteristic of protein-bound heme, and are very similar to absorption spectra of *Rhizobium* FixL. Ligand binding measurements in varying partial pressures of O₂ and CO showed that FXL1 and FXL5 both bind O₂ and CO with high affinity. This indicates that the *Chlamydomonas* FXL proteins may use an O₂-sensing mechanism analogous to that reported in nitrogen-fixing bacteria, and thereby mediate components of the anoxic regulatory responses observed in this metabolically versatile alga. The present study unequivocally indicates the discovery of putative FXL-like proteins

in *Chlamydomonas reinhardtii* and demonstrates their heme and ligand binding properties.

- To probe the physiological and metabolic differences between two structurally different algal [FeFe]-hydrogenases, we assessed H₂ production in the trebouxiophyte *Chlorella* NC64A, which is the first alga known to encode both the H and F-clusters of hydrogenases. We show for the first time that F-cluster-containing hydrogenases are coupled to both anoxic photosynthetic electron transport and dark fermentation in a green alga. Hydrogen photoproduction in *Chlorella* NC64A is as sensitive to O₂ inactivation as in *C. reinhardtii*. Phylogenetic analysis indicates that all known algal HYDA enzymes are monophyletic, suggesting that they emerged once within the algae. Furthermore, phylogenetic reconstruction indicates that the multiple *HYDA* copies in the algal taxa are the result of gene duplication events that occurred independently in each algal lineage, and that the ancestor of the Trebouxiophyceae and Chlorophyceae likely encoded a single, H and F-cluster-containing HYDA.

Future Directions

- Candidate transcription factor proteins for hydrogenase will be identified, over-expressed in *E. coli* and purified. We will perform direct interaction of transcription factor-hydrogenase promoter DNA binding assays. To understand the involvement of other downstream proteins with transcription factor, the latter will be tagged (streptavidin or histidine tag) and used to search for interacting proteins.
- Selected *C. reinhardtii* mutants showing aberrant H₂ production will be further analyzed with respect to HYDA1 and HYDA2 transcript and protein levels. Complementation of the the phenotype with the transformed gene will be performed and physiological studies will be carried out to determine the role of the disrupted gene in algal metabolism.
- To understand the involvement (if any) of FIXL proteins in signal transduction in response to O₂, promising FIXL candidates will be tagged (streptavidin or histidine tag) and over-expressed in *C. reinhardtii*. Tagged FIXL proteins will be used to search for interacting proteins involved in the signal transduction pathway.
- To understand the mechanism that underlies the anoxic regulation of hydrogenase, we will express SNAP proteins under the regulation of the HYDA1 and HYDA2 promoters into *hydA1/hydA2* single or double mutants. Additionally, we will perform DNA binding assays to identify the transcription factors binding to the promoter regions of each hydrogenase.

Objectives

The research goal of the Prezhdo group is to obtain a theoretical understanding at the molecular level of chemical reactivity and energy transfer in complex condensed-phase chemical and biological environments. Motivated by recent experiments, we are modeling charge dynamics in semiconductor and metallic nanoparticles, carbon nanotubes and nanoribbons, and related nanoscale systems. Time-domain atomistic simulations of interactions between charges, spins and phonons in these materials create the theoretical basis for photovoltaic devices, optical and conductance switches, quantum wires, logic gates, miniature field-effect transitions and lasers.

Technical Barriers

While solar-to-electric energy conversion is an established technology, current solar cells are either too expensive or too inefficient for widespread application. Many alternative designs of photovoltaic (PV) systems have been proposed, yet the precise relationships between structure and spectral properties as well as the specific mechanisms of the energy transduction are still being unraveled. Our theoretical studies will address the fundamental aspects of solar energy transfer resulting in a predictive framework for the design of efficient, cost-saving PV devices for the production of hydrogen.

Abstract

The current perspective on the nature of photoexcited states in semiconductor quantum dots (QDs) is presented. The focus is on multiple excitons and photo-induced electron-phonon dynamics in PbSe and CdSe QDs, and the advocated view is rooted in the results of *ab initio* studies in both energy and time domains. As a new type of material, semiconductor QDs represent the borderline between chemistry and physics, exhibiting both molecular and bulk-like properties. Similar to atoms and molecules, the electronic spectra of QD show discrete bands and also exhibit conduction and valence bands as in bulk semiconductors. The electron-phonon coupling in QDs is weaker than in molecules, but stronger than in bulk

semiconductors. Unlike either material, the QD properties can be tuned continuously by changing QD size and shape. The molecular and bulk points of view often lead to contradicting conclusions. For example, the molecular view suggests that the excitations in QDs should exhibit strong electron-correlation (excitonic) effects, and that the electron-phonon relaxation should be slow due to the discrete nature of the optical bands and the mismatch of the electronic energy gaps with vibrational frequencies. In contrast, a finite-size limit of bulk properties indicates that the kinetic energy of quantum confinement should be significantly greater than excitonic effects and that the electron-phonon relaxation inside the quasi-continuous bands should be efficient. Such qualitative differences have generated heated discussions in the literature. The great potential of QDs for a variety of applications, including photovoltaics, spintronics, lasers, light-emitting diodes, and field-effect transistors makes it critical to settle the debates. By synthesizing different viewpoints and presenting a unified atomistic picture of the excited state processes, our *ab initio* analysis clarifies the controversies regarding the phonon bottleneck and the generation of multiple excitons in semiconductor QDs. Both the electron-hole and charge-phonon interactions are strong and, therefore, optical excitations can directly generate multiple excitons, while the electron-phonon relaxation exhibits no bottlenecks, except at low excitation energies and in very small QDs.

Progress Report

The time-domain modeling [1] of the phonon-induced electronic relaxation performed with the novel approach [2] combining time-domain density functional theory and non-adiabatic molecular dynamics unifies the two, seemingly contradicting, experimental observations. In spite of the large line spacing in the CdSe and PbSe QD optical spectra, the phonon bottleneck to the electron-phonon relaxation does not exist. The simulation shows that the fast relaxation and the absence of the bottleneck are due to the high density of electron and hole states. Except for the lowest excitation energies and smallest QDs, the spacing between the state energies matches the phonon frequencies. The QD spectra are composed of multiple individual excitations that combine into distinct bands according to the optical selection rules. The selection rules are much more stringent for optical than for electron-phonon transitions. Even though relatively few excitations are strongly optically active, most of the excited states are available during the relaxation.

Sophisticated *ab initio* electronic structure calculations clarify the nature of the photoexcited states in the semiconductor QDs by explicitly including the high-order electron-hole interactions. Multi-excitons (ME) are found in the QD spectra above an energy threshold. PbSe in particular exhibits a unique electronic structure, creating

energy windows in which MEs completely dominate single excitons. Electronic structure calculations have also led to much progress on achieving a thorough understanding of the excitation properties of these materials when they are altered with charging, doping, or dangling bonds. The calculations show that the defects introduce new intra-band transitions, blue-shift the optical absorption spectra and increase the threshold for ME generation. Generally, doping and charging have similar effects on the excited state properties, while dangling bonds cause less severe changes.

The excited state properties determined in the ab initio calculations indicate that three mechanisms of the ME generation can take place in the semiconductor QDs. These include the incoherent II process, [3,4] the dephasing mechanism, [5] and the direct excitation mechanism. [6] Which mechanism is more important depends on the material under study. The direct mechanism should be particularly efficient in PbSe QDs, while in CdSe the other mechanisms will also play key roles.

Future Directions

A number of open questions remain in the investigations of the mechanisms and rates of the ME generation and the electron–phonon relaxation dynamics. Apart from the experimental controversies regarding the existence of MEs [8] and the phonon bottleneck, [9, 10, 11] several theoretical issues need to be solved. The mechanism of the dissociation of MEs into uncorrelated single excitons is not yet established, even though we argue here that the process can occur by the phonon-induced dephasing. This step is essential to completing the ME generation picture.

Recently, MEs were discovered in Si. [13] This discovery could lead to a major breakthrough in the solar cell industry, which is almost entirely Si-based, provided that MEs can dissociate into free charge carriers and that the free charge carriers can be extracted from Si QDs. In contrast to PbSe and CdSe, Si is an indirect bandgap semiconductor. Whether or not the mechanisms of ME generation and electron–phonon relaxation remain the same in this alternative type of semiconductor is not yet clear. Recent experiments show that small Si QDs with quantum confinement energies greater than 1 eV behave similarly to the direct gap QDs. [14] In this respect, Ge provides additional advantages, since the confinement-induced transformation to the pseudo-direct gap regime is less demanding in Ge than Si. [15]

Assemblies of QDs with other materials, such as molecular chromophores, [16] organic or inorganic semiconductors, and so on, present a new set of theoretical questions regarding the interface. The unique opportunities provided by the ab initio descriptions in time and energy domains motivate one to extend the current efforts to other related materials and problems.

Objectives

Our goal is the theoretical design of a model electrocatalytic or photo-electrocatalytic system for economical production of hydrogen from water and sunlight via the hydrogen evolution reaction. The system under investigation consists of an FeS₂ (100) surface decorated with a cluster derived by design from the active site of the di-iron hydrogenase enzyme. Immersed in acidified water with the FeS₂ the source of electrons and the water of protons, the system readily produces H₂ in simulations. Our immediate goal is to design a protective structure which inhibits the attack of the clusters and the exposed FeS₂ sites by dissolved O₂.

Technical Barriers

For economic feasibility, a system for production from sunlight and water must be made of earth abundant materials and contain a catalyst active enough to utilize efficiently electrons generated from the solar flux. The active site of the hydrogenase enzyme would meet those requirements *if* (1) it could be redesigned to retain its activity when extracted from the enzyme while stably attached to a suitable electrode and exposed to acidified water *and if* (2) it could be protected from attack by the dissolved oxygen inevitably present. Our design of the unprotected decorated pyrite surface should help overcome barrier (1). Our current research on structured overlayers should help overcome barrier (2).

Abstract

We have designed a catalytic cluster, [FeFe]_p, derived from the active cluster of the di-iron hydrogenase and functionalized the pyrite (100) surface with it. Remaining stable throughout, it produces hydrogen from acidified water with a free-energy barrier of less than 8.2 kcal/mol in

room temperature simulations. The rate-limiting step in the cycle is the first protonation, subsequent steps are barrier free and fast. A detailed mechanistic analysis of the bond switching, oxidation-state changes, and electron flow during that step was carried out. Oxygen binding studies suggested diminished O₂ sensitivity of [FeFe]_p and a need to focus on the sensitivity of the exposed pyrite Fe sites.

Progress Report

The achievements to date are: 1. design of the [FeFe]_p catalytic cluster; 2. demonstration of hydrogen production from acidified water; 3. demonstration of structural stability of the functionalized surface throughout the production cycle; 4. identification of the first protonation of the catalyst as the rate-limiting step in the cycle, with an upper bound of 8.2 kcal/mol for its free-energy barrier; 5. detailed mechanistic analysis of the bond switching, oxidation-state changes, and electron flow during the first protonation; 6. finding diminished O₂ sensitivity of [FeFe]_p.

Design of [FeFe]_p

We first studied the hydrogen production cycle by the unsupported [FeFe]_H cluster in vacuo^[1] and in acidified water.^[2] In the di-iron [FeFe]_H cluster, removed from the enzyme, two iron atoms are coordinated to CO and CN ligands and bridged by a chelating group, S-CH₂-X-CH₂-S where X can be a NH (DTMA) or CH₂ (PDT) group, Figure 1. One iron atom, Fe_p, is 6-fold coordinated, the other, Fe_d, 5-fold with a vacant coordination site V at which the reaction occurs in the active isomer, Figure 1.

We made several critical modifications to [FeFe]_H (with DTMA) to obtain a stable and functional pyrite-supported catalyst.^[3] We obtained a stable link by stripping off the thiol from Fe_p and connecting it directly to a pyrite surface

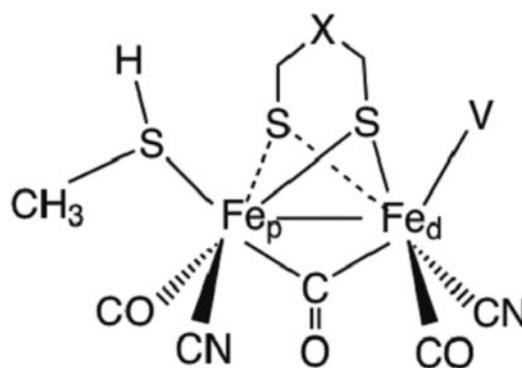

FIGURE 1. The active μ -CO isomer (after Ref. [1])

sulfur atom. Further stabilization was provided by linking a surface Fe atom to the N atom of the CN ligand of Fe_p . We interchanged the CO bridging group with the CN ligand of Fe_d to form a third stable link between the N atom and a surface Fe atom, locking the cluster into the bridging configuration. Lastly, the outer S in the chelating group was changed to an isoelectronic PH group to stabilize the Fe_d -chelating group bond to form $[\text{FeFe}]_p$, Figure 2.

Demonstration of structural stability and H_2 production

Both the cluster-electrode linkage and the cluster structure remain stable throughout the H_2 production cycle,^[4] which is started with the functionalized electrode in the $[\text{FeFe}]_p^{-1}$ state. Both proton additions take place entirely at the vacant coordination site V on Fe_d . The structural and compositional modifications leading to $[\text{FeFe}]_p$ eliminate all other protonation sites and all structural lability and greatly simplify the reaction mechanism.

In water, the first proton moves towards Fe_d by a complex pathway along which there is a free-energy barrier. Because of the barrier, simulation of the reaction was carried out by constrained FPMD to prevent the proton from wandering away from the catalyst in the brief duration of the simulation. We obtained a strong upper bound of 8.2 kcal/mol (0.36 eV) for the barrier by thermodynamic integration.^[4]

Electron flow and oxidation-state changes

First protonation is the rate-limiting step in hydrogen production from acidified water room-temperature simulations. Second protonation and desorption of the H_2 occur spontaneously during our picosecond-scale simulations.

We analyzed the mechanism of 1st protonation in Ref. [5] by computing densities of the maximally-localized Wannier functions (WD) and their centers of gravity (WC)

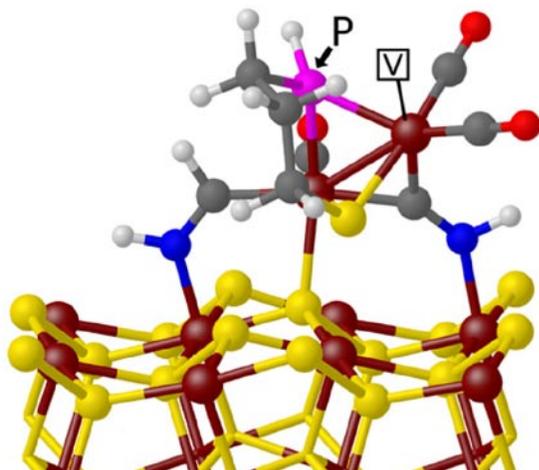

FIGURE 2. Side view of the $[\text{FeFe}]_p$ cluster linked to the FeS_2 (100) surface.

for several states along the reaction pathway established in Ref. [5]. From the locations and forms of the WD and the locations and movements of the WC, we established that only the Fe_p , Fe_d , $\mu\text{-C}$, and P atoms as well as the added H play significant roles in the reaction. We established the nature of their bonds, their oxidation states (OS), and the electron flow responsible for the OS changes and bond switching. The P atom acts as the initial proton attractor, the μC , Fe_d pair act as the redox center, and the Fe_p acts to facilitate bond switching from two 2-center μC -to-Fe bonds to one 3-center bond upon protonation. These features of the reaction mechanism are clearly displayed in Figure 3. This novel method of OS determination should be of broad use for the analysis of redox reactions; we illustrated it in [5] for the superoxide reductase enzyme as well.

O_2 sensitivity of pyrite and the catalyst

Undesirable oxidation of catalytic active centers is a common problem in catalyst design. The active center of hydrogenase is poisoned by O_2 , as modelled in Ref. [6] and could be expected for $[\text{FeFe}]_p$ as well. Moreover, the pyrite electrode reacts readily with O_2 in the presence of water.^[7,8] To address these issues, we first studied the binding of O_2 on the active center in vacuo. Table 1 shows O_2 binding energies, and $\text{Fe}_d\text{-O}$ and O-O distances in the optimized binding structure at different charge states. As shown in the

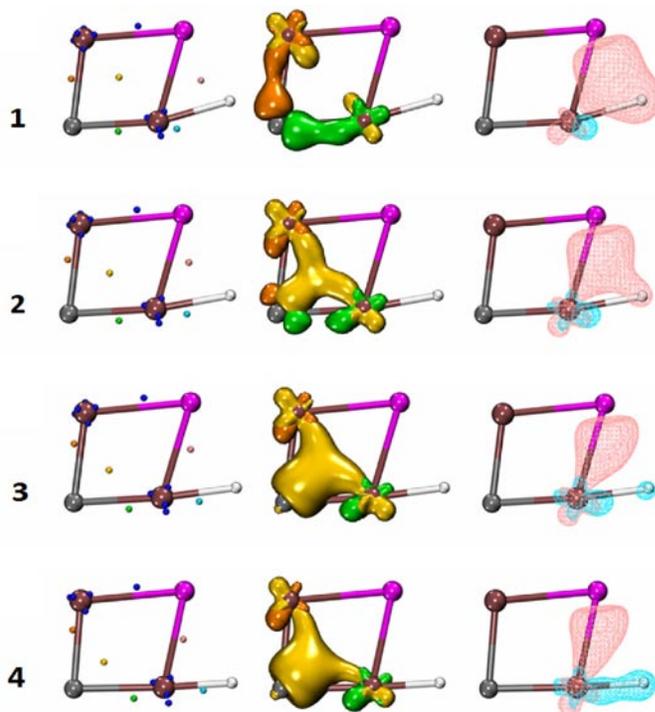

FIGURE 3. Four stages in the evolution of the relevant MLWF density and WC's as the first protonation proceeds. Fe atoms are brown; S atoms are yellow; the P atom is violet; C atoms are gray; N atoms are blue; O atoms are red; and H atoms are white. The isosurfaces are at 20% of their maximum values.

table, the neutral cluster has a small O₂ binding energy, -3.45 kcal/mol. On the other hand, the charge -1 cluster scarcely favors O₂ binding as indicated by the large Fe_d-O distance and negligible binding energy. Full-scale FPMD simulations in water are needed to confirm this weak or unfavorable binding of O₂, but these preliminary results imply that the active center could be inert to O₂ attack and focus could be placed on protecting the exposed pyrite surface.

TABLE 1. O₂ binding energies, and the Fe_d-O and O-O distances in the optimized binding structure at different charge states

	ΔE	$d_{\text{Fe-O}}$	$d_{\text{O-O}}$
[FeFe] _p ⁻¹	-0.22 kcal/mol	3.64 Å	1.24 Å
[FeFe] _p ⁰	-3.45 kcal/mol	2.02 Å	1.29 Å

Accordingly, we studied O₂/H₂O co-absorption on the pyrite surface in vacuo. We list several representative configurations in Figure 4. The corresponding absorption energies relative to an isolated O₂, an isolated H₂O, and a pristine surface are shown in Table 2. The most stable physisorption structure for O₂ is side-on where the two O atoms are linked two Fe atoms (configuration (a) and (b)). Compared to configuration (a), it is energetically less favorable for proton transfer from H₂O to the surface S, the surface Fe atoms, or O₂ in end-on binding conformation (configuration (c), (d) and (e)). A large gain in energy from configuration (a) is observed when the O-O bond breaks (configuration (f)) and the energy goes further downhill when one of the O atoms acquires a proton from H₂O (configuration (g)). This agrees with the experiments suggesting that pyrite oxidation occurs in the presence of only O₂ and that the oxidation rate is faster when water is present.

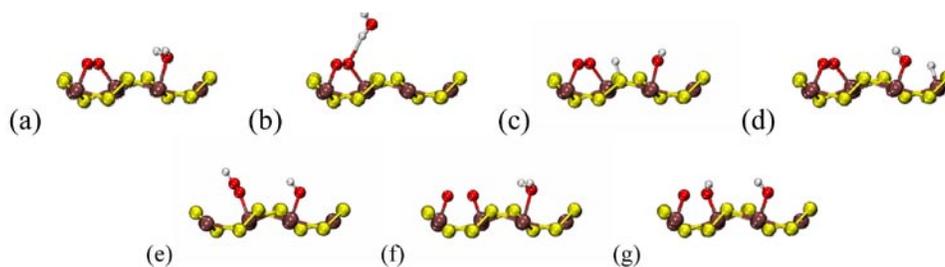

FIGURE 4. Seven representative O₂/H₂O co-absorption configurations. The corresponding binding energies are shown in Table 2.

TABLE 2. Binding energies of O₂/H₂O co-absorption configurations shown in Figure 4.

Configuration	a	b	c	d	e	f	g
Binding Energy (kcal/mol)	-29.59	-29.90	-2.32	-4.05	-20.45	-56.37	-60.65

Future Directions

The calculations of O₂/H₂O absorption on pyrite in vacuo allow us to plan full-scale FPMD simulations to reveal the detailed reaction pathways and free-energy changes of pyrite oxidation. Although the active site of [FeFe]_p exhibits weak or no affinity toward O₂ in vacuo, the presence of an aqueous environment could change O₂ sensitivity and initiate reactions with the water. Such detailed FPMD studies of O₂ and water interactions with both the active center and the exposed pyrite are necessary precursors to the design of structured protective overlayers. We therefore plan a systematic study of the reaction of the pristine pyrite surface and the decorated cluster with molecular oxygen in neutral water and in acidified water.

After the analysis of the sensitivity of the unprotected functionalized electrode, we plan to work on the individual design elements of a protective overlayer permitting nanochannel access of water and protons to the active sites and H₂ egress. We have already found that phosphonic acid forms a strong bidentate bond with the bare FeS₂ (100) surface after one OH is removed, making alkylphosphonates promising candidates for the hydrophobic channel walls. The interaction of that end group with the decorated FeS₂ (100) surface will be studied in vacuo and in water with full quantum mechanical methods, but, when the alkyl chains are added, the increased complexity will require taking recourse to classical MD or QM/MM. The chain configuration in the protective overlayer will be studied with and without the cluster present and with and without water to build up the information needed for subsequent studies of the motion of H₂, and hydronium ions into and through the channels and the inhibition of oxygen penetration.

Objectives

- Design and study of new supramolecular complexes for the production of H₂ from H₂O using molecular devices for photoinitiated electron collection.
- Understand the mechanisms of complex, coupled reactions for the solar production of fuels as facilitated by supramolecular complexes.
- Probe the role of sub-unit variation on the functioning of supramolecular H₂ production photocatalysts to explore the impact of modulation of orbital energetics and excited state dynamics on this complicated photochemistry.
- Develop a fundamental understanding of the rates and mechanisms of multielectron photochemistry and photocatalysis in supramolecular complexes.

Technical Barriers

- Controlling the high purity assembly of multicomponent supramolecular complexes with reactive metal centers needed to photocatalyze H₂O reduction to H₂ in single component systems is a developing field that requires considerable synthetic expertise to prepare target systems.
- Few molecular systems are known that photochemically collect reducing equivalents and less are known that collect electrons at a reactive site.
- Understanding the factors that control multielectron photochemistry is still in its infancy and developing this understanding in supramolecular assemblies presents additional challenges.
- The process of collecting reducing equivalents on a molecular system followed by delivery to a H₂O substrate requires a series of carefully controlled and coordinated reactions, high overall efficiency reliant on the product of efficiency of individual steps.

Abstract

The growing energy needs of our Nation require that we explore and harness a variety of new energy sources within the coming decades. Fossil fuels are currently used to supply much of our Nation's energy needs, often derived from the sun's energy, as harnessed and converted by plants into biomaterials. The rate of our use of fossil fuels makes it necessary to explore alternative means to harvest this energy or alternative energy sources. One appealing alternative energy source is solar energy harnessed without the use of plants. In the Report of the Basic Energy Sciences Workshop on H₂ Production, Storage and Use in 2003, catalyst design for H₂ production was identified as an important goal with emphasis on nanoscale systems.¹ In the report of the Basic Energy Sciences Workshop on Solar Utilization, sunlight is identified as by far the largest of all carbon-neutral energy sources with 4.3×10^{20} J per hour reaching the earth's surface.² This represented more energy than that consumed on the planet in a year. The report from the Basic Energy Sciences committee in 2008 states "The ultimate transport solution would be solar fuels, made from using sunlight to split water and produce hydrogen..."³ A major research need identified in the Workshop on H₂ Production was the development of systems that convert sunlight into chemical fuels for storage and distribution. This project addresses these fundamental issues within a molecular architecture that undergoes multielectron photochemistry and is capable of producing H₂ from water. Importantly the work aims to develop a deeper understanding of the fundamental nature of the multiple steps involved in the complex processes needed to use light energy to promote multielectron reactions as well as the catalysis of the multielectron reduction of substrates to produce transportable fuel. The basic structural motifs of interest focus on the use of Ru and Os MLCT light absorbers (LA) coupled through polyazine bridging ligands (BL) to reactive metal centers, typically Rh. These complexes contain the basic building blocks needed to prepare complexes that undergo photoinitiated electron collection (PEC) and catalyze the reduction of H₂O to produce H₂. Functioning single component systems have been developed with our understanding of their functioning allowing for substantial increases in photocatalytic turnover and quantum efficiency. Studies have focused on a development of a knowledge base concerning the role of device sub-units and excited state dynamics on functioning as well as elucidating the mechanism of functioning.

Progress Report

This project is aimed at developing and studying a class of mixed-metal supramolecular complexes with promising

redox and excited state properties. These systems couple charge transfer light absorbing metals to reactive metals such as rhodium(III) that will allow these systems to undergo PEC while possessing reactive metal sites capable of delivering collected electrons to a substrate such as H_2O to facilitate the production of H_2 . The factors impacting multi-electron photochemistry and the reduction of water to produce H_2 have been explored aimed at providing a detailed understanding of the mechanism of action of these unique photocatalysts and the factors that impact functioning. The synthetic pathway to prepare these systems is illustrated in Figure 1 and represents a building block method that allows stepwise assembly and careful purification at each step.

The Rh centered supramolecular complexes must undergo a complex series of steps in order to undergo PEC and deliver collected electrons to a substrate to produce a fuel. This includes the absorption of a series of photons, excited state electron transfer reactions, and the delivery of multiple electrons to the water substrate including the bond breaking and making processes needed to produce hydrogen. The coupling of Ru polyazine light absorbers to Rh centers with low lying $d\sigma^*$ orbitals results in many low energy excited states providing for complicated excited state dynamics. Figure 2 shows the two lowest lying triplet states that are thought to be engaged in the excited state electron transfer leading to reduction of the photocatalysts. To explore the role of each state in the PEC process a series of complexes have been studied that vary the energy of the $^3\text{MLCT}$ and $^3\text{MMCT}$ states as a function of device components as well as a system able to undergo PEC but without a reactive Rh metal center. These studies illustrated that while the $^3\text{MMCT}$ seems to play a role in PEC, the $^3\text{MLCT}$ state when alone is able to undergo excited state reduction still leading to PEC and production of H_2 from water. The absence of a Rh metal center, using an Ir centered photoinitiated electron collector does not lead to H_2 production, pointing out the role of Rh in the photocatalysis. The addition of $\text{Hg}(\text{I})$ to our photocatalytic system does not impact H_2 production, indicative of the lack of colloidal metal functioning as a catalytic surface in our system.

We have investigated the photophysics and photocatalytic properties of a series of Ru,Rh,Ru trimetallic complexes (the $\{[(\text{TL})_2\text{Ru}(\text{dpp})]_2\text{RhX}_2\}(\text{PF}_6)_5$ structural motif) as well as related bimetallic systems which couple one Ru light absorber to a cis- $\text{Rh}^{\text{III}}\text{Cl}_2$ moiety (the $\{[(\text{TL})_2\text{Ru}(\text{dpp})]$

$\text{RhCl}_2(\text{TL}')](\text{PF}_6)_3$ structural motif). The systems with $\text{X} = \text{Cl}$ or Br and $\text{TL} = \text{bpy}$, phen and most recently Ph_2phen have been studied. We have found that these complexes emit from their $\text{Ru} \rightarrow \text{dpp}$ $^3\text{MLCT}$ excited state and this emission is quenched at RT due to electron transfer to generate a lower lying $^3\text{MMCT}$ excited state. The use of Br bound to the Rh center in place of Cl leads to systems with lower emission quantum yields and excited state lifetimes but larger quantum yields for H_2 production. The use of phen as the TL in place of bpy provides systems with shorter lifetimes and lower emission quantum yields in stark contrast to the typical extension of lifetimes in related $\{[(\text{phen})_2\text{Ru}]_2(\text{dpp})\}^{4+}$ and $\{[(\text{phen})_2\text{Ru}(\text{dpp})]^{2+}$ systems relative to the bpy analogs. The newly prepared and soon to be reported Ph_2phen systems provide for photocatalysts with higher H_2 production rates and yields. The newly prepared Ru,Rh bimetallic motif, $\{[(\text{TL})_2\text{Ru}(\text{dpp})\text{RhCl}_2(\text{TL}')](\text{PF}_6)_3$, has recently been established to have similar excited state dynamics with a low lying $^3\text{MMCT}$ excited state quenching the emission of the $^3\text{MLCT}$ excited state. We have recently shown this bimetallic motif undergoes photoinitiated electron collection generating Rh(I) systems. We have also demonstrated that despite this the Ru,Rh bimetallics are not photocatalysts for water reduction to produce H_2 , as the Rh(I) form dimerizes. This is a very significant result that provides insight into the mechanism of the photocatalysis with our trimetallic systems and provides strong evidence that the supramolecular architecture remains intact and is critical to active photocatalysis.

We have explored the modification of our photocatalytic system showing our system can tolerate changes in solvent,

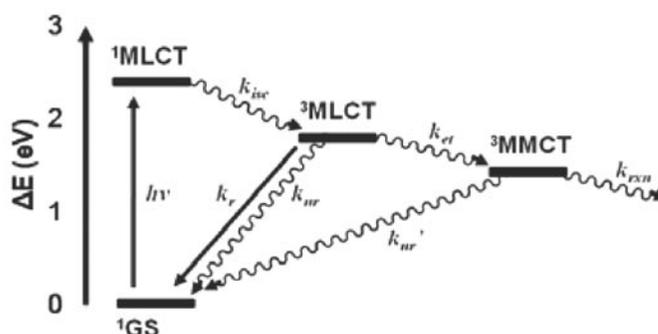

FIGURE 2. State diagram for $\{[(\text{TL})_2\text{Ru}(\text{dpp})]_2\text{RhX}_2\}^{5+}$ systems

FIGURE 1. Building block method to prepare the TL-LA-BL-EC-BL-LA-TL assembly, $\{[(\text{Ph}_2\text{phen})_2\text{Ru}(\text{dpp})]_2\text{RhBr}_2\}(\text{PF}_6)_5$, a photocatalyst for H_2O reduction to H_2 .

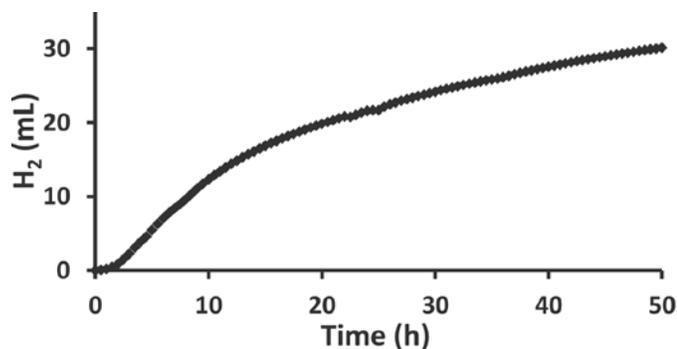

FIGURE 3. Real time H₂ production by supramolecular photocatalyst-{(bpy)₂Ru(dpp)}₂RhBr⁵⁺ in DMF.

electron donor, light flux, etc.. Our system represents the first report of a PEC system that functions in water and our system also produces H₂. We have shown that DMF as a solvent impacts photocatalytic yield producing higher amounts of H₂, Figure 3.

Future Directions

The understanding of the mechanistic details of our photocatalytic system remains an overriding goal. We have made considerable progress on this goal. The use of varied sub-units in our Ru,Rh,Ru trimetallic motif has provided insight into the role of the various excited states and the driving force for excited state electron transfer on photocatalysis. We have investigated the role of the supramolecular architecture and shown through our studies with the new Ru,Rh bimetallics that simply producing a system in which Rh(I) is generated is not sufficient to produce active photocatalysts. The studies of the bimetallic systems have uncovered the possible role of Rh-Rh bond formation as a deactivating pathway in non-functioning Rh systems. We have moved to the direct synthesis of Rh(I) complexes. This work has progressed and preliminary results show with the proper design we can produce Ru(II),Rh(I) systems that can be active photocatalysts through the protection of the Rh site with a bulky ligand. Studies are ongoing to explore the mechanistic aspects of our important photocatalysis and photoreduction reactions.

tentatively attributed to increased light scattering of Au NPs, leading to enhanced light absorptions of the CdSe QDs.²

Abstract

Hydrogen is an extremely attractive fuel for clean alternative energy. New nanocomposite structures and advanced strategies have been developed to improve the performance of PEC cells for hydrogen generation from water splitting. Systematical studies have been carried out to probe the fundamentals behind, including charge carrier properties at interfaces. One of the most important discoveries we have made is strong synergistic effects in ternary nanocomposites that show significantly enhanced PEC properties compared to binary or single component systems. These strategies are promising for advancing energy conversion technologies in the future.

Objectives

The primary objective of this project is to develop novel nanostructures with improved optical and electronic properties for photoelectrochemical (PEC) hydrogen generation from water splitting. Specifically, we seek to design and demonstrate new strategies based on combining quantum dot (QD)-sensitization and elemental doping to significantly enhance visible light absorption and thereby PEC properties of metal oxide (MO) nanostructures, e.g. TiO₂, WO₃, and ZnO. Interesting synergistic effect has been discovered from the combined use of QD sensitization and N-doping of TiO₂ nanoparticle (NP) and nanorods.¹ Similarly, combining Au NPs with CdSe QD sensitization of TiO₂ has shown strong synergistic effect as well in terms of PEC performance.² The fundamental mechanisms behind the observed synergistic effects have been proved using a combination of experimental techniques including spectroscopy, microscopy, and ultrafast laser.

Technical Barriers

Towards the development of efficient PEC cells for hydrogen generation based on nanomaterials, one of the technical barriers is to control the surface properties of all the components involved, e.g. the MO nanostructures, QDs, and metal NPs. The second technical barrier is to determine the local structures and exact energy levels of the dopant, e.g. N, since this is critical to develop appropriate models to explain the synergistic effects observed.¹ The third technical barrier is to probe and understand the exact role of metal NPs in the enhanced PEC performance, which has been

Progress Report

1. Generating hydrogen by PEC with CdSe QD sensitized and N-doped TiO₂ nanostructures

TiO₂ is the most researched material for PEC water splitting. Since the bandgap of the TiO₂ is large ($E_g=3.2\text{eV}$), it cannot absorb most of the sunlight. One effective way to increase the absorption of the sunlight is by using semiconductor QDs to sensitize the TiO₂ film. Another approach is elemental doping. PEC measurements carried out on TiO₂ NPs and nanorods demonstrated that there is a strong synergistic effect when QD sensitization is combined with N-doping.¹ The reason for the increase in photocurrent when CdSe sensitizes N-doped TiO₂ vs. TiO₂ alone is attributed to the increase in hole transport from the valence band of CdSe to the oxygen vacancies in N-doped TiO₂.

2. PEC Properties of CdSe/TiO₂ Mesoporous Hybrid Structures

In sensitizing metal oxides such as TiO₂ using QDs, small molecules are often used to link semiconductor quantum dots to TiO₂ films. Since these small molecules are mainly dielectric materials, they will block the transfer of the photoelectrons from the quantum dots to the TiO₂ film. In this project, we have developed a new method to link QDs and TiO₂ without using the small linking molecules by assembly the QDs and TiO₂ NPs together into colloid spheres.² The PEC characterization of CdSe/TiO₂ hybrid spheres shows an increase in the photocurrent when compared to TiO₂ alone and CdSe sensitized to TiO₂ using a linking molecule. The overall increase in photocurrent

from the CdSe/TiO₂ hybrid structure is believed to be due to better or stronger coupling between the CdSe and the TiO₂ when compared to the CdSe sensitized TiO₂ linked by short chain organic linker molecules.

3. Enhanced PEC Performance of CdSe QD-Sensitized Au/TiO₂ Hybrid Mesoporous Films

Metal NPs have also been considered for sensitizing of enhance PEC properties of metal oxides. We have demonstrated the first Au/TiO₂ hybrid structure (0-5%) that has also been sensitized with CdSe QDs for PEC water splitting. For the pristine TiO₂ film sample, the absorption onset is around 360 nm, with minimal visible light absorption. In contrast, the Au/TiO₂ film showed strong absorption in the visible region due to the surface plasmon resonance (SPR) of Au NPs, and the absorption increases with increasing amount of Au NPs loading. The strong enhancement for the photocurrent when Au is introduced with CdSe can be explained by an increase in scattering due to presence of the metal. The increase in scattering allows the CdSe to absorb more light and inject electrons into the conduction band of TiO₂. Since enhancement occurred over the entire visible spectral range and increased with decreasing wavelength, increased light scattering by Au NPs is suggested to be responsible for the enhanced PEC performance.

4. N-Doped ZnO Nanowire Arrays for PEC Water Splitting

N-doped zinc oxide (ZnO:N) nanowire arrays have also been studied as photoanodes in PEC hydrogen generation from water splitting. In comparison to ZnO nanowires without N-doping, ZnO:N nanowires show an order of magnitude increase in photocurrent density with photo-to-hydrogen conversion efficiency of 0.15% at an applied potential of +0.5 V (versus Ag/AgCl). These results suggest substantial potential of metal oxide nanowire arrays with controlled doping in PEC water splitting applications.

5. Photocatalytic Performance Improved in Nanorod Arrays

One way to effectively increase the photocatalytic performance of TiO₂ is to couple it with a metal, such as Ag, in order to create an effective charge-separation between the photogenerated electron-hole pairs. Ag NPs with different loadings were systematically coated onto uniformly aligned TiO₂ nanorod arrays, and their photocatalytic performance was found to be enhanced compared to bare TiO₂, and increased linearly with the Ag NP loading until a maximum photodegradation rate was reached at 0.25 wt.% Ag loading, and then decreased linearly with further increasing Ag loading. A simple reaction model was developed to explain the experimental results. Using two consecutive glancing angle depositions (GLAD) at different deposition angles and with different material, a WO₃-core TiO₂-shell nanostructure has been fabricated. The core-shell nanostructures are much more efficient in the amount of photodegradation abilities that can be extracted per nm of TiO₂ deposited. For the

core-shell nanostructures annealed at $T_a = 300^\circ\text{C}$, this ratio is 470 times, 90 times, and 18 times more efficient than the amorphous TiO₂, anatase TiO₂, and multi-layered TiO₂/WO₃ films. This huge improvement can be directly correlated to the larger interfacial area between TiO₂ and WO₃, which is optimized in this core-shell morphology.

Both WO₃/TiO₂ and TiO₂/WO₃ core/shell nanorod films were used to make electrodes for PEC water splitting. IPCE analysis showed that the WO₃/TiO₂ samples were more efficient at water splitting. The maximum efficiency for the TiO₂/WO₃ sample was under 5% at about 340 nm. The WO₃/TiO₂ achieved near 12% IPCE at 350 nm but the efficiency decreased sharply around 390 nm. These preliminary data show that the WO₃ is the better core material for these core/shell structures but improved efficiency in the visible region through sensitization or doping may allow these structures to achieve greater efficiency. Additional characterization will be needed to determine why the two structures showed such a marked difference in water splitting efficiency.

6. Double-Sided QD Co-Sensitized ZnO Nanowire Arrays for PEC Hydrogen Generation

An analogue of the typical tandem cell for PV devices has been produced by designing a photoanode which is coated on both sides with conductive substrate (FTO) and ZnO nanowires. To increase the visible light absorption, both sides have been coated in either CdS or CdSe. This unique structure integrates the motif of QD sensitization and tandem cell to provide a simple approach to enhance simultaneously the visible light absorption and carrier collection of nanostructured metal oxide photoelectrodes. The electrode with the highest photocurrent and efficiency was when the CdS/ZnO nanowire side was illuminated with light loading compared to the CdSe/ZnO on the opposite end. Controls were done on various double sided as well as single sided structures. Linear sweep measurements for the CdS/ZnO-ZnO/CdSe double sided nanowire electrodes showed enhanced photocurrent when compared to control structures. This is due to the elevation of the CdSe when the Fermi energies are aligned increasing electron and hole transport. Recombination of electrons and holes is also less in these devices which increases their overall performance.

Future Directions

Our plan for next year include optimization of composite structures in terms of ratio and morphology of constituent components, validation of the enhanced hole transport model proposed using ultrafast laser techniques using the new fs laser system acquired recently, and improvement of overall PEC performance by carefully considering, determining and controlling the key factors involved, including electrode, interfacial interaction, and optical absorption. A combination of microscopy, spectroscopy, dynamics, and electrochemistry techniques will be employed. Collaboration with appropriate groups will be

sought, including possible theoretical modeling in relation to the experimental work.

Objectives

Our long-term objective is to harness the energy of the sun for the production of inexpensive chemicals and fuels useful to mankind. We aim to achieve this with simple, design-flexible artificial proteins called maquettes. Maquette protein designs are informed by engineering and structural principles we learn from impressive natural photosynthesis. Our aim is to turn these principles into guidelines for the practical assembly of maquettes equipped for tailored photochemistry.

Technical Barriers

Creation of very long-lived, light-activated charge-separated states will allow the accumulation of reductants and oxidants in the vicinity of catalytic centers within the protected environment of the artificial protein. With these lifetimes, even slow catalytic centers with significant activation energy barriers for making hydrogen or other fuels can operate, and then be iteratively redesigned to improved speed and function.

Abstract

There is an urgent need to meet global demands for clean, inexpensive and renewable sources of energy. Sunlight is an abundant energy source tapped by biological photosynthesis. Our project is inspired by the efficiency and speed of biological photosynthesis that draws on water as its source of electrons for reduction of CO₂ to produce its cellular materials and fuels. Our project is directed to the abstraction of key engineering and construction principles from natural photosynthetic proteins and their application to the creation of a family of artificial photosynthetic proteins tailored to harnessing solar energy to drive production of useful chemicals and fuels including hydrogen. It is also our intention that any artificial proteins proving valuable to mankind as planned, will be

designed ready for expression in bacteria for minimized costs of scaled production and assembly.

Progress Report and Future Directions

Generic tunneling barriers in natural proteins: The theoretical basis for our electron tunneling expressions and their utility for calculating relevant tunneling parameters in natural and man-made photosynthetic systems is empirical. The generality of the expressions so far developed for analyzing parameters of electron tunneling in protein is therefore subject to reconsideration and refinement when new electron-transfer data from well-characterized proteins is received. The addition of over 20 new non-physiological electron tunneling reactions from semi-synthetic proteins continues to support our view that tunneling-barrier height has not been naturally selected to help or hinder electron transfer in natural photosynthesis. The barrier height does dictate the spatial essential required for light activated charge separating elements to generate high yield charge separated states stable into the millisecond times. Thus, natural reaction center proteins are scaled to approx 2.5 nm (25Å) while covalently bridged biomimetics require 5 nm (50 Å) and hence must be over twice as large to achieve the same performance.

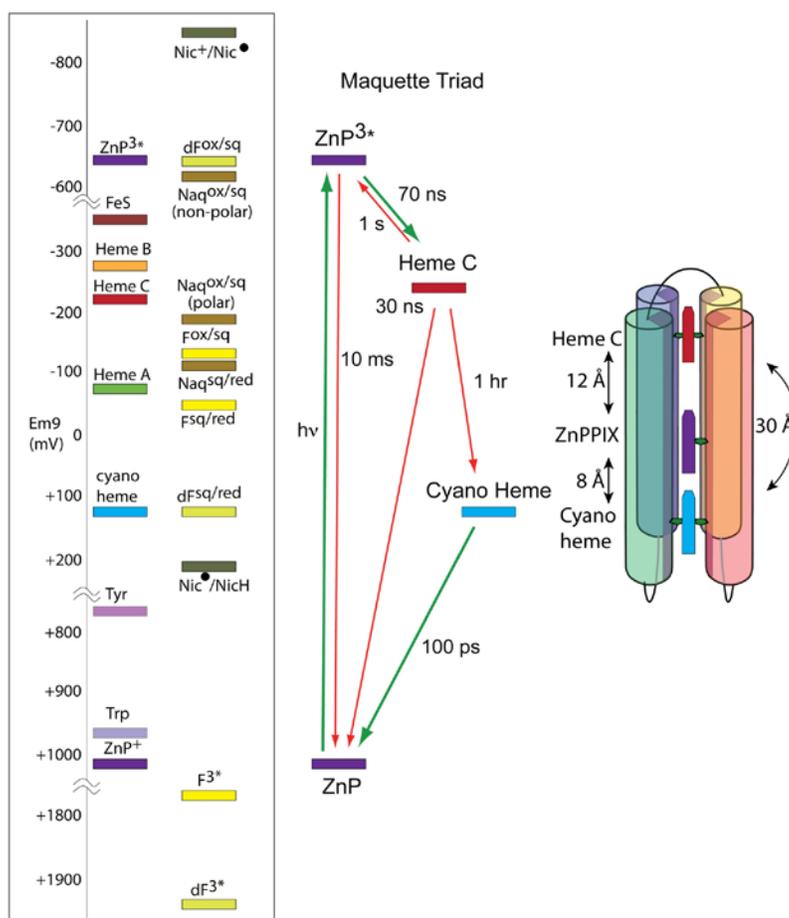

Coupling electron tunneling to redox catalysis: We have extended our expressions to guide the engineering and construction of maquettes that catalyze oxidative and reductive chemistries. We are moving from pure electron tunneling, now beginning to be well described, to simple catalysis involving two-electron hydride transfer that occurs in the large class of dehydrogenases and to two-or-more electron transfers linked to bond forming/breaking common in oxidative and reductive catalysis. There is an important interplay between distance and driving force in the design and engineering of natural oxidoreductases when an overall exergonic series of electron transfers includes one or more endergonic (uphill) steps. To some extent the increased height of an uphill step can be compensated for by shrinking the distance between donor and acceptor while still maintaining overall sequential electron-tunneling rates within the approximately millisecond working threshold. We find that the balance between tunneling distance and uphill driving force sketches an unexpectedly broad engineering choice in distances and driving forces to achieve acceptable nanosecond to milliseconds sequential electron-transfer rates. The distance/energetic boundaries where sequential electron-transfer mechanisms become unworkably slow are clear.

Synthetic protein backbone design: Our aims to reproduce photochemical energy conversion and chemical oxidation-reduction catalysis require the development

of maquette interiors that collect the characteristics fundamental to catalytic fitness in nature. Maquette interior design and the incorporation of cofactors go hand in hand. Despite the apparent low dielectric interior of the unlinked homodimeric maquettes, H/D exchange measurements indicate they offer comparatively little restriction for the entry of water. Regulation of water access is vital to the design of sites engaged in initial charge separation (low reorganization energies) and catalysis (chemical transformation sharply promoted or suppressed by water). We disulfide-linked maquette helices in a candelabra-like geometry, restricting helical motions, to dramatically slow H/D exchange and restrict water access to the interior of our simple maquettes well beyond the millisecond time scales of typical catalysis. We note that the interior of an analogous single-chain maquette excluded water despite substantial protein motion during rapid heme ligand exchange.

Tetrapyrrole designs: The lower symmetry of the single-chain maquette allows new design and assembly opportunities including covalent anchoring at specific positions of tetrapyrroles such as heme C as well as binding of single light activated centers such as Zn protoporphyrin IX and Zn-pheophorbide and bacteriochlorophyllide in the presence of companion redox centers and tetrapyrroles. We have found the new single chain maquette family avidly binds tetrapyrroles with nanomolar dissociation constants provided they are polar on one side and nonpolar on one or other sides. We are finding that the maquettes that support the fastest and simplest binding time courses are those that in the apo form are known to have multi-structured interiors that become structured upon porphyrin/chlorin coordination as indicated by NMR. We can secure porphyrin cofactors at 9.4 and 15.9 Å edge-to-edge distances by constructing histidine ligation sites along a helix 3 or 4 turns apart. We avoid 1 or 2 turns because of steric collision between adjacent porphyrins. However, there is no such limit to histidine placement in an adjacent helix. Presently, we secure porphyrins in adjacent helices at the level of 0, 2 or 4 helical turns which leads to edge-to-edge distances between different tetrapyrroles of 3.4, 7.2 and 17.9 Å. The demonstrated flexibility in controlling which tetrapyrroles bind where (bis-histidine sites bind Fe tetrapyrroles, mono-histidine sites Zn, covalent sites Fe or Zn) and the spacing between tetrapyrroles provide a good palette for positioning these cofactors at optimal locations, orientations and distances apart in the design of reaction center maquettes and for catalysis.

Multi-electron redox cofactors: We have designed non-tetrapyrrole cofactors to serve as other candidates for light-activated-triad electron donors and acceptors, for cofactor relays to add stability to the initial charge-separated states and for multi electron function at catalytic sites. These include a naphthoquinone amino acid (Naq), which is functionally similar to the natural menaquinone or vitamin K family and structurally can substitute for tryptophan. We use an intein strategy to splice synthetic Naq peptides with expressed sequences. We have also developed a nicotinamide amino acid and secured various flavins to the maquette frameworks. Commonly, we react brominated flavins with Cys sulfur. We are increasing the flexibility of the approach by modifying flavins for attachment through the 8-a-methyl position, which tends to raise the flavin midpoint potential, in addition to our traditional 6-H position. We have also demonstrated the synthesis and characterization of a $(m-SR)_2Fe_2(CO)_6$ complex coordinated to a simple, α -helical peptide via two cysteine residues. Although this prototype showed no H^+/H_2 exchange

Average energy levels of redox centers secured inside maquettes. The first column on the left lists one-electron donors/acceptors and the second column two-electron cofactors. The middle schematic shows energy levels and lifetime selected in a triad presently under construction depicted on the right.

catalysis, the peptide serves as a first generation [FeFe]-hydrogenase maquette and opens the chemical door through redesign for the creation of more sophisticated peptides containing second coordination sphere residues designed to modulate the properties of the di-iron site. We have also reengineered the four-helix bundles of a natural bacterioferritin to include light-activated chlorins that serve to photo-oxidize Mn, in a manner analogous to the photo-assembly of the Mn cluster of the oxygen evolving center in natural photosynthetic photosystem II.

Light-activated maquettes: We have explored the nanosecond to milliseconds spectral signatures of light activated electron transfer along the length of maquettes in chromophore dyads, using Zn PPIX or flavins as light-activated centers and various hemes as donors and acceptors. Longer charge separated lifetimes will be available in the light-activated triads we are currently constructing and testing in the single-chain four-helix bundle maquette designs (see figure). On the basis of our electron tunneling analysis, our current triad design should allow stable charge separation on the many minutes timescale, longer than any present chemical or biological construct, making it easier to achieve successful oxidative or reductive electron transfer at catalytic sites within the maquette. After successful construction of very long-lived charge-separated states, we will add a terminal cluster of redox centers to accumulate reductants within the maquette for catalysis at promising chemically constructed hydrogen producing centers secured within the maquettes.

Objectives

Photocatalysis using solar radiation represents a significant opportunity for the development of renewable energy sources (H₂ production). In general, the visible-light-driven photocatalysis reactions that have been explored thus far exhibit low quantum efficiency for solar energy conversion, which limits their practical utility. The goal of the project is to develop protein-templated approaches for the synthesis and directed assembly of semiconductor nanomaterials that are efficient for H₂ production from water under visible light irradiation.

Technical Barriers

The low quantum efficiency for visible-light-driven photocatalysis is primarily because of materials-related issues and limitations, such as the control of the band gap, band structure, photochemical stability, and available reactive surface area of the photocatalyst. Synthesis of multicomponent hierarchical nano-architectures using biomimetic approaches, consisting of semiconductor nanoparticles with desired optical properties fabricated to maximize spatial proximity for optimum electron and energy transfer, represents an attractive route for addressing the problem.

Abstract

A variety of sulfide nanomaterials with controlled size, phase structure, and three-dimensional architectures have been synthesized using *E. Coli* bacteria and genetically engineered virus (P22) as affinity bio-templates. Photoelectrodes fabricated using the *E. Coli* templated synthesis of hollow CdS nanostructures exhibit excellent performance for photocatalytic hydrogen production with a photoconversion efficiency of 4.2 % under global AM 1.5 illumination in the presence of a sacrificial electron-donor of mixed S²⁻ and SO₃²⁻. This is significantly better

than the 1.34% efficiency obtained using CdS nanoparticles synthesized utilizing the same procedure in the absence of *E. Coli*. The potential of utilizing the P22 virus architecture to improve efficiency and durability of the IrO₂-Zn Porphyrin system for the water splitting reaction is also being explored. Moreover, the ability of the icosahedral P22 structures to act as scaffolds for energy harvesting via Förster resonance energy transfer (FRET) is being investigated.

Progress Report

(a) Bacterial syntheses of quantum dots, nanocrystals, and hollow nanostructures: Sulfide semiconductors have a wide variety of optical, electrical, and photoelectric applications. CdS has a narrow band gap and a valence band at relatively negative potentials, which offer them good visible-light-active photocatalysts. Nanoporous hollow nanostructures are one of the best architectures since they avoid agglomeration of the NCs and reduce bulk/interface electron/hole recombinations. However, it is challenging to assemble NCs into highly ordered hollow nanostructures. We have developed a general biotemplate synthesis approach to prepare hollow CdS nanostructures by taking advantage of the natural morphology of the common bacteria *E. coli*. The CdS nanostructures are prepared with high yield under mild ambient conditions with the assistance of sonochemistry using cadmium acetate dehydrate and thioacetamide as reactants. The CdS coating on the *E.coli* can be controlled in the form of monodisperse quantum dots (1-2 nm), near monodisperse NCs (7-8 nm), discontinuous CdS NC agglomerates, and uniform porous coating of NCs. Both the band gap and crystal structure of these CdS NCs can be tuned by simply adjusting the synthetic conditions, such as reaction time and the concentration of precursors (Figure 1 a-c). The photoelectrodes fabricated using the synthesized hollow CdS nanostructures exhibit excellent performance for photocatalytic hydrogen production with a photoconversion efficiency of 4.2 % under global AM 1.5 illumination in the presence of a sacrificial electron-donor of mixed S²⁻ and SO₃²⁻ (Figure 1d). The method has been extended to the synthesis of other sulfides including ZnS, PbS, AgS, etc., with controlled size, structure, and optical adsorption properties.

(b) Virus protein-templated three-dimensional sulfide nanoarchitectures: We have successfully developed a facile bioinspired approach for the synthesis of ordered 3D nanostructures of sulfide NC assemblies over genetically engineered P22 viral capsids (Figure 2a-e). The assembly procedure consists of (1) the self-assembly of spherical protein templates from genetically engineered P22 coat protein, and (2) the nucleation and growth of NCs on the self-assembled protein templates (Figure 2c). We

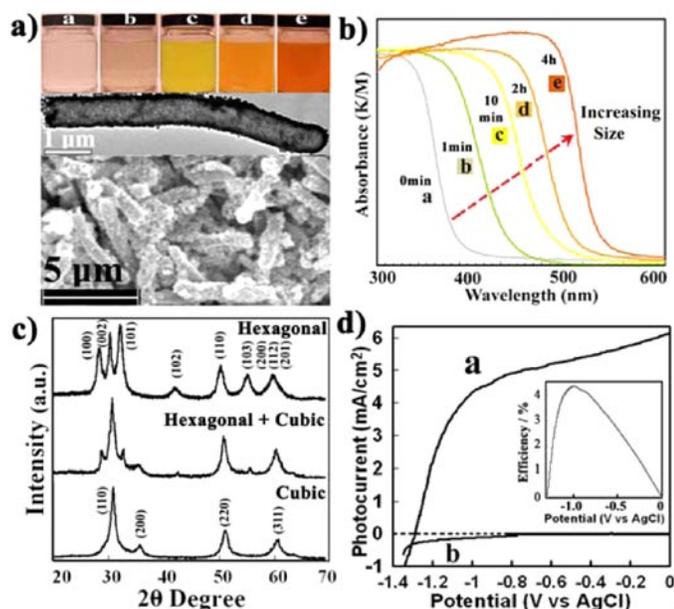

FIGURE 1. (a) SEM and optical images, (b) reaction time-dependent UV-vis spectra, (c) XRD patterns of *E. coli*-templated nanoporous hollow CdS microrods. (d) Photocurrent density (a) and dark current (b), and photoconversion efficiency (the inset) of a photoelectrode fabricated using nanoporous CdS hollow microrods.

have used ZnS and CdS grown on the engineered P22 coat protein assembly as a model system since binding peptides with strong affinity for these sulfides have been identified. Furthermore, the structure and assembly of the P22 coat proteins is reasonably well understood. By changing the reaction time and reactant concentration, the final protein-directed sulfide growth is expected to exhibit different structures, such as well ordered spherical NC assemblies (Figure 2d) during the early stage of growth that eventually develop into spherical hollow nanostructures for longer growth periods (Figure 2e). Both the diameter and configuration of the self-assembled P22 coat protein template can be controlled over a specific range by heating in solution at temperatures of up to 70 °C. This offers some degree of control over the size and shape of the synthesized inorganic nanostructures. Additionally, the crystallite size of the NCs can be varied by changing the reactant concentration and the reaction time. The synthetic strategy is quite general and can be extended to the fabrication of a variety of other nanostructures.

(c) Synthesis of IrO₂-Zn porphyrin labeled phage capsids: Filamentous viruses carrying Zn porphyrins which act as a photosensitizer and IrO₂ oxide hydrosol clusters which act as a catalyst have been demonstrated to effect photocatalytic water splitting, although immobilization

of the viruses in a microgel was required to improve the structural durability. To evaluate the potential of spherical virus architecture to improve efficiency and durability we have inserted an IrO₂ binding peptide into the exterior surface of the bacteriophage P22 capsid and have taken advantage of a internal uniquely chemically reactive site (engineered in section 1.4 below) to conjugate a Zn porphyrin to the interior of the particle. A commercially available Zn porphyrin starting material was modified by the laboratory of Trevor Douglas by the introduction of a maleimide group which in turn is capable of efficient conjugation to the thiol group of the amino acid cysteine. Preliminary experiments suggest a modest level of conjugation of the porphyrin to the interior of the capsid at natural pH and optimization of the reaction is currently underway.

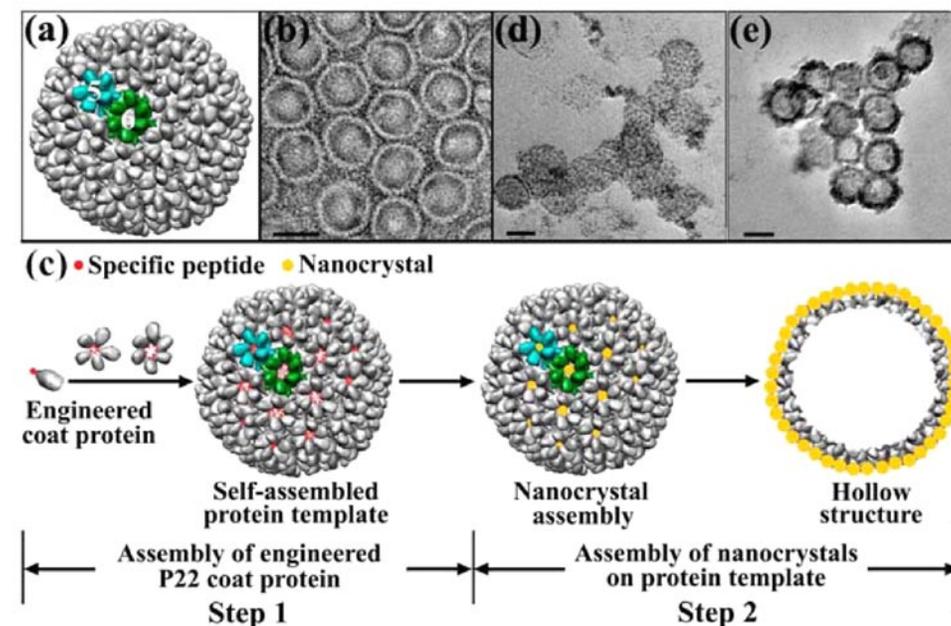

FIGURE 2. (a) Three-dimensional surface representation of P22 procapsid viewed along a 3-fold axis; (b) TEM image of stained protein assemblies of genetically engineered P22 coat protein; (c) Schematic illustration of the formation of ordered NC assemblies over self-assembled genetically engineered P22 coat proteins. Step 1: assembly of P22 coat proteins (gray) genetically engineered with specific peptide (red). Step 2: protein-directed nucleation and growth of NCs (yellow) on the protein assembly. (d and e) TEM images of sulfide NC assemblies grown on the self-assembled protein templates shown in Figure 1b. All scale bars represent 50 nm.

(d) Antenna effect studies using spherical P22 capsids: The antenna effect is the ability

of an ensemble of chromophores with similar absorbance bands to transfer energy to a common acceptor, hence to act as photon collecting antennas. We have analyzed the antenna effect displayed by chromophores on the exterior of the 60 nm spherical P22 capsid particle over a range of photon acceptor and donor densities. Our data indicated that the degree of donor emission increased with increasing fraction of labeled subunits up to a value of approximately 10% (~50 subunits) after which it decreased. The decrease was due to donor/donor collisional quenching. Under the most favorable conditions the antenna effect was limited to value of approximately 2 (meaning two donors could transfer to an acceptor). By mapping the site of the modification onto the capsid lattice it became evident that rather than being uniformly distributed on the capsid surface, as a result of the capsid architecture, the sites are locally clustered. It is the local clustering that result in the donor quenching and limited antenna effect. In collaboration with Reidun Twarock of the York Center for Complex Systems Analysis, an alternative site for modification which would result in a more uniform distribution of chromophores was identified.

(e) Construction of P22 phage capsids with internal chemically reactive sites: We have constructed a set of plasmids whose expression results in the production of P22 procapsids with chemically reactive amino acid residues located on the interior face of the capsid wall. Cysteine residues were inserted into a long α -helical region of the coat protein and the protein was tested for its ability to assemble into procapsids and the chemical reactivity of the cysteine residue in the various states of the procapsid was determined. Substitution of a cysteine at residue 110 of the capsid protein results in the formation of a properly dimensioned capsid in which the cysteine is reactive in the unexpanded procapsid form but unreactive in the expanded “wiffle ball” form. In contrast, substitution of residue 118 with cysteine results in a capsid in which the cysteine is reactive in the “wiffle ball” form but relatively unreactive in the procapsid form.

Future Directions

During the last phase of the current project, we are focusing on the fabrication of multicomponent inorganic nano-architectures over genetically engineered P22 capsids. The specific peptide sequences responsible for binding to different materials, including PbS, CdS, Fe₂O₃, and TiO₂, will be fused into the scaffolding protein of P22. The genetically engineered P22 capsids with the specific affinity for binding to PbS, CdS, Fe₂O₃, and TiO₂ will then be used to prepare porous hollow nanoballs, possibly consisting of multiple components. We will optimize synthetic conditions for control of the shell structure, the size of NC subunits, and the assembly of heterogeneous components. The physical and chemical properties of the products will be studied in detail. Photocatalytic activity and photoconversion efficiency of the obtained heterogeneous nanoarchitectures will be evaluated.

Objectives

- **Learn to design improved band-gap-narrowed semiconductors:** Design and characterize BGNSCs that are stable toward photo-oxidation, yet efficiently absorb a large fraction of solar radiation and with bands positioned to generate sufficiently energetic electrons and holes to drive H₂ and O₂ production reactions.
- **Elucidate homogeneous water oxidation catalysis pathways:** Understand and improve homogeneous water oxidation catalysis, where defined structure and mechanistic studies can give deep insight the 4e⁻ water-oxidation pathways
- **Understand interface-bound water oxidation catalysts:** Elucidate the factors controlling kinetics and efficiency of interface-bound catalysts through study of immobilized molecular catalysts and nanostructured inorganic catalysts.
- **Develop insight on water interactions and reactivity at band-gap-narrowed semiconductors:** Understand water interactions and reactivity at BGNSC interfaces and differences from wide band-gap semiconductors. Characterize photocatalysis of water at BGNSC interfaces with and without attached water oxidation catalysts.

Technical Barriers

- We need to design and characterize stable, low-cost and light absorbing materials as photoanodes for solar-driven water splitting
- There are no thermodynamically efficient and kinetically robust interface-bound oxidation catalysts that can facilitate charge transfer of holes from the semiconductor and catalyze water oxidation.

- The breakthroughs in overall device efficiency needed to support a hydrogen economy require integrated expertise in the co-dependent areas of semiconductor and catalyst development.

Abstract

We are attacking four major issues hindering progress in solar-driven water splitting using an integrated experimental and theoretical approach that offers fundamental insights into the underlying photoelectrolysis processes occurring in band-gap-narrowed semiconductor and catalyst components. First, we are tuning known photostable semiconductors to control their light-harvesting and charge-separation abilities in order to achieve a better understanding of their structural and electronic properties, and, in addition, design and characterize new classes of visible-light photoactive semiconductors. Second, we are developing viable catalysts for the difficult four-electron water oxidation process by exploring the catalytic activity and mechanisms of molecular transition-metal complexes. Third, we have begun immobilizing molecular catalysts and (non-precious) metal oxide catalysts on electrodes and/or metal-oxide nanoparticles in order to determine the kinetics of electrochemical water oxidation in the absence of mass transport limitations, and identify the intermediates by spectroscopic techniques. Finally, we plan to explore the interfacial water-decomposition reactions that occur at bare and catalyst-functionalized semiconductor surfaces using carriers generated by visible-light irradiation with the goal of understanding semiconductor catalyst water charge transport.

Progress Report

The combined experimental and theoretical research in our second funding period has resulted in a number of advances in the following areas. We investigated: (1) the properties of solid solutions of GaN/ZnO; (2) preparation and characterization of epitaxial LaTiO₂N electrodes; (3) a number of new pyrochlore and pyrochlore-related semiconductors such as AgBiNb₂O₇ with strong visible light absorption ($E_g \sim 2.7$ eV) and band edges appropriately positioned for overall water splitting; (4) the detailed mechanism for water oxidation by the so-called "Tanaka catalyst," [(Ru^{II})₂(OH)₂(Q)₂(btpyan)]²⁺ (Q = 3,6-di-*tert*-butyl-1,2-benzoquinone; btpyan = 1,8-bis(2,2':6',2''-terpyrid-4'-yl)anthracene) (Fig. 1, left) that stands apart from other dinuclear ruthenium catalysts not only in its stability and high turnover number but in the respect that it functions in an entirely different manner involving its redox-active quinonoid ligands; and (5) characterization of intermediates

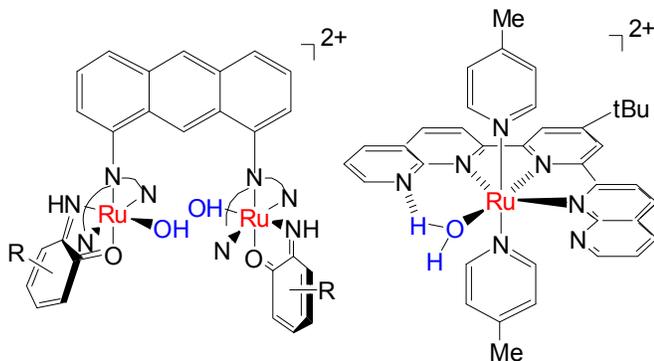

FIGURE 1. Structures of $[(Ru^{II})_2(OH)_2(O)_2(btpyan)]^{2+}$ (left) and $[Ru(OH_2)(NPM)(pic)_2]^{2+}$ (right).

of Thummel's mononuclear water oxidation catalyst $[Ru(OH_2)(NPM)(pic)_2]^{2+}$ (NPM = 4-t-butyl-2,6-di-1',8'-(naphthyrid-2'-yl)-pyridine, pic = 4-picoline) (Fig. 1, right). Furthermore, we demonstrated that the Co metal hydrous oxide can be immobilized on a suspension of TiO_2 or SiO_2 nanoparticles in basic aqueous solution, and that it is a very effective catalyst for water oxidation. Here we present some of our studies.

1. Photocatalytic Water Oxidation at the GaN (10 $\bar{1}$ 0) – Water Interface. We constructed an atomistic model and proposed a sequence of intermediate steps for water oxidation at a pure GaN(10 $\bar{1}$ 0)/water interface. Ab initio molecular dynamics simulations examined the fully solvated aqueous interface at ambient temperature. An appropriate cluster model, that includes a polarizable continuum in addition to explicit solvent water molecules, was cut out from snapshots of these AIMD simulations for additional DFT-based calculations of the water oxidation mechanism. The reaction intermediates follow a sequence of four proton-coupled electron transfers. Four UV photons are consumed to generate the four photo-holes which drive the oxidation, producing $4H^+ + O_2$ from $2H_2O$. Calculated standard free energies show that the photogenerated holes in GaN have sufficient energy to drive the overall water oxidation reaction. Implications for the operation of GaN/ZnO alloy photocatalysts, which absorb in the visible wavelength range, are presented. The calculated potentials show a remarkable parallelism to the known potentials for the sequential one-electron oxidation of water in homogeneous aqueous solution, suggesting that the proposed sequence may apply more generally than for the specific GaN (10 $\bar{1}$ 0) surface catalyst.

2. Phase Diagram, Structure and Electronic Properties of $(Ga_{1-x}Zn_x)(N_{1-x}O_x)$ from DFT-Based Simulations. We constructed an accurate cluster expansion (CE) for the $(Ga_{1-x}Zn_x)(N_{1-x}O_x)$ solid solution based on density functional theory (DFT). A subsequent Monte Carlo simulation revealed a phase diagram which has a wide miscibility gap and an $x = 0.5$ ordered compound. The disordered phase displays strong short range order (SRO) at synthesis

temperatures. To study the influences of SRO on the lattice and electronic properties, we conducted DFT calculations on snapshots from the MC simulation. Consistent with previous theoretical and experimental findings, lattice parameters were found to deviate from Vegard's law with small upward bowing. Bond lengths depend strongly on local environment, with a variation much larger than the difference of bond length between ZnO and GaN. The downward band gap bowing deviates from parabolic by having a more rapid onset of bowing at low and high concentrations. An overall bowing parameter of 3.3 eV is predicted from a quadratic fit to the compositional dependence of the calculated band gap. Our results indicate that SRO has significant influence over both structural and electronic properties.

3. Characterization of the Intermediates Involved in Water Oxidation: A detailed characterization of intermediates in water oxidation catalyzed by a mononuclear Ru polypyridyl complex $[Ru-OH_2]^{2+}$ ($Ru = Ru(NPM)(pic)_2$) (Fig. 1, right) has been carried out using electrochemistry, UV-vis and resonance Raman spectroscopy, pulse radiolysis, stopped flow, and ESI-MS with $H_2^{18}O$ labeling experiments, and theoretical calculations. The results reveal a number of intriguing properties of intermediates such as $[Ru=O]^{2+}$ and $[Ru-OO]^{2+}$. Two consecutive one-electron steps take place at the potential of the $[Ru-OH]^{2+}/[Ru-OH_2]^{2+}$ couple, which is higher than the potential of the $[Ru=O]^{2+}/[Ru-OH]^{2+}$ couple. While pH-independent oxidation of $[Ru=O]^{2+}$ takes place at 1410 mV vs NHE, bulk electrolysis of $[Ru-OH_2]^{2+}$ at 1260 mV vs NHE at pH 1 (0.1 M triflic acid) and 1150 mV at pH 6 (10 mM sodium phosphate) yielded a red colored solution with a Coulomb count corresponding to the *net four-electron oxidation*. ESI-MS with labeling experiments clearly indicate that this species has an O–O bond. This species required an additional oxidation to liberate an oxygen molecule, and without any additional oxidant it slowly decomposed to form $[Ru-OOH]^+$ in 2 weeks. We have assigned this species as $^1[Ru-\eta^2-OO]^{2+}$ based on our electrochemical, spectroscopic, and theoretical data alongside a previously published conclusion by T.J. Meyer's group (*J. Am. Chem. Soc.* **2010**, *132*, 1545-1557).

Future Directions

Our *four-part plan* for developing functional photocatalytic systems builds upon the advances we have made in water oxidation catalysis and the elucidation of the properties of appropriate band-gap-narrowed semiconductors for use as photoanodes. First, we will work towards identifying new and promising semiconductors to serve as photoanodes in our mechanistic water oxidation studies. This will involve not only tuning their band gaps and absolute band edge energies, but also consideration of their suitability for use in well-defined interfacial mechanistic studies (*e.g.*, single crystals vs. films of powders). Second, we will develop improved transition-metal based

molecular catalysts for mechanistic investigation of water oxidation. Third, we will compare their electrochemical water-oxidation activity when immobilized on conducting electrodes with that in homogeneous aqueous solution. Fourth, we will pursue advances in these areas to uncover the core scientific challenges to the efficient coupling of the catalytic functions at the water interface under irradiation. This will be accomplished through the study of water oxidation at complex aqueous interfaces following the transfer of stored photo-produced electrical energy from a semiconductor through a catalyst into water.

We will also engage in related collaborative research to address the origin of two enhancement effects (*i.e.*, Cs ion pretreatment of semiconductors and the addition of carbonate ion) on efficient solar water splitting, originally discovered by K. Sayama's group (AIST). Using funds from METI, Japan *via* a program called U.S.-Japan Cooperation on Clean Energy Technologies, the AIST researchers will be able to stay at BNL for an extended period to carry out that related proposed work.

Objectives

UV light, incident on a semiconductor-water interface, has been used to split water, but it is not known exactly how this happens or how to extend the wavelength range to the visible. The semiconductor alloy GaN/ZnO has been found promising by Domen's group in Japan. The objective of this research program is to use computational theory to help unravel how the oxidation process occurs, when photo-excitations in the semiconductor arrive at the semiconductor/water interface. What surface is most effective, how do photo-holes liberate protons from water molecules on the surface, what are the reaction sites and reaction intermediates, and what constraints must the semiconductor properties satisfy? How can we design materials to improve the efficiency and increase the wavelength range of the useful light?

Technical Barriers

Technical challenges to this kind of modeling are daunting. Density-functional theory makes band gap and self-interaction errors, and available computer power forces less-than-optimal system sizes to be modeled. Experiments are only slowly yielding microscopic details to guide theory. Water is a difficult molecule to model because of quantized nuclear motions and complicated polar properties causing bonding to be a mixture of electrostatic and covalent interactions. The relevant semiconductor surface is not yet firmly identified, and the degree of alloy disorder and surface alloy enrichment are poorly known, so that theory must attempt to answer a very large list of questions.

Abstract

Domen's group [1] found that GaN/ZnO alloys were particularly effective at absorbing sunlight and harvesting photo-holes, which then oxidize water to protons and O₂. A separate catalyst is needed to harvest the photo-electrons,

which reduce the protons to H₂. The SWaSSiT* group (at Stony Brook University and Brookhaven National Lab) uses computational theory (mainly density-functional theory, DFT) to try to understand the process and how to optimize it. Most of our work, so far, has used the pure GaN (10-10) (non-polar) surface-to-water interface as a simplified model. We find this surface a particularly effective water oxidizer, since water has a strong tendency (according to theory) to dissociate into H⁺ (attached to surface N atoms) and OH⁻ (attached to surface Ga atoms). The dissociated structure is found both for a monolayer of water at T = 0 (by static DFT), and for a thick water layer at room temperature (by DFT-driven Born-Oppenheimer molecular dynamics, AIMD). To analyze the photo-electro-chemical reaction, we make a cluster calculation, using B3LYP (partial exact exchange), explicit waters of hydration, and implicit waters represented by a polarizable medium. We propose a reaction path where the surface-bound OH⁻ interacts with photo-holes and water molecules. We find a sequence of four proton-coupled electron transfers (PCET). In each step, a photo-hole transfers to the surface-bound anion, releases a proton, and forms a new, bound, and hydrated, anion species: (1) O⁻, (2) OOH⁻, (3) OO⁻, finally returning to (4) OH⁻, releasing O₂ in this last step. This accomplishes the overall reaction 2H₂O → 4H⁺ + O₂. Our attention is now turning in many new directions, some of which will be discussed. For example, the semi-polar (10-11) surface has recently been identified experimentally in powders of the alloy, and may play a role. We study its surface structures using a new DFT-based implementation of a genetic algorithm. We are starting to analyze the possible roles of semiconductor polarity in photocatalysis. We have studied the alloy thermodynamics of GaN/ZnO, and the concentration dependence of the band gap, using DFT with large supercells, supplemented by a cluster expansion and Monte-Carlo simulation. The resulting model has a stable binary compound (GaN)_{0.5}(ZnO)_{0.5} which disorders above 850K, and wide miscibility gaps. Above 850K there is complete solid solubility, and materials formed above this temperature are likely to remain supercooled and completely miscible at lower T. There is significant short-range order at temperatures of 1400K and below, and a correlation between lower free-energy and larger band-gap configurations.

*Other members of SWaSSiT are Marivi Fernandez-Serra, Mark Hybertsen, Li Li, James Muckerman, Artem Oganov, Xiao Shen (emeritus), Yolanda Small, and Jue Wang.

Progress Report

As outlined in the abstract, three parts of the project were completed, another part was completed by colleagues funded by a separate DOE project, and a fifth

part is underway. These are (1) studies of a monolayer of water at $T=0$ on the GaN (10-10) surface; (2) ab initio molecular dynamics (AIMD) for the interface of bulk water at 300K with GaN (10-10); (3) quantum-chemical modeling of photo-hole-induced reactions which produce a likely pathway for oxidation of water into H^+ and O_2 ; (4) thermodynamics, local order, and band gap reduction in bulk GaN/ZnO alloys; and (5) studies of the semipolar (10-11) surface of GaN and its interaction with water.

Future Directions

We should soon be able to predict surfaces of GaN (10-11) without and with a water monolayer. We will give these to our colleague Fernandez-Serra for AIMD modeling. There are many important future directions, and we will pursue a number of them simultaneously. We expect to stimulate experiments that will help us choose the most promising directions for modeling studies. (1) Obvious future directions are studies of reaction routes on the GaN (10-11) semi-polar surface, and on surfaces of alloys, both (10-10) and (10-11). (2) A project in the advanced planning stages is the interaction of water with ferroelectric thin film surfaces with controllable polarity. (3) A project that will be initiated with a new graduate student is studies of the hole mobility, hole trapping, and hole transfer dynamics in GaN with various surface terminations, and in GaN/ZnO alloys. These projects cannot be done by the PI alone. Project (1) will probably be done in close collaboration with colleagues at BNL. Project (2) involves experimental collaborators at Stony Brook and BNL, and collaboration with SWaSSiT theorists, especially Fernandez-Serra and Oganov. Project (3) will involve collaborators at both BNL and Yale.

Objectives

We are developing new photoelectrocatalytic systems based on semiconductor nanocrystalline materials, ultimately intended to be the active layers in solar fuel forming systems. Photoactive nanocrystals are decorated with electron-rich ligands, and captured into asymmetric matrices that ensure efficient energy capture and vectorial photoelectrochemical energy conversion. New materials are being designed in parallel with unique spectroscopic and electrochemical characterization of their frontier orbital energies, to ensure highest possible rates of charge transfer in the critical energy conversion steps.

Technical Barriers

- There are significant challenges to the formation of stable low bandgap semiconductor nanocrystalline “dots” and “rods;”
- There are even greater challenges to the alignment of semiconductor nanorods into asymmetric arrays, which ensure electron transport in one direction (vectorial), and keep oxidation and reduction processes spatially separated;
- The frontier orbital energy levels of these nanocrystalline materials are difficult to characterize in photoelectrochemically-relevant environments; addition of protective ligands or polymer hosts can further alter these energies; nanocrystal-nanocrystal interactions also alter these energies, and need to be studied for isolated crystals, small aggregates and full assemblies.

Abstract

Our DOE Solar Photochemistry supported research (DE-FG03-02ER15753) has focused on the development and characterization of new semiconductor nanorod

(SC-NR) materials coupled asymmetrically to conducting polymer hosts, or either metal or metal oxide supports, and the development of new nanocrystalline materials decorated with both metallic catalytic sites and metal oxide nanoparticles. The asymmetric structure of these nanomaterials is designed to ensure vectorial electron transfer in photoelectrochemical processes which may ultimately provide pathways for the formation of chemical fuels from sunlight. Recent activities have been centered on: (i) the formation of new nanomaterials and nanocrystals (NCs); (ii) the demonstration of photoelectrochemical processes with SC-NCs tethered to the surface of a conducting polymer; (iii) the characterization of the energetic of these materials by unique protocols involving photoemission spectroscopies of monolayer-tethered SC-NCs; and (iv) the spectroelectrochemical characterization of charge injection into surface-tethered SC-NCs on unique waveguide platforms.

Progress Report

Recent efforts (Fig. 1) have focused on the creation of functional nanocrystalline monolayers and ensemble materials, e.g. CdSe SC-NCs capped with ligands terminated with the monomer of CPs such as (poly(ethylenedioxythiophene) – PEDOT, and its ProDOT and di-ethylProDOT derivatives. New electrochemical protocols were developed to capture close packed monolayers of these NCs on the surface of the CP, following which we interrogated the relative rates of photoelectrochemical reduction of a solution electron acceptor by the CP, using the CdSe NC as the photosensitizer. Electron donation to the photoexcited NC by the CP ($r_{c,2}$) is the rate limiting step and is exponentially related to the excess free energy controlled by the quasi-Fermi level in the CP, and by the NC diameter, which controls E_{VB} . These results demonstrate an enabling method for the capture of SC-NCs in a functional format, which can be used to tailor the architecture of new materials where compositional and energetic asymmetry is required. For photoelectrochemical systems such as this both the electronic coupling and the excess free energy at each heterojunction (e.g. $E_{HOMO}^{MOx} - E_{LUMO}^{SC-NC}$; $E_{HOMO} \approx E_{VB}$; $E_{LUMO} \approx E_{CB}$) control the photovoltage of the complete system, and rates of ET for the redox reactions coupled to this structure.

We have recently developed new ways of characterizing frontier orbital energies of the NC in both high vacuum and solution environments. We demonstrated the successful capture of sub-monolayers of pyridine-capped CdSe NCs

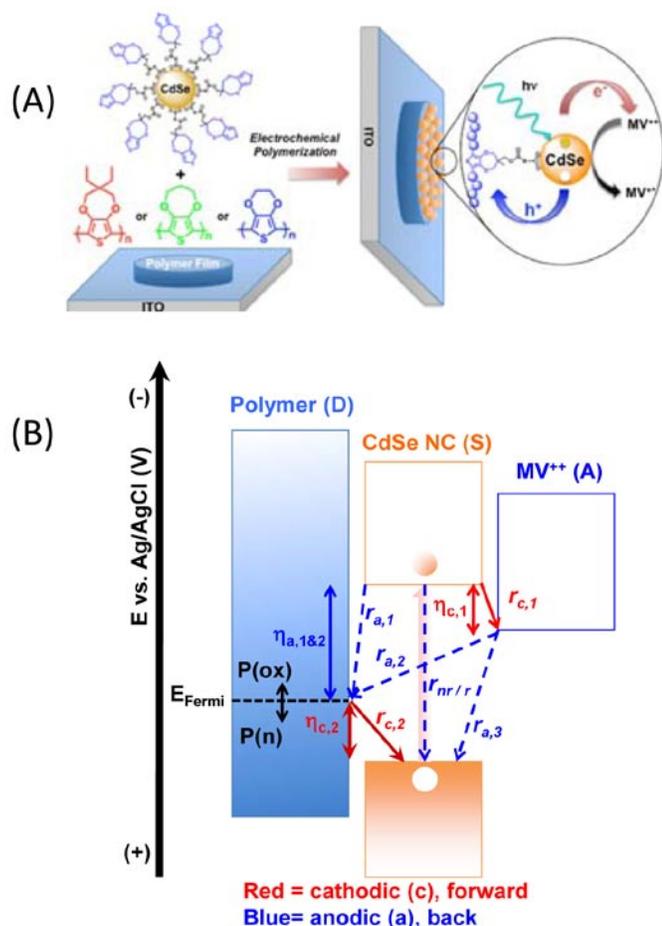

FIGURE 1. (A) Schematic view of the capping of CdSe NCs with ProDot-terminated ligands, followed by the electrochemical capture of the NCs at the surface of CPs based on PEDOT, ProDOT or di-ethylProDOT. A compositionally and energetically asymmetric material combination results, which can reduce a solution electron acceptor, with the CdSe NC acting as the photosensitizer; (B) The overall rate of MV^{2+} reduction is determined by a complex series of ET events, and for this first generation of materials the slow step appears to be electron capture from the CP by the photoexcited NC. Excess free energy relationships summarized in Fig. 3 show that $r_{c,2}$ (for cathodic photocurrents) is determined by the free energy difference between the quasi-Fermi potential in the CP and E_{VB} of the NC.

(pyr-CdSe) on Au surfaces modified with a short dithiol modifier, and characterized their composition and frontier orbital energies (ionization potential (IP), E_{VB}) for the bare NC, and for NCs modified with short dipolar ligands that vary in their polarizability. We were able to account for the large (up to 1.0 eV) shift in vacuum level caused by even 15% of a monolayer of CdSe NCs adsorbed via dithiols to Au, and the additional increases or decreases in vacuum level caused by dipolar capping ligands.

We developed an alternative approach to characterization of frontier orbital energies of tethered NCs using spectroelectrochemical methods on waveguide substrates. Monolayers of thiol functional carboxylic acids

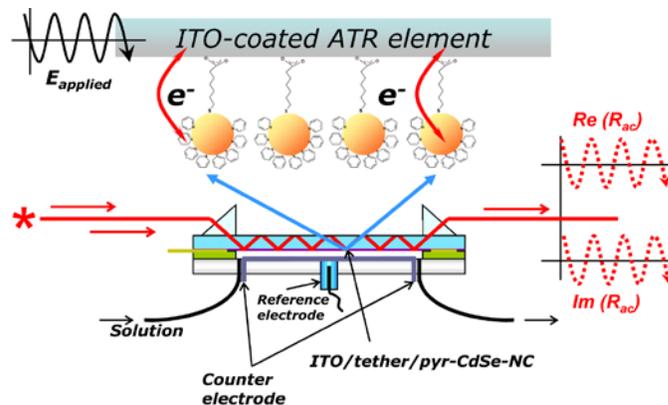

FIGURE 2. Schematic view of the spectroelectrochemical characterization of CdSe NCs, tethered at sub-monolayer coverages to ITO/ATR waveguide platforms. The potential (versus N.H.E. and vacuum) at which full bleaching of the lowest energy excitonic feature (at λ_{ex}) is used to estimate E_{CB} in solution environments. Modulation of the potential then provides in-phase and out-of-phase optical responses, which are used to estimate switching rates, related to k_{ET} to/from the NC.

are adsorbed to indium-tin oxide (ITO) substrates (the electroactive component of an ATR/waveguide element), which can then act as a capture surface for solution pyr-CdSe NCs. The lowest energy excitonic feature is reversibly bleached at a midpoint potential which leads to an estimate of $E_{\text{CB}} \approx -3.5$ eV versus vacuum. Subsequent modulation of the electrode potential around this midpoint potential while measuring both in-phase and out-of-phase components of the ATR/reflectance signal allows for estimation of rates of bleaching/recovery of the monolayer tethered NC (k_s).

We have recently demonstrated the synthesis of p-type cobalt oxide nanowires and heterostructured Au- Co_3O_4 nanowires via *Colloidal Polymerization*. In these systems, metallic cobalt nanoparticles assemble into 1-D mesostructured “wires” in solution via magnetic dipolar interactions, and are subsequently converted into hollow oxide nanowires via oxidation reactions. Hollow Co_3O_4 nanowire networks were formed on ITO and were shown to be electrochemically active. UPS measurements provided an estimate of $E_{\text{VB}} \approx 5.3 \pm 0.2$ eV for the as-deposited oxide nanowires, which appears to be close to the valence band energy required to drive OER in a photoelectrochemical energy conversion system, without external bias. As discussed further below, these band edge energies will provide large driving forces for photoelectrochemical processes when the oxide NP is married to semiconductor NCs or NRs, such as CdSe, forming true “Type II” heterojunctions. To enhance their catalytic properties these cobalt oxide nanowires were subsequently modified with noble metal inclusions. We demonstrated the ability to insert Au or Pt nanoparticles into the interior or exterior of the cobalt oxide nanowires. We saw a significant enhancement of the electrochemical activity associated with the change of redox states of the cobalt oxide as a consequence of noble metal inclusions.

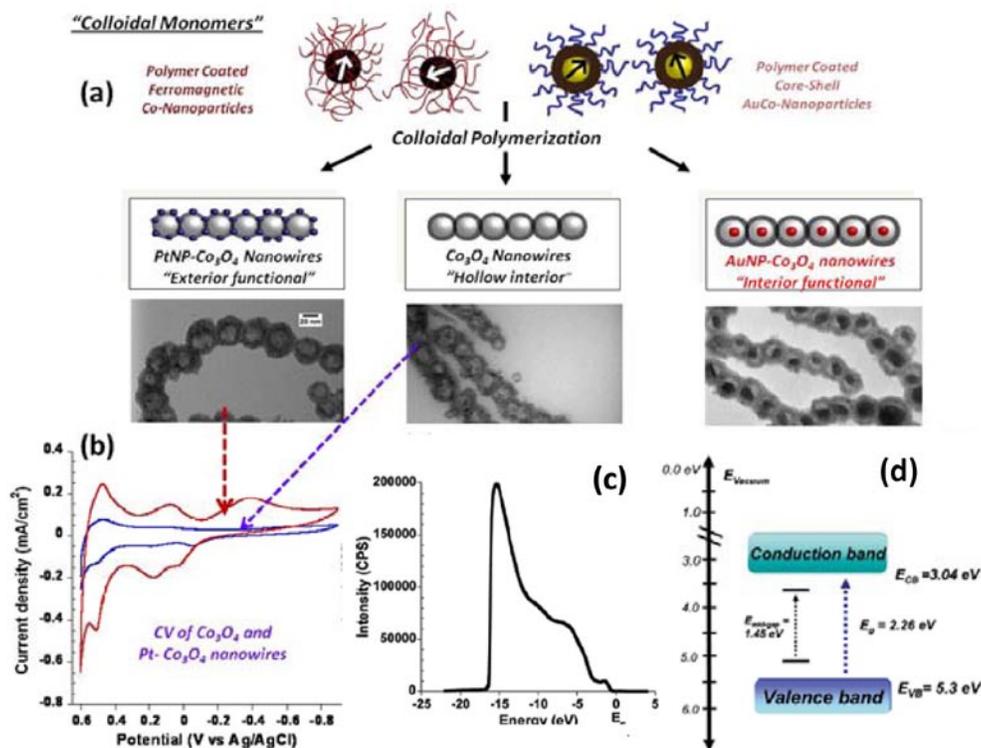

FIGURE 7. (a) Schematic for preparation of hollow Co_3O_4 nanowires, Au- Co_3O_4 nanowires with Au inclusions on the interior of nanowires and Pt- Co_3O_4 nanowires with Pt inclusions on exterior of nanowire. (b) CV of hollow Co_3O_4 vs. Pt- Co_3O_4 nanowires indicates a 7-fold enhancement of electroactivity as a consequence of Pt inclusions (c) UV-photoemission spectroscopy (He(I) UPS) of hollow Co_3O_4 nanowires and (d) estimated band edge energies of Co_3O_4 nanowires constructed from UPS and optical absorption data.

Future Directions

1. We will develop ligand-capped SC-NCs and SC-NRs providing for selective and asymmetric addition of metallic and oxide (e.g. cobalt oxide) catalytic sites, with control over their placement, electronic coupling, and catalytic activity.
2. We will explore directed self-assembly of rod-like molecular objects into vertically aligned arrays.
3. We will characterize band edge energies of monolayer-supported NCs and NRs using photoemission spectroscopies (UPS/XPS), characterizing E_{VB} and vacuum level changes as a function of NC coverage and capping ligand. We will probe NC-NC and NR-NR interactions and extend these studies to either randomly adsorbed or aligned NRs which have been modified with oxide or metallic catalytic sites.
4. We will extend our protocols for spectroelectrochemical study of SC-NCs on electroactive waveguides, to study NC-NC and NR-NR interactions which influence E_{CB} as a function of surface coverage, types of capping ligands, the introduction of asymmetric nanorods, and nanorods modified with catalytic sites.

5. We will develop the first prototypes of membrane encapsulated ensembles of these asymmetric, modified SC-NCs and the first demonstration of proton pumping in response to photoelectrochemical events on either side of the membrane.

Objectives

The main problem with photoelectrochemical water splitting is that no semiconducting materials are known that satisfy all the requirements necessary to construct an efficient and stable solar photoelectrolysis system. Metal oxide semiconductors can satisfy the stringent requirement that a photoelectrode will be stable in an electrolyte under full or concentrated sunlight for many years. However no stable metal oxide semiconductors with the proper band gap and band positions are known. Therefore we have developed a combinatorial search strategy to quickly and efficiently produce many thousands of metal oxides and screen them for photoelectrolysis activity.

Technical Barriers

- A metal oxide semiconductor that can meet stability and efficiency requirements will probably contain at least three different metals, greatly increasing the number of potential materials to be produced and screened.
- Once several promising materials are identified it will take considerable effort to optimize the electronic properties and nanostructured morphology to final have a few materials to construct a practical and efficient photoelectrode for a solar water splitting system.

Abstract

A combinatorial method to produce and screen for efficient photoelectrolysis activity was developed. The method employs high-throughput ink-jet printing of patterns of multiple oxide precursors onto conductive glass substrates. Subsequent pyrolysis yields a library of oxide electrodes that are screened for photoelectrolysis activity by immersing in an electrolyte and scanning a laser over the electrodes to map the photocurrent response.

Iron oxide is a d-band semiconductor that serves as a prototype for a future material that may be useful in a photoelectrolysis device. Therefore it is useful to explore how to optimize the photoactivity of this material. Since there are literature reports that “doping” small amounts of impurities could greatly influence the properties of $\alpha\text{-Fe}_2\text{O}_3$, we investigated the effect of adding small amounts of Ti, Si, and Al on the photoelectrochemical activity of $\alpha\text{-Fe}_2\text{O}_3$ was investigated using our combinatorial protocols. When Si and Al are individually added to iron oxide at the levels we studied, the photoelectrolysis activity decreased whereas low levels of Ti addition enhanced the photocurrents. Synergistic effects were observed resulting in enhanced photocurrents when multiple impurities were added to $\alpha\text{-Fe}_2\text{O}_3$.

It was also found that the photoelectrolysis activity of the Bi-V oxides could be improved by the addition of various levels of W, Cu, Fe, Mg and Mn to Bi-V binary oxides. Some Bi-V-W ternary oxides had improved photoresponse of up to 18 times of that of the well-known BiVO_4 phase whereas Bi-V-Mo ternary oxides had very little photoresponse. However, when elements like Fe, Cr and Mg were introduced to the Bi-V-Mo oxides, their photoresponse could be increased.

Progress Report

With DOE Hydrogen Program support we have been pursuing a novel high throughput combinatorial search strategy for the identification of multicomponent metal oxide materials with suitable band gaps and band positions for water photoelectrolysis operating as either a photoanode or a photocathode. Our combinatorial search strategy uses ink jet printing of overlapping patterns of metal oxide precursors on to conductive glass substrates. Metal nitrates, one class of simple oxide precursors that we use, decompose to form metal oxides, oxygen and NO_2 by heating at relatively low temperatures (500 °C). Scanning a laser over the printed and fired electrodes while it is in an electrolyte produces a false color map of photocurrent response that can be related to the printed compositions. It is desirable for many groups to help with this search since it is easy to calculate the numbers of combinations that may have to be produced and screened. If we prepare all possible ternary oxides, mixing N materials three at a time there are $N!/3!(N-3)!$ combinations if we only consider 1:1:1 stoichiometries. Since there are ~60 possible candidate metals in the periodic table this results in >34,000 combinations to be produced and tested with only this simple stoichiometry. If a quaternary material is needed then there are $N!/4!(N-4)!$ > 480,000 possible combinations. Again these numbers do not consider producing and screening the many possible stoichiometries. It is also possible that a ternary or quaternary material

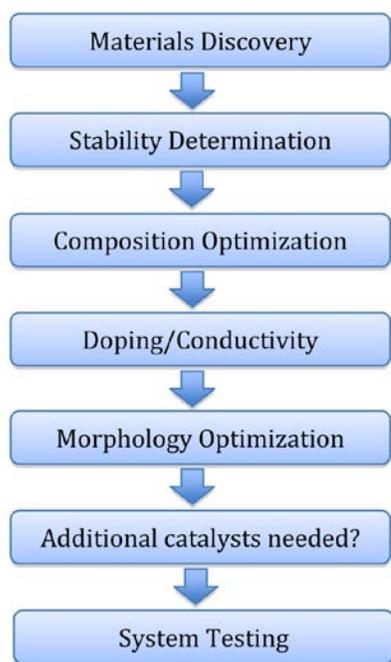

FIGURE 1. A flow chart illustrating the steps from a combinatorial discovery process through composition and conductivity optimization and progressing through configuring the materials for high device efficiencies.

will require small amounts of an additional element that acts as an electrical dopant to optimize its conductivity. These small amounts can often exist as impurities in the metal oxide precursors or may have to be discovered by additional combinatorial screening (discussed later in this chapter) greatly multiplying the number of experiments that must be done. However, some combinations could be excluded because it would not make sense to, for example, mix only large band gap oxide materials (i.e. Ti-Zr-Si-Y oxides) and expect visible light absorption. It is clear that given the large number of possible mixtures that need to be produced, a “high throughput” approach is needed as well as multidimensional experimental design to explore the parameter space more rapidly. And while it may not be reasonable to produce and test ALL of the possible combinations, it is certainly imperative that the throughput of materials screening be rapid relative to the serial approaches previously used.

Future Directions

New metal oxide semiconductors will be produced and screened for photoelectrolysis activity. Also we will be following up on “hits” obtained by the SHaRK (Solar Hydrogen Activity research Kit), our outreach program that provides the tools to undergraduate and high school students to join the search for the “holy grail” of

photoelectrochemistry. Currently we have over 40 sites participating. We will also support the efforts of DOE’s newly funded Solar Hub at Caltech who have taken our idea and will expand it to an automated robotic high throughput screening.

Objectives

The objective of this work is to engineer a hybrid biological/organic half-cell that couples Photosystem I to [FeFe]-hydrogenase using molecular wire technology. The construct will carry out the light-driven half-cell reaction $2\text{H}^+ + 2\text{e}^- + 2\text{h}\nu \rightarrow \text{H}_2$. The methodology involves constructing a Photosystem I variant and a [FeFe]-hydrogenase variant so that a molecular wire can be attached directly to their surface-located iron-sulfur clusters. The objectives include optimizing the coupling chemistry between the two proteins; measuring the quantum yield and rate of dihydrogen production; and engineering long-term stability of the Photosystem I–molecular wire–[FeFe]-hydrogenase half-cell.

Technical Barriers

Three preconditions must be met for the proposed hybrid photochemical half-cell to function: (i) Photosystem I must be engineered so that a cysteine ligand to the terminal [4Fe-4S] cluster on the PsaC subunit is replaced with a glycine residue. (ii) An [FeFe]-hydrogenase variant must be engineered so that a cysteine ligand to one of the [4Fe-4S] clusters is similarly replaced with a glycine residue. These changes will expose iron atoms in Photosystem I and in [FeFe]-hydrogenase to the medium, allowing the -SH ‘rescue ligand’ from the molecular wire to form a strong coordination bond. (iii) A ‘molecular wire’ must be synthesized, which contains an electron transfer cofactor and a -SH group at each end so that the latter can serve as ‘rescue’ ligands to the modified [4Fe-4S] clusters on Photosystem I and on the hydrogenase. When all of these conditions are met, and in the presence of a sacrificial donor, Photosystem I will convert two photons into energetic electrons; these electrons will be transferred through the molecular wire to the tethered hydrogenase, which will reduce two protons to hydrogen.

Abstract

A molecular wire is used to connect two proteins through their physiologically relevant redox cofactors to facilitate direct electron transfer. Photosystem I (PS I) and an [FeFe]-hydrogenase serve as the test bed for this new technology. By tethering a photosensitizer module with a hydrogen-evolving catalyst, attached by Fe/S coordination bonds to the F_B iron-sulfur cluster of PS I and the distal iron-sulfur cluster of H_2 ase, efficient electron transfer between the two components can be assayed via light-induced hydrogen evolution. These hydrogen producing nanoconstructs additionally self-assemble when the PS I variant, the hydrogenase variant and the molecular wire are combined.

Progress Report

We have recently reported the assembly of biological/organic hybrid nanoconstructs that generate hydrogen in the light. In these nanoconstructs, electrons are transferred directly from a photochemical module, Photosystem I (PS I), to a catalytic module, either a Pt nanoparticle (NP) or an [FeFe]-hydrogenase via a covalently attached molecular wire. In neither case are any spectroscopic changes visible that would allow electron transfer to be monitored between the photochemical and catalytic modules. In this

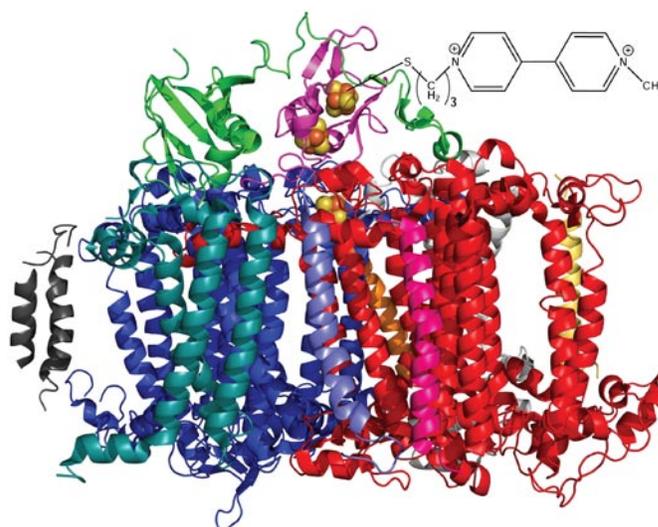

FIGURE 1. Depiction of the PS I—(3-thiopropyl)-1'-(methyl)-4,4'-bipyridinium construct. The electron transfer cofactors F_x , $F_{A'}$, and F_B (from bottom to top) are shown as spheres within the protein scaffold. The molecular wire is attached at the F_B cluster, located inside the PsaC subunit (pink). The PsaD subunit (green) resides on top of the membrane spanning portion and adjacent PsaC. The TPMBP moiety is not drawn to scale.

study, the catalytic module was replaced with an organic cofactor consisting of 1-(3-thiopropyl)-1'-(methyl)-4,4'-bipyridinium chloride that allowed electron transfer to be measured to a spectroscopically observable marker. EPR and optical spectroscopy showed that the tethered redox cofactor was attached to PS I through the F_B cluster of PsaC. Under steady-state illumination, the rate of reduction of the 4,4'-bipyridinium cofactor was comparable to the rate of H_2 evolution observed for the PS I–molecular wire–Pt-NP and PS I–molecular wire–[FeFe]-hydrogenase nanoconstructs. These observations provide proof-of-concept for incorporating a redox cofactor in the molecular wire, thereby setting the stage for monitoring the rate and yield of electron transfer between PS I and the tethered [FeFe]-hydrogenase.

We have recently optimized our biohybrid biological/organic nanoconstruct that uses a covalently bonded molecular wire to connect the F_B cluster of the Photosystem I (PS I) from *Synechococcus* sp. PCC 7002 directly with the distal [4Fe-4S] cluster of the [FeFe]-hydrogenase I from *Clostridium acetobutylicum*. These studies show that in the presence of cross-linked Cyt c_6 , with 1,8-octanedithiol as the molecular wire, in potassium phosphate buffer at pH 6.5, the PS I–molecular wire–[FeFe]-hydrogenase nanoconstruct evolves H_2 at a rate of 2850 $\mu\text{moles mg Chl}^{-1} \text{h}^{-1}$, which is equivalent to an electron transfer throughput of 5700 $\mu\text{moles mg Chl}^{-1} \text{h}^{-1}$, or 142 $\mu\text{moles } e^- \text{PS I}^{-1} \text{s}^{-1}$.

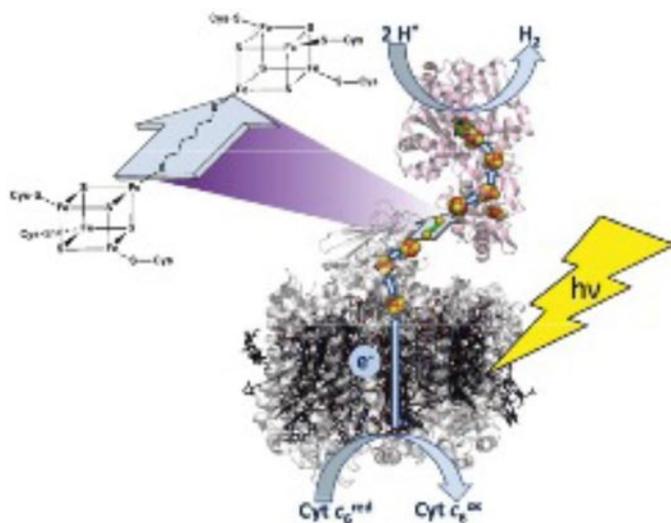

FIGURE 2. Schematic of the PS I-molecular wire-[FeFe]-hydrogenase nanoconstruct. Assembled photosynthetic nanoconstructs where the connecting wire is 1,6-hexanedithiol. Soluble electron donors include cytochrome c_6 , ascorbate and PMS. Arrows indicate electron transfer through the system, including reduction of protons to H_2 .

Putting this into perspective, cyanobacteria evolve O_2 at a rate of $\sim 400 \mu\text{moles mg Chl}^{-1} \text{h}^{-1}$, which is equivalent to an electron transfer throughput of 1600 $\mu\text{moles mg Chl}^{-1} \text{h}^{-1}$, or 46 $e^- \text{PS I}^{-1} \text{s}^{-1}$, assuming a PS I to PS II ratio of 1.8 as occurs in the cyanobacterium *Synechococcus* sp. PCC 7002. The significantly greater electron throughput by our hybrid biological/organic nanoconstruct over *in vivo* oxygenic photosynthesis validates our concept of tethering proteins through their physiologically relevant redox cofactors to overcome diffusion-based rate limitations on electron transfer.

Future Directions

Our plans for the future include (i) measuring the quantum yield of hydrogen evolution in the PS I–molecular wire–[FeFe]-hydrogenase nanoconstruct; (ii) docking the PS I–molecular wire–[FeFe]-hydrogenase nanoconstruct on either a graphene or gold electrode so that it functions as a cathode of an electrochemical cell; (iii) tethering a variant of an oxygen-tolerant [NiFe]-hydrogenase on the PS I–molecular wire module; (iv) investigating other entry portals for the molecular wire, including [2Fe-2S] clusters and cysteine residues placed near organic or inorganic cofactors of redox enzymes; (v) developing methods to produce these nanoconstructs biologically.

Objectives

The goal of this work is to develop a fundamental understanding of the properties and photoelectrochemical performance of Si wire-array based photocathodes for H₂ evolution. This work has three general scientific objectives: to develop a fundamental understanding of Si microwire arrays, H₂ evolving catalysts, and solution-based mass transport and bubble phenomena associated with H₂ production. We will systematically vary the geometric, electronic, and compositional characteristics of the Si microwire arrays, to understand, and thus gain control over, the photoelectrochemical behavior of such systems. Experiments using the combined microwire array-catalyst material will be performed in order to determine active H₂ catalysts based on alternatives to Pt, e.g. Ni-Mo alloy and MoS₂, and ideal catalyst loading, for optimization of the Si microwire array photoelectrochemical performance and catalytic turnover. Computational modeling, in conjunction with experimental measurements on Si microwire arrays under operating conditions, will be used to obtain a fundamental understanding of the energy penalty associated with mass-transport limitations, and complications due to production of H₂ bubbles, for various photoelectrode geometries.

Technical Barriers

Current photovoltaic and photoelectrochemical technologies employ a planar-junction design, requiring the use of expensive, high-purity semiconducting materials for efficient and stable operation. Si microwire arrays afford rapid radial charge separation while using a fraction of the material and with relaxed purity requirements, while the micron-scale interwire spacing can present interesting, not-yet-elucidated issues involving mass transport of reactants and products under operating conditions. In addition, the formation of bubbles due to efficient H₂ evolution at Si microwire array electrodes can reduce the overall photoelectrode performance. Realization of efficient technologies for photoelectrochemical H₂ evolution using Si microwire arrays requires that the geometry and photophysical properties of the microwire arrays, light scattering elements, and electrocatalysts be optimized. Also, because noble metal materials, like Pt, are too expensive to serve as feasible components in a globally scalable H₂-evolving photoelectrode, other potential catalysts must be identified.

Abstract

We have investigated and made significant progress on key components of a solar-driven water splitting scheme: Si microwire photocathodes, and metal oxide photoanodes. Radial p-n⁺ (n⁺p) junction Si microwire arrays functionalized with Pt or Ni nanoparticulate metallic electrocatalysts functioned as efficient photocathodes for H₂ evolution. Further exploration of geometric parameters that influence the photoelectrochemical response of the Si microwire arrays is proposed. In addition, experimental measurements and computational modeling will be employed to investigate how catalysis is affected by mass-transport limitations, H₂ bubble formation, and the use of alternative electrocatalysts. The photoresponse of WO₃ photoanodes was improved by implementation of a porous film geometry.

Progress Report

We have made very significant progress toward the goals listed under the DOE hydrogen fuel initiative project grant (DE-FG02-05ER15754) for p-Si microwire photocathodes and porous WO₃ photoanodes. We have demonstrated a high level of control over the material and light absorption properties of p-Si microwire array photocathodes. We have tested the performance of p-Si microwire arrays embedded

in a flexible, processable set of polymeric membranes and have further demonstrated the ability to reuse the planar Si(111) growth substrate after the Si wire arrays were removed from the growth substrate. We have introduced a radial n⁺p junction to improve the photoconversion efficiency of these electrodes in both regenerative and fuel-forming photoelectrochemical configurations. We have developed techniques to deposit Pt and Ni electrocatalyst particles onto the wire arrays, and have investigated their stability and performance for the hydrogen evolution reaction. Toward the development of a photoanode, we have synthesized a porous film morphology that improves the photoresponse of WO₃ toward the oxygen evolution reaction. We have also developed a method to reduce the bandgap of WO₃ from 2.6 eV to 1.8 eV by calcining ammonium para- or meta-tungstate in O₂ at 420°C.

Future Directions

We are investigating the fundamental photoelectrochemical properties of Si wire-array based photocathodes for H₂ evolution. The proposed research will focus on Si microwire arrays, H₂ evolving catalysts, and solution-based mass transport and bubble phenomena associated with H₂ production. Our recent demonstration of solar-driven H₂ evolution from water at an n⁺p-Si microwire array photocathode will be the starting point for the studies. The proposed work will elucidate the fundamental effects of interfacial structure on the chemistry and physics of such photocathodes. We will systematically vary structural variables, including the wire diameter, height, spacing, and pattern, as well as functional variables, including the doping density and junction area, of the Si microwire arrays, to comprehend, and thus gain control over, the photophysical and photoelectrochemical behavior of such systems. The fundamental properties of electrocatalysts on Si wire-array electrodes are also not yet understood. An effective catalyst, such as Pt, will be used to explore how the deposition and coverage affect the catalytic function on both planar Si and on Si microwire arrays. After gaining insight into those variables, other potential catalysts, such as Ni–Mo alloy and MoS₂, will be investigated. The enhanced physical surface area of wire arrays affords increased rates of catalytic H₂ evolution (per projected area) relative to planar Si. However, the aforementioned alternative microwire geometries, junction locations, and placement of electrocatalysts can result in issues involving mass transport of reactants and products and electrical and optical complications due to production of H₂ bubbles. Computational modeling, in conjunction with experimental measurements on Si microwire arrays under operating conditions, will be used to obtain a fundamental understanding of these problems. The proposed fundamental science will aid in the development of systems not exclusively derived from Si microwire arrays. General guidelines for the design and implementation of successful systems that utilize interfacial reactions driven

by light absorption at the photocathodes will be realized. Thus, the fields of photoelectrochemistry and photoinduced heterogeneous catalysis will both benefit from the results garnered by the proposed studies.

photoanode and photocathode need to be electronically coupled to nanocrystalline electron-conducting and hole-conducting supports. The system must also be photostable and avoid photocorrosion of both photoelectrodes; one approach is to isolate the surfaces of the photoelectrodes from contact with water.

Abstract

The research objective of this HFI program is to conduct the basic science that will lead to the discovery and ultimate development of photoconversion approaches that can produce hydrogen via H_2O splitting at costs competitive with or less than their present cost derived from steam reforming of natural gas. This will require a system with very high conversion efficiencies ($>32\%$), coupled with very low capital costs ($< \$200/m^2$). We will focus on solar water splitting using two coupled photosystems (a photocathode and a photoanode), analogous to what occurs in biological photosynthesis, but where one of the photoelectrodes is based on a molecular chromophore that exhibits efficient singlet fission (SF), a photophysical process wherein two triplet states are created from the first excited singlet state produced by absorption of a single photon. We have demonstrated a 200% QY of triplet states formed from the first excited singlet state via SF in molecular crystals of diphenylisobenzofuran (DPIBF). Thermodynamic calculations show that such coupled photosystems have the highest possible theoretical conversion efficiencies, exceeding those of single photoelectrode water-splitting cells by 50%. The system is also expected to have significantly enhanced conversion efficiency ($> 20\%$ increase depending on overvoltage) when concentrated solar power is used; this effect will be experimentally investigated for the first time.

Progress Report

Thermodynamics

Our research shows clearly that the use of two photosystems produces much higher theoretical conversion efficiencies (by a factor of $\sim 50\%$) for solar water splitting at all values of the total cell overpotential compared to cells with just one photoelectrode. These results are summarized in Figure 1. The lower lines show the maximum efficiency for a single photoelectrode cell as a function of the total cell overvoltage for H_2O splitting, and the upper lines show the efficiency dependence on overvoltage for a double-electrode tandem cell with different types of the two photoelectrodes. SF/M1 is the result when one photoelectrode produces SF and the second generates just $1 e^-/photon$. SF/M2 has one electrode producing SF and the second producing $2 e^-/$

Objectives

The objective of this HFI project is to conduct the basic science that will lead to the discovery and ultimate development of photoconversion approaches that can produce hydrogen via H_2O splitting at costs competitive with or less than their present cost derived from steam reforming of natural gas. This will require a system with very high conversion efficiencies ($>32\%$) coupled with very low capital costs ($< \$200/m^2$). We focus on solar water splitting using two coupled photosystems (a photocathode and a photoanode), analogous to what occurs in biological photosynthesis, but where one of the photoelectrodes exhibits efficient photogenerated electron-hole pair multiplication via singlet fission (SF), a process that produces two triplet states from a singlet state. Thermodynamic calculations show that such coupled photosystems have the highest possible theoretical conversion efficiencies, exceeding those of single photoelectrode cells by $\sim 50\%$, and that only one photoelectrode needs to undergo SF.

Technical Barriers

SF in the photoanode or photocathode must be very efficient, and for a tandem cell with both photoelectrodes in series optically and electrically, the SF chromophore should have its first excited singlet state at ~ 2 eV and its lowest triplet state at ~ 1 eV. The second photoelectrode should have a bandgap of ~ 1 eV and the energetic alignment of the two photoelectrodes must allow appropriate recombination of an electron and hole from the photoanode and photocathode, respectively, to maintain charge balance. In one optimum configuration the two chromophores at the

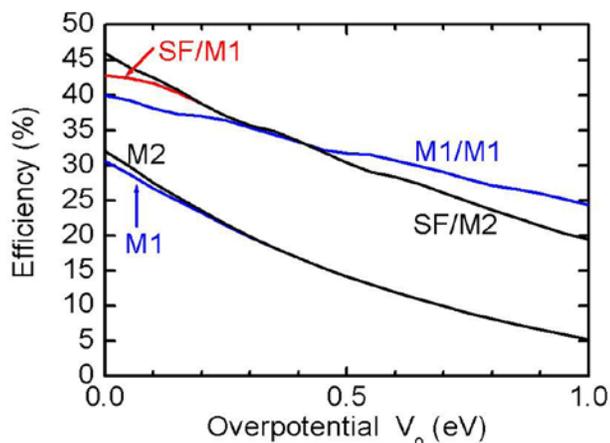

FIGURE 1. Maximum thermodynamic water-splitting conversion vs. total cell overvoltage for cells with single photoelectrodes (M1 and M2, bottom curves) and cells with two photoelectrodes (SF/M1, M1/M1, and SF/M2(SF), top curves). Definitions of the M1, M2, and SF characteristics are described in the text and shown in Fig. 2.

photon after the photoexcitation equals twice the bandgap (E_g) energy; for our purposed here M2 is the same as SF. Finally, M1/M1 is a conventional electrode system in which both electrodes produce $1 e^-$ /photon. For SF, the molecular bandgap is defined as the triplet state energy, which is close to one-half the first excited singlet state energy, because it is the triplet energy at which the photogenerated electrons are emitted. Thus, SF is analogous to an indirect-bandgap semiconductor in which the lowest energy transition is forbidden. Figure 2 shows the QY characteristics as a function of photon energy normalized to the bandgap (E_{photon}/E_g) that defines M1, M2 (SF), Mmax, SF (L3 is a linear characteristic that is not considered here.)

Singlet Fission

We report the first designed molecular system that exhibits perfect SF efficiency, producing two triplet states from an excited singlet state of the molecule (1,3-diphenylisobenzofuran (DPIBF)—Figure 3). Our experiments indicated a quantum yield at 77K of 200% for the creation of the two triplets in DPIBF. Both molecular design principles and broader concepts of coupling chromophores into functional networks were key advances that produced 200% QYs via SF. The compound DPIBF was identified as a promising candidate by using theory to direct a search for chromophores likely to have a desirable ratio of singlet and triplet excitation energies, the latter being difficult to measure experimentally. Recent theory led to the discovery that the natural geometry that the molecules adopt while packing into crystals, a staggered stacked sandwich type orientation, was optimum for SF.

Thin polycrystalline films of DPIBF were made by subliming the compound in vacuum onto substrates. When done correctly, the films showed strong spectroscopic signatures indicating a high yield of triplets. In order to

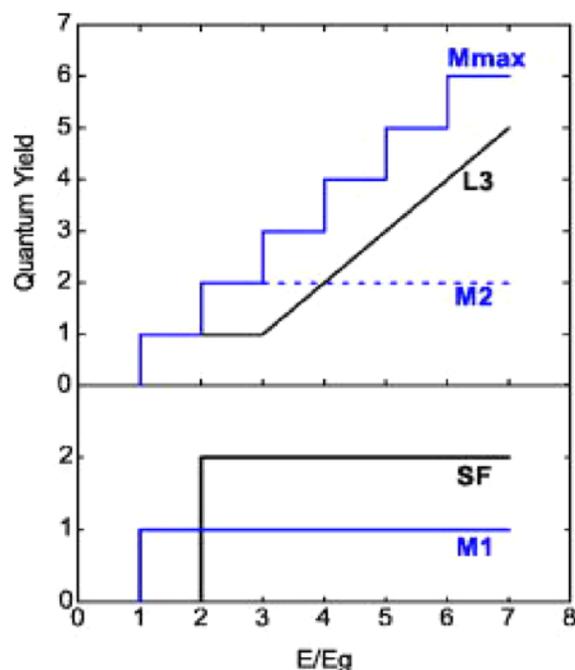

FIGURE 2. Characteristics of the QY vs. (photon energy/bandgap) that define M1, M2, Mmax, and SF. Characteristics labeled L(n) apply to the behavior of quantum dots and are not considered in this proposal.

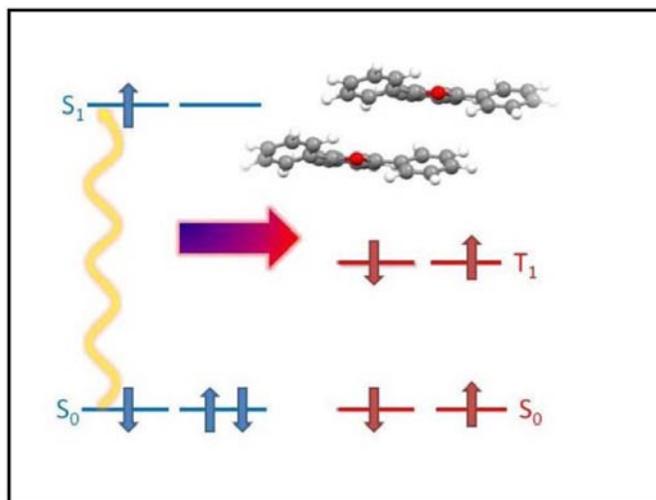

FIGURE 3. Depiction of the singlet fission process by which single absorbed photon creates an excited singlet state that evolves into two triplet states. Electron transfer can then occur from the two triplet states to produce two electrons per absorbed photon in a solar cell device. The molecules shown are DPIBF in a staggered stacking orientation known from its crystal structure.

quantify the yield, ultrafast laser experiments were performed to accurately measure the initial populations of photoexcited singlet states and their time evolution into triplets on a picosecond time scale. A careful analysis of the data led to yields approaching 200% and an increase in the triplet formation rate of more than ten thousand compared with

the isolated DPIBF molecule. Both observations support the notion that efficient singlet fission is occurring and that the design criteria set forth may be quite general.

Nanocrystalline Hole Conductors

One objective of the research was to develop porous hole-conducting nanocrystalline semiconductor supports to capture photogenerated holes from the ground state of optically excited chromophores (e.g., QDs and molecular dyes) and transport them to the hole-collecting substrate, which contacted a dark catalytic anode to drive water oxidation. Toward that end, we developed synthetic protocols for preparing inverse opal nanocrystalline films as hole conductors. Ordered polystyrene (PS) bead films were prepared as templates for directing the growth of ordered porous semiconducting materials. We developed a methodology to deposit 3–4- μm -thick films of 300-, 400-, and 500-nm PS beads arranged in a hexagonal close-packed array with periodic porosity. These PS templates were used to prepare CdSe inverse opals by electrochemical deposition. The resulting structures displayed significant light absorption over a wide portion of the near-infrared region. The unexpected enhanced light absorption in this spectral region was shown to result from a disordered pore structure and a high refractive index contrast present in the CdSe inverse opal architecture. Similar PS templates were used recently to prepare Cu–CuO core-shell inverse opals. Both of the copper oxides are intrinsically p-type with respective bandgaps of 1.4 eV for CuO and 2.1 eV for Cu_2O . An examination of the photonic bandgap of Cu_2O shows that it shifts from 680 to 895 nm when the pore size is increased from 300 to 400 nm. Transmission electron microscopy (TEM) and X-ray energy dispersive spectroscopy (EDS) measurements of the Cu–Cu_xO inverse opal electrodes showed a continuous Cu core surrounded by a 20-nm-thick oxide wall (Figure 4). We found that the Cu–CuO core-shell structures were about 15-fold more conductive than cupric oxide inverse opal electrode. The fact that adding a metal core to a poor conductor, such as the CuO, improved its electrical conductivity suggests that a similar approach might be useful for improving the conductivity of other poorly conducting p-type and n-type materials. We also prepared nanocrystalline films of ZnSe and ZnTe nanocrystals that were suitable for studying dye-sensitized hole injection and transport. Films comprising these nanocrystals with thicknesses of 2–3 μm were prepared by spin coating from concentrated solutions followed by thermal or amine-based chemical treatments to remove an initial surface layer of electrically insulating oleate ligands.

Future Directions

1,3-Diphenylisobenzofuran (1), cibalaktrot (2), and pentacene (3) are all compounds that fulfill the important relations $E(S_1) \geq 2E(T_1)$ and $E(T_2) > E(S_1)$ for efficient SF (see Figure 5). We will expand our efforts from (1) to also investigate (2) and (3). We will study complete water

splitting cells with two photoelectrodes, one of which exhibits efficient SF at the cathode. We will optimize new hole conducting nanocrystalline supports for the anodic

photoelectrode and investigate new hole-injecting dyes. We will study the effects of solar concentration on cell performance, which is predicted to greatly increase the water splitting efficiency based on initial thermodynamic calculations.

III. HYDROGEN DELIVERY

III.0 Hydrogen Delivery Sub-Program Overview

The Hydrogen Delivery sub-program supports research and development (R&D) of technologies that enable low-cost, efficient, and safe delivery of hydrogen to the end-user. Activities include the development of technologies required for hydrogen transport, either as a liquid (in tanker trucks) or as a compressed gas (in pipelines or tube trailers). Cost-effective methods of transporting hydrogen from central production facilities are required to achieve sustainable, widespread commercialization of hydrogen fuel cells. In addition, there are several activities within the Delivery sub-program focused on developing innovative methods of compressing, storing, and dispensing hydrogen at the point of refueling. Advances in these technologies will facilitate reductions in the cost of hydrogen that is produced at both centralized and distributed facilities

Goal

The goal of this sub-program is to reduce the costs associated with delivering hydrogen to a point at which its use as an energy carrier in fuel cell applications is competitive with alternative transportation and power generation technologies.

Objectives¹

The key objective of this sub-program is to develop low-cost, efficient, and safe technologies for delivering hydrogen from the point of production to the point of use—including stationary fuel cells and fuel cell electric vehicles (FCEVs). This objective applies to all of the possible delivery pathways. Interim and ultimate targets for various delivery components are being updated in the Fuel Cell Technologies Program's *Multi-Year Research, Development, and Demonstration Plan (MYRD&D Plan)*. Key objectives for specific delivery components include:

- **Tube Trailers:** Reduce the cost of compressed gas delivery via tube trailer by increasing vessel capacity and lowering trailer cost on a per-kilogram-of-hydrogen-transported basis.
- **Pipeline Technology:** Develop mitigation strategies for combined material fatigue and hydrogen-induced embrittlement in steel pipelines; advance the development and acceptance of alternative composite pipe materials that can reduce installed pipeline costs; and develop lower-cost, higher-reliability compression technology for hydrogen transmission by pipeline.
- **Liquefaction:** Reduce the capital and operating costs of hydrogen liquefiers and bulk liquid storage vessels.
- **Forecourt Technologies:**
 - **Compression:** Develop lower-cost, higher-reliability hydrogen compression technology for terminal and forecourt applications.
 - **Storage:** Develop lower capital cost off-board bulk storage technology and confirm the technical feasibility of geologic storage for hydrogen.
- **Analysis:** Conduct comprehensive analyses on potential near- and longer-term hydrogen delivery options, comparing the relative advantages of each and examining possible transition scenarios between the two timeframes.

Fiscal Year (FY) 2011 Technology Status

The projected costs for the delivery of hydrogen, based on current technologies, range from \$3/gasoline gallon equivalent (gge) to \$10/gge, depending on the quantity and distance transported. These projections include the costs of compression, storage, and dispensing at the refueling site. Progress towards current goals and targets is summarized in the following table.

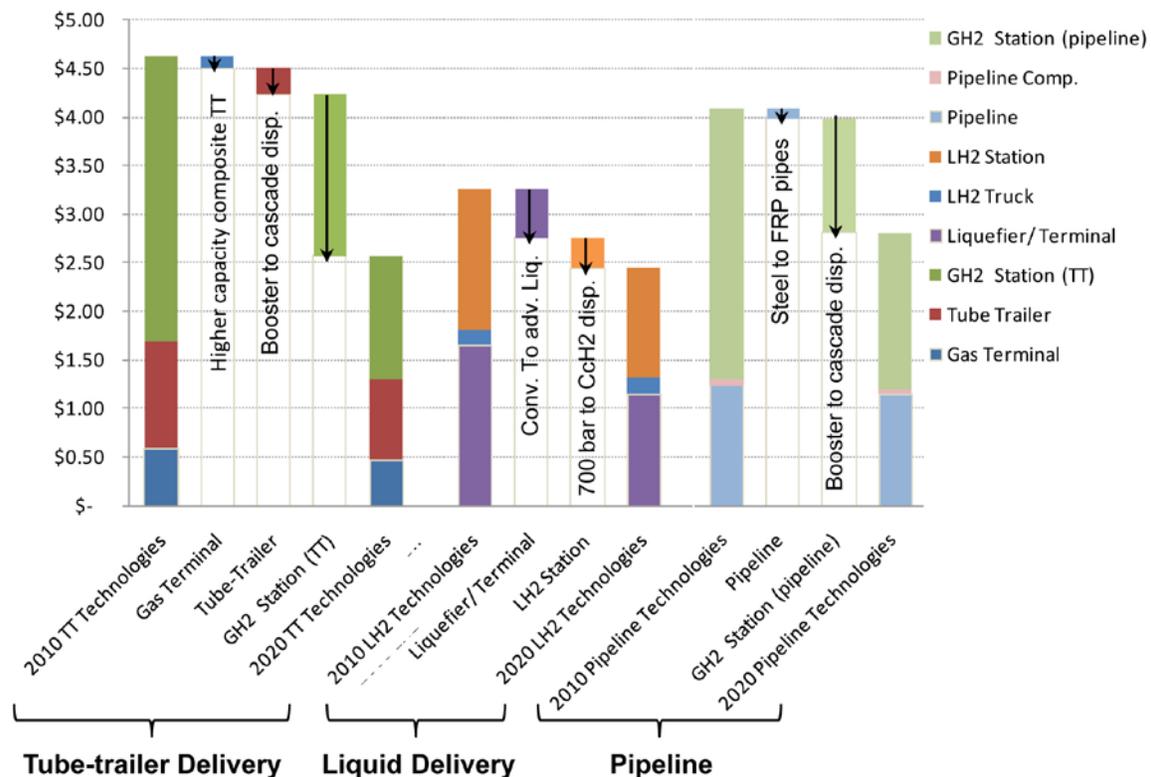

¹Note: Targets and milestones are under revision; therefore, individual progress reports may reference prior targets.

Delivery Element	Targets (2015/2017) ¹	Status ²
Tube Trailers	<ul style="list-style-type: none"> Reduce capital cost to <\$200,000 Increase capacity to 1,100 kg 	<ul style="list-style-type: none"> Capital cost: \$470,000 (250 bar carbon fiber vessel) Capacity: 550 kg Cost contribution: \$0.9/kg H₂
Pipeline Technology	<ul style="list-style-type: none"> Reduce cost/mile (installed) to <\$490K 	<ul style="list-style-type: none"> Installed steel pipeline cost: \$3M/mile Cost contribution: \$1.7/kg H₂ Compressor cost contribution: \$0.1/kg H₂
Liquefaction	<ul style="list-style-type: none"> Reduce installed capital cost to \$100M Increase energy efficiency to 87% 	<ul style="list-style-type: none"> Installed capital cost: \$170M System efficiency: 80% Cost contribution: \$1.6/kg H₂
Forecourt Compression (1,000 kg/day station)	<ul style="list-style-type: none"> Reduce installed capital cost to \$187.5K for 700 bar dispensing 	<ul style="list-style-type: none"> Capital cost: \$1.5M for 700 bar dispensing (cost contribution of \$2/kg H₂) Capital cost \$0.5M for 350 bar dispensing (cost contribution of \$0.8/kg H₂)
Forecourt Storage (1,000 kg/day station)	<ul style="list-style-type: none"> Reduce tank cost stored to \$300 per kg of stored H₂ 	<ul style="list-style-type: none"> Storage tank cost: \$1,000 per kg of stored H₂ (cost contribution of \$0.4/kg H₂)

¹ Based on current targets in the Fuel Cell Technologies Program's MYRD&D Plan. These are in the process of being updated.

² High-volume projections based on HDSAM version 2.3 (preliminary analysis; peer review underway).

Figure 1 shows the projected reduction in hydrogen delivery cost for various pathways due to technological advancement.

FIGURE 1. Projected Reductions in Hydrogen Delivery Costs. Projections are based on Hydrogen Delivery Scenario Analysis Model (HDSAM) V2.3 for a well-established hydrogen market demand for transportation (15% market penetration). The specific scenarios examined assume central production of hydrogen that serves a city of moderately large size (population of about 1.2 million).

FY 2011 Accomplishments

Tube Trailers and Bulk Storage

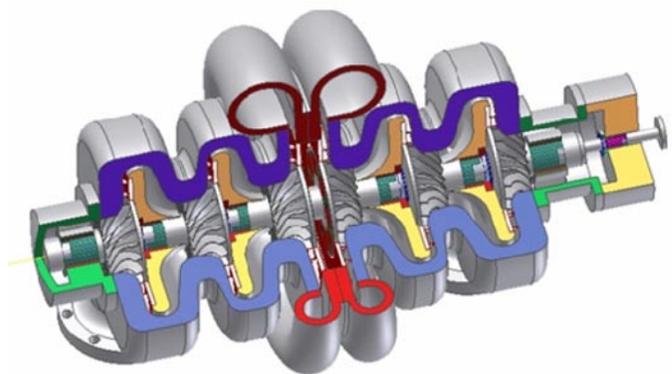

- Lincoln Composites completed a design trade study for a 5,000 pounds per square inch (psi) vessel, which includes a projected 33% increase in capacity at 15°C and ~10% reduction in capital cost on a per kilogram of transported hydrogen basis.
- Lawrence Livermore National Laboratory scaled up their design of a glass fiber pressure vessel to a full diameter of 23 inches and successfully hydroburst tested the vessel at strains above trailer design levels. The concept has the potential to reduce current tube trailer transport costs by up to 50% (Figure 2).

FIGURE 2. Carbon Fiber Composite Tube Trailer Pressure Vessel and International Standards Organization Container

Pipeline Technology

- Savannah River National Laboratory completed burst testing on fiber reinforced polymer pipe with 40% through-wall flaws, demonstrating a 3x margin above the rated pressure for the pipe. Researchers also demonstrated that industry-standard compression fittings will meet Department of Transportation requirements for joint leakage between pipe segments.
- Fatigue crack growth relationships determined by Sandia National Laboratories for X52 base metal and electric resistance welded seam specimens cut from actual pipeline were found to be quite similar, despite some variability in replicate data sets. The results indicate that the reliability and integrity of steel hydrogen pipeline likely will not be determined by the properties of the electric resistance welded seam.
- Concepts ETI completed the detailed design of a centrifugal compressor capable of providing 240,000 kg/day of hydrogen at 1,280 psi for pipeline-grade service and have initiated procurement of the major gearbox components for fabrication and testing. Mohawk Innovative Technology also completed the design of a centrifugal pipeline compressor that will employ advanced Ti-based rotors to achieve the tip speeds needed to meet the DOE's 2015 targets for this technology (Figure 3). They are currently fabricating components for initial laboratory testing.

Mohawk Innovative Technologies, Inc.

FIGURE 3. Double-Entry Centrifugal Compressor for Pipeline Compression

Liquefaction

- Praxair Inc. demonstrated a reduction in overall power consumption of ~2.5% by developing and employing a new ortho-para catalyst in the high-temperature heat exchanger of a traditional hydrogen liquefier design. Additionally, results from process modeling indicated that improved gas compression technology for these units can increase overall liquefier efficiency by 3%–6%.
- Prometheus Energy integrated all of the subsystems for their Phase-I linear active magnetic regenerative liquefier and demonstrated a sustainable magneto-thermal based reduction in temperature from 290 K to 120 K. Lessons learned are being applied to a Phase-II rotary design that will span 290 K to 20 K (Figure 4).

FIGURE 4. Active Magnetic Regenerative Refrigerator for Hydrogen Liquefaction

Forecourt Technology

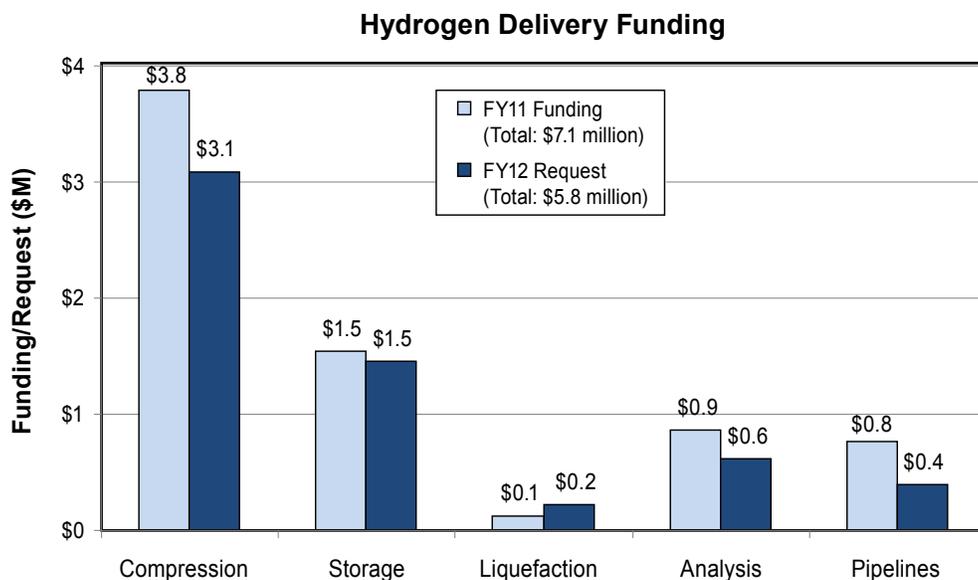

- FuelCell Energy developed a two-stage electrochemical hydrogen compressor that achieved 420 bar of compression, or a compression ratio of 300:1. To date, they have demonstrated 20 successful pressure cycles and 500 hours of durability with the device. They will be fabricating the support facilities to test this compressor to the ultimate pressure capability target of 840 bar.
- Conceptual designs for a steel-lined reinforced concrete hydrogen pressure vessel were completed at Oak Ridge National Laboratory. Preliminary cost estimates indicate that this concept has the potential to meet DOE's 2015 cost target for off-board bulk hydrogen storage.

Analysis

- Argonne National Laboratory completed cost and price index updates to HDSAM, evaluated factors affecting the capital and levelized cost of refueling stations, and carried out an analysis of key hydrogen infrastructure cost drivers in preparation for the sub-program's revised section of the *MYRD&D Plan*.
- Pacific Northwest National Laboratory completed a detailed analysis of pipeline costs, which was integrated into the updated HDSAM model.
- The National Renewable Energy Laboratory completed an analysis of hydrogen delivery by rail, finding this option to be the least costly means of transporting hydrogen over distances of more than 600 miles for early market scenarios—for example, when hydrogen is produced by renewable resources that are far from large demand centers. An analysis of hydrogen production and delivery costs from wind sources at remote, low-electricity-cost locations was also completed. It was found that under certain scenarios this option can provide dispensed hydrogen at a cost as low as \$6/kg.

Budget

The FY 2011 budget provided \$7.1 million for continued hydrogen delivery R&D. The President's FY 2012 budget request for the Office of Energy Efficiency and Renewable Energy provides \$5.8 million for hydrogen delivery, with an emphasis on reducing pipeline and forecourt compression cost, increasing tube trailer capacity, and identifying viable low-cost early-market delivery pathways.

FY 2012 Plans

In FY 2012, the Delivery sub-program portfolio will be focused on two key areas:

- Long-term technologies expected to have market impact in 10–20 years.** In FY 2012 the Delivery sub-program portfolio will continue efforts on fiber reinforced polymer pipeline characterization for design code development; centrifugal compressor development and demonstration for pipeline transmission; hydrogen transmission as a cold, pressurized fluid; magnetic refrigeration; and electrochemical compression. Recognizing that hydrogen storage on-board future FCEVs may not be in the form of compressed gas (as is current practice) the Delivery and Storage sub-programs will collaborate to identify delivery challenges for future materials-based storage technologies. Analysis efforts will be initiated to evaluate options for the transition from compressed gas stations serving early vehicle markets to stations that could provide hydrogen for next generation FCEVs.
- Near-term technologies that reduce hydrogen delivery costs for emerging hydrogen and fuel cell applications (e.g., forklifts and backup power) and early adopter FCEV markets.** In FY 2012, the emphasis in these near-term areas will be on strategic analyses to: (a) determine delivery options that can reduce the cost of 700-bar compression at light-duty-vehicle refueling stations; (b) evaluate hydrogen delivery costs for sustainable non-automotive markets and establish possible “lessons learned” that can be applied to early localized FCEV markets; and (c) identify station costs not related to process operations (e.g., insurance and safety system requirements) and potential market incentives that can drive business decisions on station construction. Results from these analyses will be used to identify barriers for early market technologies and to help focus subsequent technology development efforts. A key FY 2012 Program milestone will be to identify delivery pathway(s) that can achieve a current, as-dispensed (350 bar) hydrogen cost of <\$4/gge. Additional near-term R&D will include work to increase the hydrogen carrying capacity of current composite tube trailer designs by 15% or more and continued development of steel-lined reinforced concrete pressure vessels for station storage.

Project Start Date: January 2007

Project End Date: Project continuation and
direction determined annually by DOE

Technical Targets

The principal target addressed by this project is the following (from Table 3.2.2):

- Pipeline Reliability/Integrity

The salient reliability/integrity issue for steel hydrogen pipelines is hydrogen embrittlement. One particular unresolved issue is the performance of steel hydrogen pipelines that are subjected to extensive pressure cycling. One of the objectives of this project is to enable safety assessments of steel hydrogen pipelines subjected to pressure cycling through the use of code-based structural integrity models. This structural integrity analysis can determine limits on design and operating parameters such as the allowable number of pressure cycles and pipeline wall thickness. Efficiently specifying pipeline dimensions such as wall thickness also affects pipeline cost through the quantity of material required in the design.

Fiscal Year (FY) 2011 Objectives

- (1) Demonstrate reliability/integrity of steel hydrogen pipelines under cyclic pressure conditions:
 - Measure fatigue crack growth rates and fracture thresholds of line pipe steels in high-pressure hydrogen gas, emphasizing welds.
 - Evaluate performance of steel pipelines by applying code-based structural integrity model coupled with steel properties measured in hydrogen gas.
 - Quantify effects of gas impurities (e.g., O₂) in mitigating hydrogen-accelerated fatigue crack growth.
- (2) Enable development of micromechanics models of hydrogen embrittlement in pipeline steels:
 - Establish physical models of hydrogen embrittlement in line pipe steels using evidence from analytical techniques such as electron microscopy.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Delivery section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (D) High Capital Cost and Hydrogen Embrittlement of Pipelines
- (K) Safety, Codes and Standards, Permitting

FY 2011 Accomplishments

Fracture properties for X52 line pipe steel were measured in high-pressure hydrogen gas to provide data for evaluating the reliability/integrity of steel hydrogen pipelines:

- Conducted replicate measurements of fatigue crack growth relationships for X52 base metal and seam weld in high-pressure hydrogen gas.
- Compared fatigue crack growth relationships for X52 base metal and seam weld, revealing that the reliability/integrity of steel hydrogen pipelines is not limited by the seam weld.

Introduction

Carbon-manganese steels are candidates for the structural materials in hydrogen gas pipelines, however it is well known that these steels are susceptible to hydrogen embrittlement. Decades of research and industrial experience have established that hydrogen embrittlement compromises the structural integrity of steel components. This experience has also helped identify the failure modes that can operate in hydrogen containment structures. As a result, there are tangible ideas for managing hydrogen embrittlement in steels and quantifying safety margins for steel hydrogen containment structures. For example, fatigue crack growth aided by hydrogen embrittlement is a well-established failure mode for steel hydrogen containment structures subjected to pressure cycling. This pressure cycling represents one of the key differences in

operating conditions between current hydrogen pipelines and those anticipated in a hydrogen delivery infrastructure. Applying code-based structural integrity models coupled with measurement of relevant material properties allows quantification of the reliability/integrity of steel hydrogen pipelines subjected to pressure cycling. Furthermore, application of these structural integrity models is aided by the development of micromechanics models, which provide important insights such as the hydrogen distribution near defects in steel structures.

Approach

The principal objective of this project is to enable the application of code-based structural integrity models for evaluating the reliability/integrity of steel hydrogen pipelines. The new American Society of Mechanical Engineers (ASME) B31.12 design code for hydrogen pipelines includes a fracture mechanics-based design option, which requires material property inputs such as the fracture threshold and fatigue crack growth rate under cyclic loading. Thus, one focus of this project is to measure the fracture thresholds and fatigue crack growth rates of technologically relevant line pipe steels in high-pressure hydrogen gas. These properties must be measured for the base materials but more importantly for the welds, which are likely to be most vulnerable to hydrogen embrittlement.

A second objective of this project is to enable development of micromechanics models of hydrogen embrittlement in pipeline steels. The focus of this effort is to establish physical models of hydrogen embrittlement in line pipe steels using evidence from analytical techniques such as electron microscopy. These physical models then serve as the framework for developing sophisticated finite-element models, which can provide quantitative insight into the micromechanical state near defects. Understanding the micromechanics of defects can ensure that structural integrity models are applied accurately and conservatively.

Results

The principal activity during FY 2011 was measuring the fatigue crack growth relationships for the base metal and electric resistance weld (ERW) from X52 line pipe steel in hydrogen gas. The fatigue crack growth rate (da/dN) vs. stress-intensity factor range (ΔK) relationship is a necessary material-property input into structural models that enable engineering analysis of the design life of steel hydrogen pipelines. One such design life methodology for steel hydrogen pipelines was recently published in the ASME B31.12 code. The measurements of subcritical cracking thresholds and fatigue crack growth relationships in this task thus support the objective of establishing the reliability/integrity of steel hydrogen pipelines.

The X52 line pipe steel was selected for this task because of its recognized technological relevance for hydrogen pipelines. The X52 steel from the round robin

tensile property study (FY 2008) was tested for the following reasons: 1) some characterization of the material was already provided from the round robin study, 2) ample quantities of material were still available, and 3) the X52 steel was in the form of finished pipe, which is the most relevant product form and also allows samples to be extracted from the ERW seam.

The hydrogen-affected fatigue crack growth relationship (da/dN vs. ΔK) for the structural steel is the basic element in pipeline reliability/integrity models. The ASME B31.12 code requires measurement of the fatigue crack growth relationship for pipeline steels at the hydrogen gas operating pressure. Initial measurements of the fatigue crack growth relationship for X52 steel base metal were conducted in 21 MPa hydrogen gas (the upper limit specified for hydrogen pipelines in the ASME B31.12 code) at a load-cycle frequency of 1 Hz (Figure 1). This load-cycle frequency was selected to balance test effectiveness and test efficiency, since fatigue crack growth rates can be enhanced at lower test frequency but the test duration can become prohibitively protracted. Even at this relatively high load-cycle frequency, measurement of the fatigue crack growth relationship over the relevant range of ΔK could require several days. For example, the duration of the test conducted at a load ratio of 0.5 was 6 days. (Load ratio, R , is the ratio of minimum applied load to maximum applied load.)

Although the accepted trend is that increasing load-cycle frequency leads to lower (i.e., non-conservative) fatigue crack growth rates in hydrogen gas, this trend is predominantly based on fatigue crack growth rates measured for steels at relatively high ΔK , e.g., greater than 15 MPa $m^{1/2}$. The possibility of effectively measuring fatigue crack growth rates at high load-cycle frequency in the lower (and technologically relevant) range of ΔK was explored for the X52 steel in 21 MPa hydrogen gas. Fatigue crack growth rate relationships were measured at 10 Hz for two R ratios (0.1 and 0.5), and the results are compared to the fatigue crack growth relationships measured at 1 Hz in Figure 1. Although the fatigue crack growth relationships at 1 Hz and 10 Hz are not exactly coincident, there are only moderate differences in the fatigue crack growth rates over the ΔK range investigated. These preliminary results suggest that reliable fatigue crack growth relationships may be measured at high load-cycle frequency, which would allow the testing to be conducted more efficiently.

The fatigue crack growth relationship for the X52 ERW was also measured in 21 MPa hydrogen gas. Since steel microstructures in welds are not easily controlled, these weld microstructures can be inhomogeneous. Consequently, it is important to conduct replicate fatigue crack growth tests on welds to characterize potential variability in the data. Figure 2 shows the fatigue crack growth relationships measured for the X52 ERW from replicate tests. These tests were conducted at $R=0.1$ and 1 Hz so that the results could be directly compared to those for the X52 base metal. The following details are notable in Figure 2: 1) the da/dN vs. ΔK relationships for the X52 ERW exhibit significant variability,

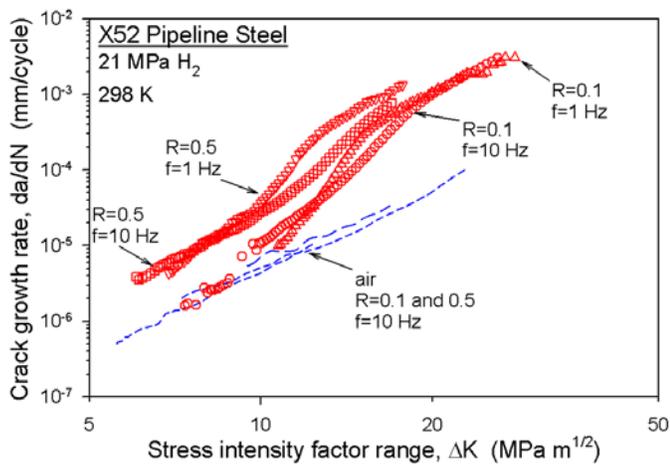

FIGURE 1. Fatigue crack growth rate (da/dN) vs. stress-intensity factor range (ΔK) plots for X52 steel base metal in hydrogen gas and air.

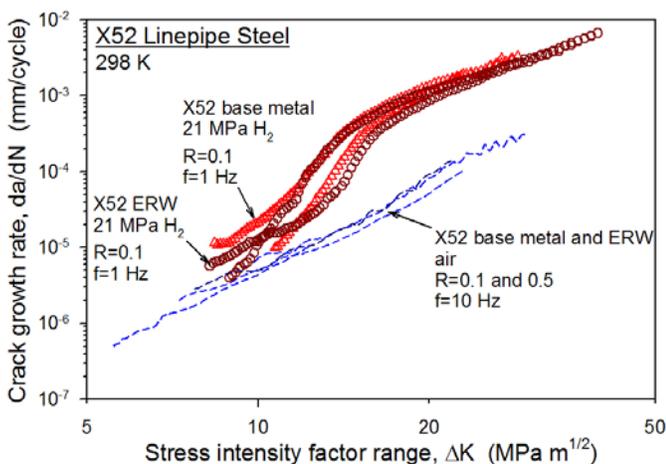

FIGURE 2. Fatigue crack growth rate (da/dN) vs. stress-intensity factor range (ΔK) plots for X52 steel base metal and ERW seam in hydrogen gas and air. Unstable cleavage fracture was observed for the ERW tested in air at $K_{\max} > 40 \text{ MPa m}^{1/2}$.

2) the da/dN vs. ΔK relationships for the X52 base metal also exhibit variability, and 3) despite the variability in the da/dN vs. ΔK relationships, it is apparent that the fatigue crack growth rates are similar for the base metal and the weld in hydrogen gas.

While microstructure is one salient variable that can contribute to variability in the da/dN vs. ΔK relationships for X52, other variables must be considered as well. For example, the hydrogen test gas was sampled at the conclusion of both tests conducted on the X52 ERW. The leak rates from the pressure vessel were unusually high, and such an abnormal operating condition prompted sampling of the test gas. The hydrogen test gas contained relatively high concentrations of oxygen (>10 vppm) for both tests. Since oxygen is known to inhibit hydrogen uptake into steels, it is

possible that the high levels of oxygen in the test gas affected the results. Additional tests are in progress on the ERW material to clarify whether variability in the da/dN vs. ΔK relationships can be attributed to oxygen in the test gas.

A fatigue crack growth test was also conducted on the X52 ERW in air. Such data serves as a baseline for comparison to measurements on the ERW in hydrogen gas as well as for comparison to measurements on the base metal in air. Test conditions for the ERW in air included $R=0.5$ and a load-cycle frequency of 10 Hz. Figure 2 shows that the da/dN vs. ΔK relationship for the ERW measured in air is similar to the relationship measured for the base metal in air. However, the test on the ERW was unexpectedly terminated at $K_{\max} \sim 40 \text{ MPa m}^{1/2}$ by unstable crack extension associated with cleavage fracture. This result suggests that some region of the ERW microstructure has extremely low fracture toughness. The consequence of this inherently low fracture resistance on hydrogen-assisted subcritical cracking must be explored.

Conclusions and Future Directions

Conclusions

- Fatigue crack growth relationships for X52 steel measured in hydrogen gas enable evaluation of reliability/integrity of steel pipelines under cyclic pressure conditions. Hydrogen embrittlement can be accommodated by coupling structural design models and measured fracture properties following the ASME B31.12 pipeline standard.
- The measured fatigue crack growth relationships for X52 base metal and ERW seam are similar. This trend was evident despite variability in replicate data sets. These results demonstrate that reliability/integrity of steel hydrogen pipelines is not limited by the ERW seam.

Future Directions

- Determine the threshold level of oxygen impurity concentration required to mitigate accelerated fatigue crack growth of X52 steel in hydrogen at gas pressures up to 21 MPa.
- Complete measurements of fatigue crack growth relationships for low-strength pipeline steel girth welds in hydrogen gas.

Technical Targets

The project is developing and using a computer model to evaluate alternative delivery infrastructure systems and components. Insights from the model are being used to help identify elements of an optimized delivery system which could meet DOE's long-term delivery cost target.

FY 2011 Accomplishments

- Completed a review and update of pipeline cost functions. Changes include:
 - Steel transmission and distribution pipelines:
 - Updated material, labor, right-of-way and miscellaneous cost estimates.
 - Developed revised equations for nine U.S. regions and total U.S.
 - Fiber-reinforced piping:
 - Review of current applications and technologies.
 - Evaluation of material, labor and total cost estimates and trends especially as compared to steel pipe.
 - Incorporation of revised equations into HDSAM pipeline model.
- Updated cost/price indexes in HDSAM.
- Analyzed factors affecting HDSAM fuel station capital investment and levelized cost, including:
 - Scale: station size
 - Station utilization
 - Investment and rate of return
 - Fuel cell vehicle (FCV) onboard storage option
 - Station design configuration
- Conducted delivery cost target analyses to:
 - Investigate impact of delivery technology options and economies of scale on hydrogen delivery cost.
 - Identify components for which research and development (R&D) offers greatest potential cost reduction.

Introduction

Initiated as part of the H2A project, the Hydrogen Delivery Scenario Analysis Model (HDSAM) is an Excel-based tool that uses a design calculation approach to

Fiscal Year (FY) 2011 Objectives

- Refine technical and cost data in the Hydrogen Delivery Scenario Analysis Model (HDSAM) to incorporate additional industry input and evolving technology improvements.
- Expand the model to include advanced technologies and other pathway options leading to new versions of the models.
- Improve methodologies for estimating key aspects of delivery system operation and optimizing cost and performance parameters.
- Explore options to reduce hydrogen delivery cost, including higher pressure and/or lower temperature gases, and operating strategies.
- Provide analyses to support recommended hydrogen delivery strategies for initial and long term use of hydrogen as a major energy carrier.

Technical Barriers

This project directly addresses technical barrier A (which implicitly includes barriers B, C, D, F, H and J) in the Delivery Technical Plan, as well as barriers B, C and E in the Systems Analysis Plan of the Fuel Cell Technologies Multi-Year Research, Development and Demonstration Plan. These are:

- (A) Lack of Hydrogen/Carrier and Infrastructure Options Analysis
- (B) Stove-Piped/Siloed Analytical Capability

estimate the contribution of individual components of delivery infrastructure to hydrogen cost, energy use and greenhouse gas emissions. The model links the individual components in a systematic market setting to develop capacity/flow parameters for a complete hydrogen delivery infrastructure. Using that systems level perspective, HDSAM calculates the full, levelized cost (i.e., summed across all components) of hydrogen delivery, accounting for losses and tradeoffs among the various component costs. A graphical user interface (GUI) permits users to specify a scenario of interest. A detailed User's Guide and access to the DOE Energy Efficiency and Renewable Energy help desk also assist users in running HDSAM.

Results

Work continued on updating and expanding the HDSAM. Pipeline cost data were updated and equations were re-estimated. Factors affecting fuel station investment and levelized cost were examined. A delivery cost target analysis was conducted to investigate the impact of alternative technologies and scale on delivery cost and to identify those components for which R&D offers the greatest potential cost reduction.

Cost Updates

All cost estimates within HDSAM were updated to 2007 dollars using appropriate indices. Pipeline costs were re-estimated in a separate effort in which additional cost data were obtained, converted to 2007 dollars and analyzed. For transmission pipelines, a 30-yr time-series of steel pipeline cost data, compiled by the Oil and Gas Journal, was used to refine costs by element (material, labor, right-of-way, miscellaneous), diameter and census region (for the lower 48 states). A similar analysis of distribution pipelines was conducted using data compiled by the Pipeline and Gas Journal. Results of the two analyses were used to update transmission and distribution pipeline cost functions contained within HDSAM.

A separate analysis of fiber-reinforced piping was conducted to determine whether that technology might be cost competitive with steel piping. Although more costly than steel to purchase, reduced installation labor costs more than offset the difference. Fiber-reinforced pipe is commonly used in small-diameter natural gas gathering lines. Its inherent flexibility allows pipe diameters up to 6 inches to be wound onto a spool and then unwound during installation, significantly reducing pipe handling and joining costs. Because flexible fiber-reinforced pipe is relatively new, future cost reductions from installation learning and competition are expected. Such reductions could make multiple parallel fiber-reinforced pipes less costly than a single larger transmission line.

Refueling Station Analyses

Depending on delivery pathway, dispensing hydrogen at a refueling station can account for \$800,000 to well over \$2.5 million in capital investment and add \$1-3/kg to the delivered cost of the fuel. In addition to station size or daily throughput (see Figure 1), a number of other factors – including learning, station utilization and the form in which hydrogen is used on board the vehicle – can affect both total investment and delivery cost.

Figure 2 shows the effect of station utilization on the station contribution to the levelized cost of hydrogen. For a 200 kg/day station, increased utilization brings hydrogen cost down from over \$10/kg to under \$4/kg at full utilization. Reductions occur proportionally in both installed capital and operations and maintenance (O&M).

Figure 3 shows how onboard storage affects station capital investment. For a 200 kg/day station with 700-bar onboard storage additional compression, storage and refrigeration equipment are needed at the station. Cryo-compressed (CCH₂) onboard storage replaces some of the compression and refrigeration needs with cryo-pumping

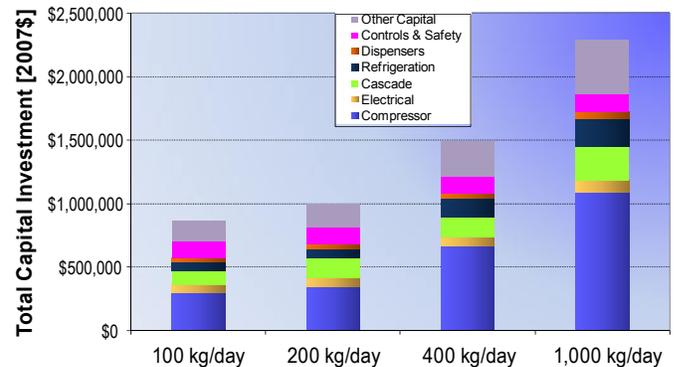

FIGURE 1. Effect of Size on Hydrogen Refueling Station Capital Investment

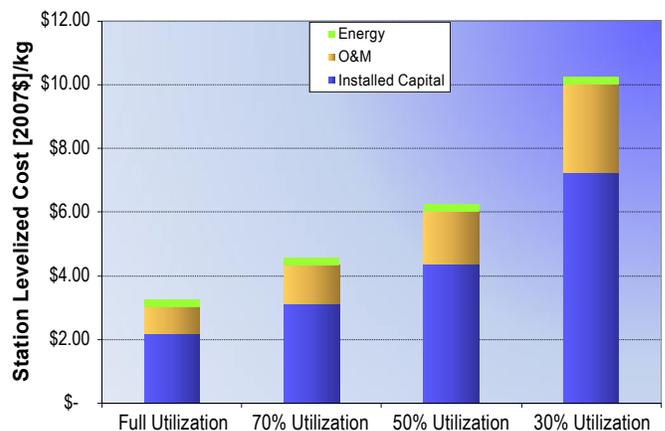

FIGURE 2. Effect of Station Utilization on Levelized Hydrogen Cost

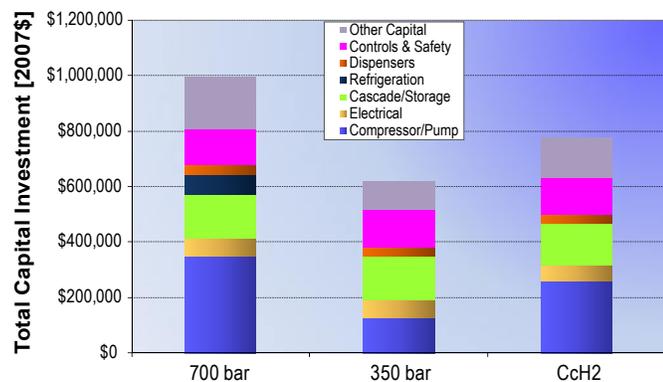

FIGURE 3. Effect of Onboard Storage Option on Station Capital Investment

which is less costly at the station (although some of the cost is shifted to the upstream component of liquefaction where it may be offset by economies of scale).

Delivery Cost Target Analyses

By combining delivery technologies into pathways and examining the cost of various combinations under different market assumptions, HDSAM permits the user to better understand the impact of a number of factors on hydrogen delivery cost. In addition to investigating the effect of delivery technology, scale, utilization, learning, and onboard storage, HDSAM provides insight into the individual components with the greatest impact on delivery cost. As shown in Figure 4, for pathways serving small, medium or large FCV markets with correspondingly small,

medium or large fueling stations, preliminary analysis shows that hydrogen delivery costs drop from roughly \$7 to \$9/kg to below \$3/kg. For liquid delivery pathways, liquefaction accounts for the largest share of delivery cost, followed closely by station costs; for gaseous pathways, the station represents the largest cost. Other costs (e.g., trucking or pipeline transportation, terminal and infrastructure storage) represent much smaller shares.

Conclusions and Future Directions

Hydrogen delivery infrastructure analysis seeks to identify aspects of hydrogen delivery that are likely to be especially costly (in capital and operating cost, energy and greenhouse gas emissions) and estimate the impact of alternative options on those costs. For the Fuel Cell Technologies Program this project has developed a model of hydrogen delivery systems to quantify those costs and permit analyses of alternative technologies and operating strategies. This work has been conducted collaboratively by staff of Argonne National Laboratory, Pacific Northwest National Laboratory and the National Renewable Energy Laboratory with the advice and assistance of several industrial partners. Regular interaction has also occurred with the Fuel Pathways and Delivery Tech Teams.

Through FY 2011, results affirm that hydrogen delivery could add \$2.30 to over \$9.00 to the levelized cost per kg of hydrogen “at the pump.” The most promising options for reducing delivery cost tend to level demand (thereby reducing the need for hydrogen storage) or increase the energy density of the delivered fuel (by maintaining low temperature or high pressure in the delivery pathway).

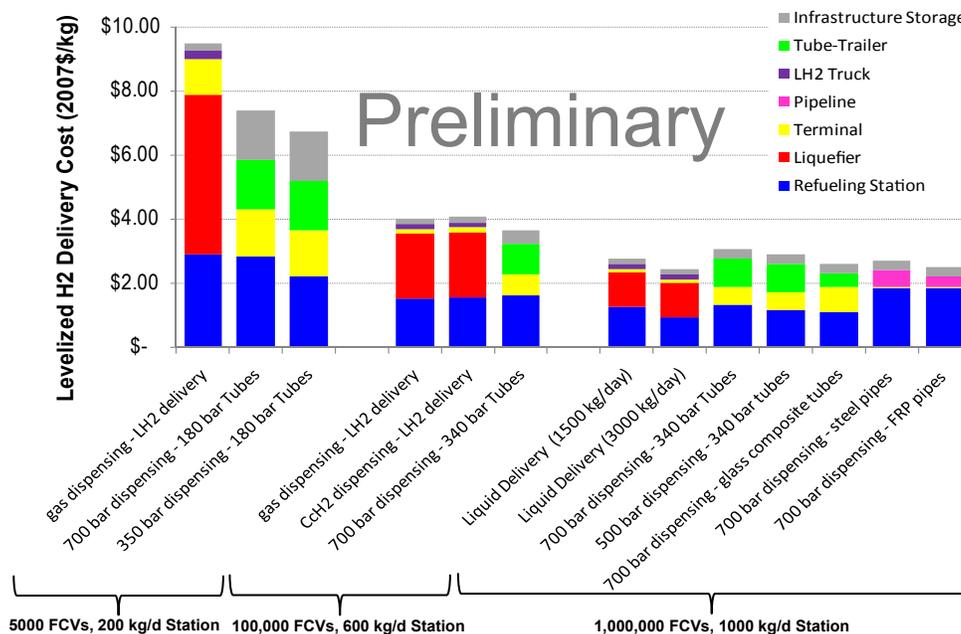

FIGURE 4. Levelized Hydrogen Delivery Cost for Select Pathways by Market Demand and Station Size

Improving the performance of individual, relatively costly delivery components is another promising option. Fueling station compressors are among the most costly of those components. In FY 2012 efforts will be directed to further study of advanced fueling compressor options, particularly as they relate to the HDSAM, and updating the model to reflect those options. In FY 2012, HDSAM will also be extended to model hydrogen delivery for early (non-automotive) fuel cell markets, especially forklift and cell tower backup power applications. Better understanding of delivery options for these early markets is critical to reducing hydrogen delivery cost for both automotive and non-automotive fuel cell applications.

Subcontractors:

- Global Engineering and Technology, Camas, WA
- MegaStir Technologies, Provo, UT
- Victor Li Independent Consultant, Ann Arbor, MI

Project Start Date: October 1, 2010

Project End Date: Project continuation and direction determined annually by DOE

Fiscal Year (FY) 2011 Objectives

- Develop engineering designs and fabrication technology for cost-effective high-pressure hydrogen storage system for stationary applications. In particular, the stationary storage vessel will utilize:
 - Cost-effective commodity structural materials.
 - A systematic, integrated vessel design to mitigate hydrogen embrittlement associated with the use of high-strength steels for high-pressure hydrogen storage.
 - High-productivity and low-cost fabrication technology.
 - Application of embedded sensors to ensure the safe and reliable operation of the storage system.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Delivery section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (F) Gaseous Hydrogen Storage and Tube Trailer Delivery Cost
- (G) Storage Tank Materials and Costs

Technical Targets

This project is to develop and demonstrate a cost-effective design of composite steel/concrete vessel for bulk high-pressure hydrogen storage and associated fabrication technology that can be adopted to meet different stationary storage needs such as those at refueling stations and renewable energy generation sites. Insights gained from this project will be applied toward the manufacturing of off-board gaseous hydrogen storage tanks that meet the following DOE 2015 hydrogen delivery targets:

- Storage Tank Purchased Capital Cost (\$/kg of H₂ stored): \$300 - Primary objective of this project.
- Volumetric Capacity (kg H₂/liter of storage volume): >0.035 - Secondary objective of this project.

FY 2011 Accomplishments

- Completed conceptual engineering design of the inner layered steel vessel for hydrogen storage capable of sustaining 5,000 psi design pressure based on industry standard American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel (BPV) Code - Section VIII. The conceptual designs for the outer reinforcement sleeve made of pre-stressed concrete and the interface between inner steel and outer concrete vessels will be completed by September/October 2011 timeframe.
- Preliminary cost estimate showed that the proposed design of composite steel/concrete vessel and fabrication technology have a sound basis for meeting the revised DOE cost target for off-board bulk storage. Improved cost modeling based on the conceptual engineering designs is expected to be completed by September/October 2011 timeframe.
- Efforts are ongoing for demonstrating technical proof-of-feasibility of key design concepts and construction technology including hydrogen embrittlement mitigation and friction stir welding of high-strength steels.

Introduction

Low-cost off-board bulk stationary storage of hydrogen is a critical element in the overall hydrogen production and delivery infrastructure. Stationary storage is needed at central production plants, geologic storage sites, renewable energy generation sites, terminals, and refueling stations. Stationary storage also provides the surge capacity to handle hourly, daily, and seasonal demand variations. Figure 1

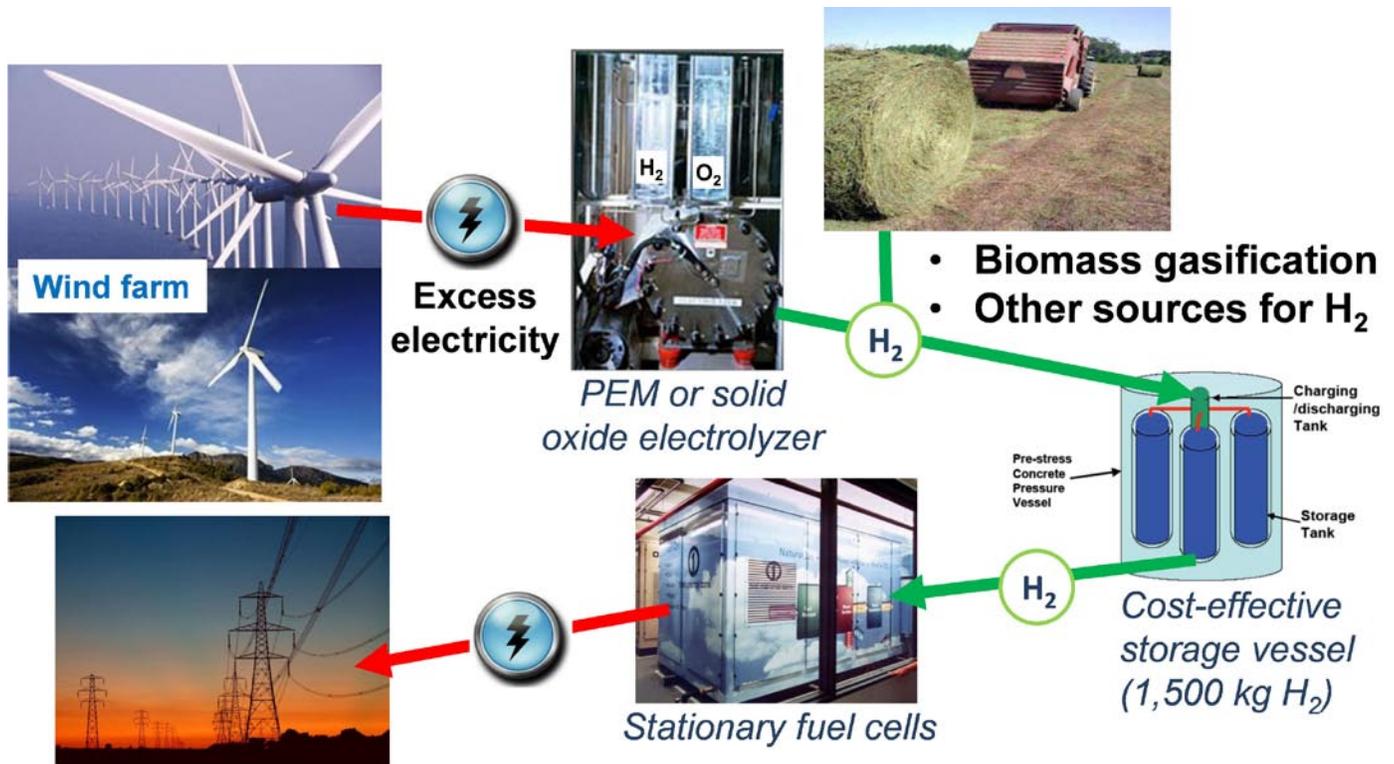

FIGURE 1. Application of Stationary Hydrogen Storage Vessel At Refueling Station

illustrates a potential application of the cost-effective hydrogen storage vessel for refueling of hydrogen. The vessel is designed to store 1,500 kg of gaseous H_2 , which is sufficient to refill about 267 passenger cars (based on a 5.6 kg H_2 tank per car [1]). Another potential application of the hydrogen storage vessel at renewable energy generation sites is shown in Figure 2. The hydrogen, produced from water electrolysis using excess electricity from wind farms and/or biomass gasification, will be stored in the vessel. The 1,500 kg of H_2 can be used to generate about 24,200 kWh [2]

(or 3 MW for peak-load daytime) back into electrical grid, sufficient electricity to power 780 U.S. homes per day [3].

The size and volume of the stationary hydrogen storage are expected to vary considerably depending on the intended usage, the location and other economic and logistic considerations. For instance, the storage vessel at a renewable energy generation site may have a lower hydrogen pressure but much larger storage volume compared to that at a refueling station. Therefore, it is important the storage vessel is “scalable” (i.e., it can be readily scaled for different

PEM - proton exchange membrane

FIGURE 2. Another application of stationary hydrogen storage vessel at renewable energy generation site for utility-scale load leveling and peak shaving (in conjunction with fuel cells).

sizes and pressures). In this project, ORNL leads a diverse multidisciplinary team consisting of industry and academia to develop and demonstrate a cost-effective integrated steel/concrete high-pressure hydrogen storage vessel design and fabrication technology that could be adopted to meet different stationary high-pressure hydrogen storage needs. Safety and economics are two prevailing drivers behind the integrated hydrogen storage technology.

Approach

Figure 3 is a schematic drawing of the overall engineering concept of the high-pressure hydrogen storage vessel. It has a modular design with scalability and flexibility for meeting different stationary storage needs. The particular design shown in Figure 3 is a composite structure with four inner steel tanks that are reinforced by an outer pre-stressed concrete sleeve. Commodity materials such as structural steels and concretes are used for cost-effectiveness. It is noted that the project team led by ORNL is working closely with the DOE Delivery Tech Team. Alternative designs may be studied based on the directions set forth by DOE.

A key enabler for the overall composite storage vessel is the use of a layered steel vessel for the inner steel tank. The layered steel vessel technology is proven and has shown significant cost and safety advantages over the conventional single solid section steel vessel. In this project, new designs and fabrication technology will be developed for the layered steel-based hydrogen storage including: (1) novel vessel design to avoid hydrogen embrittlement of high-strength structural steels, and (2) advanced fabrication technology based on friction stir welding (FSW) for layered steels. Sensors will be embedded into both inner steel tanks and outer concrete sleeve to ensure safe and reliable operation. Steel tanks are self-contained and can be shut down individually for improved reliability and safety. Finally, recently developed high-performance concretes will be evaluated for the interface material between the steel tank

and the concrete sleeve to ensure the structural compatibility between the two.

Results

There are three major activities in this first year (FY 2011) of the project: (1) preliminary cost estimate of the composite storage vessel, (2) preliminary design and engineering of key vessel components including steel tank, concrete, and interface between the two, and (3) technical proof-of-feasibility study of key design concepts and construction technology. The results from the first year of substantial development are discussed as follows.

Preliminary Cost Estimate of Composite Storage Vessel

Table 1 shows the preliminary rough-order-of-magnitude (ROM) cost estimate for three different design concepts. As shown in this table, the steel tank, though much cheaper than other materials such as carbon fiber composite tank, still represents a major cost item in the composite vessel. By shifting more structural loads from the inner steel tank to the outer pre-stressed concrete vessel, the required thickness for the steel tank is reduced. Even though the concrete vessel cost increases, the decrease in the steel tank cost (due to thinner wall) is sufficient to reduce the total cost of composite vessel. It is noted that the preliminary ROM cost estimate does not include the expected additional cost reduction attainable by the use of new steel vessel fabrication technology, new vessel design/engineering concepts, and ultra-high strength steels that are being pursued in the project. The ROM cost estimate does not account for engineering challenges and costs in high-strength concrete materials and integration of the inner steel vessel and the outer concrete containment. An improved cost analysis model is being developed which will take into account the detailed engineering and designs of key vessel components.

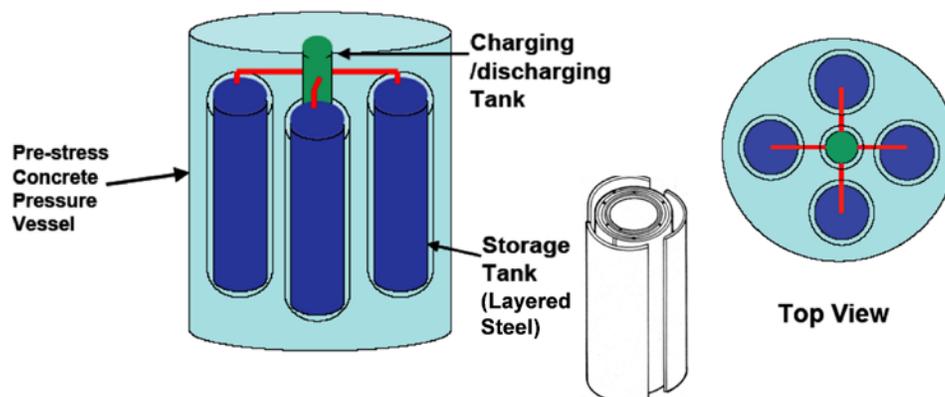

FIGURE 3. Schematic drawing of the overall engineering concept of the composite vessel for high-pressure hydrogen storage.

Cost per kg H₂, \$	\$667	\$754	\$837	\$902	\$593	\$640	\$678	\$352	\$360	\$368

* The basic premises in cost analysis include: (1) Reference vessel: a cylindrical vessel with semi-sphere heads, 12 ft. diameter and 21.7 ft. long (2,000 ft³ storage volume), with piping attachment and maintenance access. (2) 50 ksi inner steel vessel design allowable stress (SA724 100 ksi grade high-strength steel) and 190 ksi steel tendon design stress (Grade 270 steel), per ASME Boiler and Pressure Vessel (BPV) Section VIII Division III design rules and material specification. (3) ASME BPV stress formulas to determine steel vessel wall thickness. (4) Layered steel vessel: steel plate cost at \$2/lb, labor cost at \$100/hr., and 6,000 hours to fabricate the reference vessel, estimated by a major steel vessel construction. (5) Pre-stressed concrete pressure vessel: material and construction cost for rebar, high-strength tendon, and high-strength concrete are \$2.5/lb, \$3.5/lb, and \$400/cubic yard, respectively, based on 2007 steel and concrete market prices.

Design and Engineering of Key Vessel Components

The conceptual engineering design of the inner layered steel tank capable of sustaining 5,000 psi hydrogen pressure is developed based on industry standard ASME BPV Code - Section VIII. The layered steel tank consists of an inner thin liner with thin segmental cylinders wrapped around it to form the layered shells. The steel plate thickness is chosen to be 0.25 inch for ease of fabrication and to minimize the need for post-weld heat treatment. The concentric wrapped shells are welded to a single solid section steel head at each end. Special rules for welding, post-weld heat treatment and non-destructive examination required for layered steel tanks are included in the design. Such ASME code-based design is important for the industry acceptance and technology transfer and commercialization in a later stage of the project.

The conceptual designs for the outer reinforcement pre-stressed concrete pressure vessel and the interface between inner steel and outer concrete vessels are expected to be completed by the September/October 2011 timeframe. Structural analysis based on finite element modeling is being developed and used to aid the design of compatibility between steel and concrete vessels. Figure 4 shows preliminary results of stress distribution in a cross-section of the composite vessel at an internal hydrogen pressure of 5,000 psi. The predicted stress distribution is important to ensure the structure has enough capacity to sustain the design pressure.

Technical Proof-Of-Feasibility Study

The use of layered steels offers significant opportunities for further cost-reduction and safety and performance improvement. First, FSW has demonstrated to produce joint with superior mechanical strength when compared to conventional arc welding [4]. In the layered steel vessel construction, FSW can be used for the longitudinal seam weld of 0.25-in.-thick steel shells. Second, a novel design taking advantage of layered steel shells is being evaluated for mitigation of hydrogen embrittlement to high-strength structural steels. Finally, mechanical and chemical sensors can be embedded into both the steel and concrete vessels for monitoring structure health. In particular, state-of-the-art piezoelectric sensors are being studied for measuring strain/stress variations in the structure. These proof-of-concept studies are important to ensure the technical readiness of the proposed composite storage vessel.

Conclusions and Future Directions

From the above results gained in this first year of substantial development, it can be concluded: (1) the composite storage vessel utilizing commodity steel and concrete materials and advanced fabrication technology has a sound technical basis to meet the DOE revised cost target for off-board bulk storage, and (2) the preliminary engineering

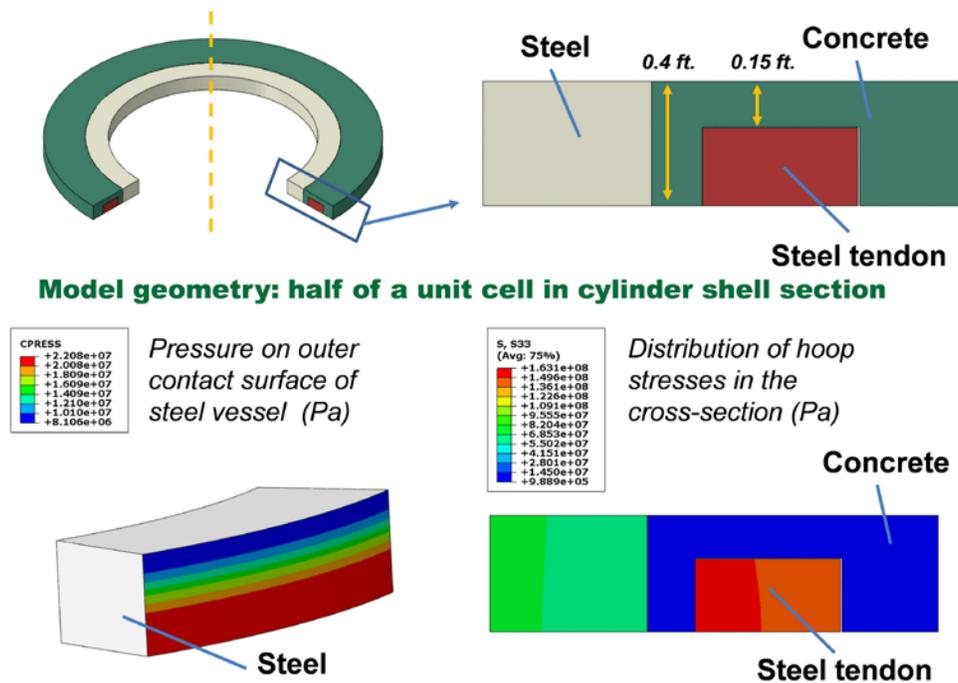

FIGURE 4. Preliminary results of finite element modeling for understanding stress distribution in the composite vessel.

design of inner layered steel vessel can sustain 5,000 psi hydrogen pressure based on relevant ASME BPV Code.

For the remainder of FY 2011, we plan to complete the preliminary designs of the outer pre-stressed concrete vessel and the steel/concrete interface. Detailed design and engineering analyses (including system cost), and mock-up vessel construction, testing and demonstration are planned in out-years.

Project Start Date: Fiscal Year (FY) 2004
Project End Date: Project continuation and
direction determined annually by DOE

FY 2011 Objectives

- Provide hydrogen delivery cost analysis
- Update and maintain the H2A Delivery Components Model
- Design new delivery components and scenarios
- Support the other hydrogen models with delivery data

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Delivery section of the Fuel Cell Technologies (FCT) Program Multi-Year Research, Development and Demonstration Plan:

- (A) Lack of Hydrogen/Carrier and Infrastructure Option Analysis
- (F) Gaseous Hydrogen Storage and Tube Trailer Delivery Costs

Technical Targets

This project aims to improve the efficiency of the hydrogen delivery process through analyzing various delivery pathways to understand the behavior and drivers of the fuel and vehicle markets and to meet Milestone 12 from the FCT Multi-Year Research, Development and Demonstration Plan: “By 2017, reduce the cost of hydrogen delivery from the point of production to the point of use at refueling sites to less than \$1 per kg.”

FY 2011 Accomplishments

- Completed analysis of hydrogen delivery by rail in comparison with the other delivery options and reviewed the congestion of U.S. railroad network.

- Introduced a pipeline branching algorithm and tested the delivery components for the multi-node delivery scenario model.
- Analyzed hydrogen delivery by composite tube-trailers with capacity of 550 kg of hydrogen, and reviewed highway regulations.
- Analyzed hydrogen delivery via existing natural gas pipelines, and reviewed U.S. natural gas networks.

Introduction

At NREL, for hydrogen delivery analysis, we use multiple models, such as the H2A Delivery Components Model, Scenario Evaluation, Regionalization and Analysis (SERA) Model, Fuel Cell Power Model and others. The H2A Delivery Components Model is an Excel-based, fully transparent model for the user, and publicly available. It can be used to calculate the cost of delivering hydrogen through multiple delivery pathways. SERA is an NREL dynamic optimization model. It is geographic information system (GIS)-based, java-coded software that determines the optimal production and delivery infrastructure build-outs and traces its evolution. The H2A Delivery Components Model also serves as a delivery cost data source for the NREL H2A Production Model, DTI HyPro Model, SERA Model, as well as for the NREL Biogas Model, Macro-System Model (through interconnection with HyPro), and HyDRA (through interconnection with SERA).

Approach

Since its start in 2004, the project has followed the general H2A approach and guidelines: closely collaborating with industry to update cost data and technical specifications, keeping consistency of the cost inputs across all H2A models, employing H2A standard assumptions, and maintaining publicly available models.

Results

Addressing barrier (A) - Lack of Hydrogen/Carrier and Infrastructure Option Analysis, we completed analysis of hydrogen delivery by rail in comparison with the other delivery options and performed a review on the U.S. railroad network congestion. Liquid hydrogen delivery by rail is the least expensive option for the large range of distances and demands (Figure 1). Therefore, it is well suited for delivering hydrogen produced from renewable sources for both early and mature markets. Analysis of the U.S. railroad networks [1] showed that 88% of the railroads are below capacity and could be potentially used to transport hydrogen.

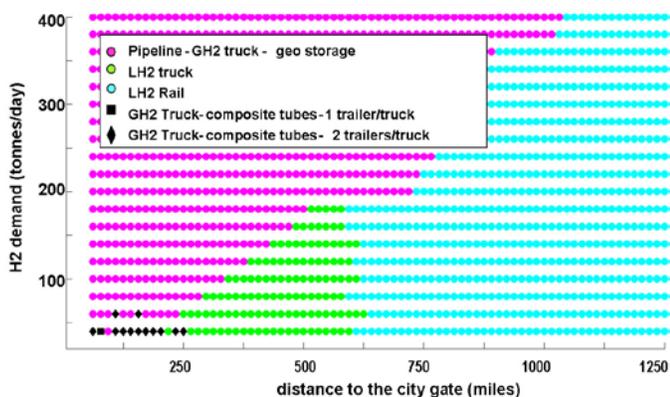

FIGURE 1. Lowest Delivery Cost Pathways

Barrier (A) was also addressed though analyzing the delivery of hydrogen via existing natural gas infrastructure. This assessment [2] revealed that up to 20% hydrogen can be safely injected into the natural gas pipeline with no major concern for hydrogen induced failures and aging. Hydrogen addition to the distribution mains involves some modification for integrity management. Among the available gas separation technologies (membranes, electrochemical separation, and pressure-swing adsorption [PSA]), the PSA is the most commercially ready technology for today. We assessed the cost of hydrogen extraction by a PSA unit, assuming mass production and mature PSA technology. For 10% hydrogen concentration and 20% hydrogen recovery factor, the estimated cost of hydrogen extraction by PSA from a 300 psi distribution pipeline ranges from \$3.3 to \$8.3/kg of hydrogen extracted, depending on recovery rate. For 20% hydrogen concentration and 20% hydrogen recovery factor, the extraction cost ranges from \$2.0 to \$7.4/kg (see Figure 2). If hydrogen extraction can take place at a pressure reduction facility, (so the high recompression cost of natural gas can be avoided), the extraction cost would range from \$0.3 to \$1.3/kg of hydrogen extracted, depending on recovery rate.

We also addressed barrier (A) by assessing scenarios where hydrogen can play a role as an energy carrier. We designed and evaluated two wind-to-liquid hydrogen scenarios: grid-independent with seasonal storage, and grid-connected. Both scenarios assume hydrogen production in the amount of 40 tonnes daily near Albuquerque, New Mexico, and delivery by rail to Long Beach, California. We used NREL Wind Resource data [3], modified NREL’s Fuel Cell Power Model [4] for wind farm optimization, and the H2A Delivery Components model for delivery cost. Also, we used NREL GIS data [5] for location and capacity of geologic storage, and for the nearest transmission line location and capacity. The cost of dispensed hydrogen in grid-independent case is \$11.3/per kg, and \$10.6 per kg in grid-connected case. As sensitivity analysis showed, there is a cost reduction possibility. Production cost is highly sensitive to the wind turbine cost. Recently, wind turbine

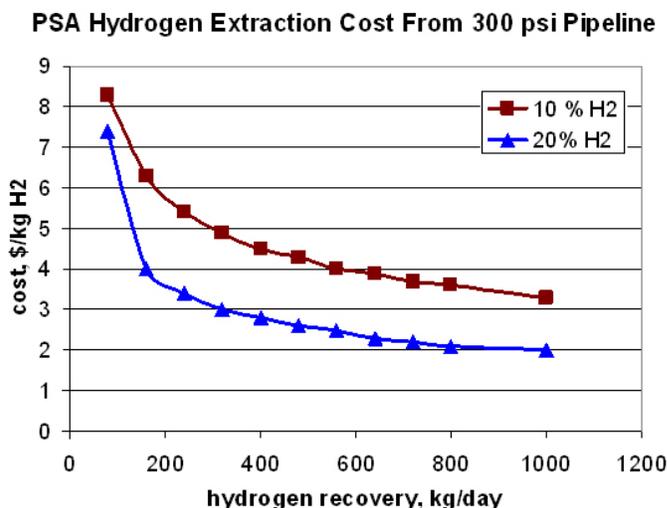

FIGURE 2. Estimated Cost of Hydrogen Extraction by PSA unit from 300 psi Distribution Pipeline (Assumed hydrogen recovery factor is 80%.)

market showed extensive volatility [6]. If wind turbines can be installed for \$1,000/kW (instead of \$1,500/kW – the number we used in the analysis), production cost can be dropped more than three times (to \$2/kg instead of \$6.6/kg) (see Figure 3). The grid-independent case is an attractive scenario in terms of energy sustainability. Nevertheless, it requires a significant amount of storage to accommodate seasonal wind variations. With the storage in geologic formation being the least expensive option for large hydrogen amounts, it is not currently feasible country-wide. Additional research and analysis has to be done to assess hydrogen storage in geologic formations.

Addressing barrier (F) - Gaseous Hydrogen Storage and Tube Trailer Delivery Costs, we analyzed the possibility of delivering gaseous hydrogen in a composite tube-trailer with a tube pressure of 250 bar and 550 kg of hydrogen capacity. Also, we reviewed Federal Highway Administration

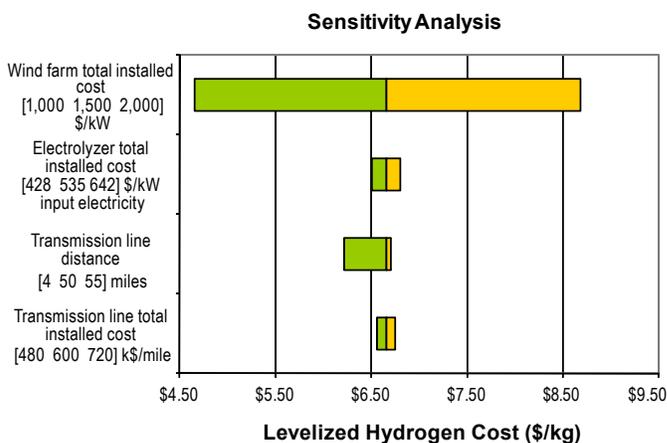

FIGURE 3. Sensitivity of Levelized Hydrogen Production Cost to Select Input Parameters

(FHWA) regulations regarding size and weight limitations on commercial motor vehicles [7]. For renewable (long-distance) hydrogen delivery, composite tube-trailers can compete with rail delivery only if a second trailer for a single truck can be allowed (Figure 4). As FHWA weight and size regulation review showed, this possibility potentially exists in the states of AK, AR, CO, ID, IN, IA, KS, MO, MT, NV, ND, OH, SD, UT, NM, NY, WY, and OR. Composite truck delivery also shows a potential for intra-city delivery, when a hydrogen production plant can be placed at the city border. The transportation cost in this case can be decreased twice with allowing for a second trailer, or increasing tube pressure up to 550 bar.

Barrier (F) was also addressed through developing a novel method of hydrogen delivery when a hydrogen plant not necessarily serves only one city, but can accommodate demand from multiple cities. By introducing these multi-node delivery scenarios, we can model pipeline and hydrogen storage systems shared between multiple cities that potentially can decrease the cost of storage designed for plant outage and demand surge. For designing multi-node delivery networks, we used the SERA Model. Considering that the SERA Model is not completely ready for multi-node delivery task, we enhanced the SERA delivery data block with coding delivery components directly into the SERA Model. The second phase of this process was completed this year. Fourteen delivery components were coded, and 10 of them were successfully tested against the H2A Delivery Components data.

Conclusions and Future Direction

In FY 2011, analyzing multiple delivery options, we reached the following conclusions:

- Hydrogen delivery by rail is the least expensive option for a large range of distances and volumes. Therefore, it is well suited for delivering renewable hydrogen; as in

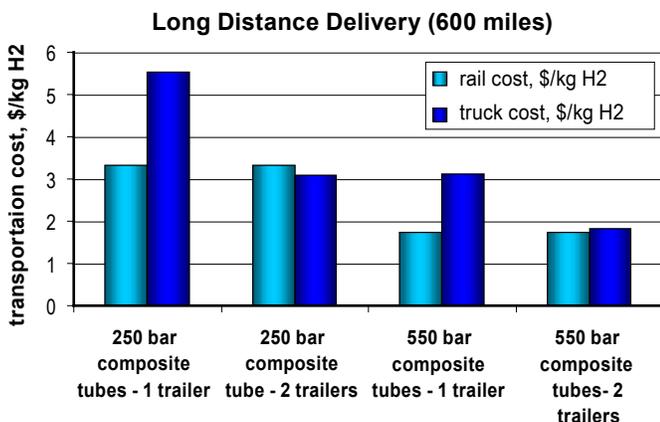

FIGURE 4. Total Cost of Gaseous Hydrogen Delivery by Rail or Truck over 600 Miles Distance

most cases, significant renewable sources are located far away from large demand centers.

- Delivering hydrogen in existing natural gas pipelines can be a safe and feasible option for up to 20% of hydrogen concentration. Although, the cost of this option seems to be prohibitively high except for limited cases when hydrogen extraction can be arranged at the pressure reduction facilities.
- Producing hydrogen from wind at the wind-abundant and low-electricity cost locations and delivering it to the centers of high energy demand over long distances can be a viable option to provide energy shortcomings for these areas. Such options can provide hydrogen (produced and dispensed) at the cost as low as \$6/kg.
- Delivering hydrogen in composite tube-trailers has a potential of decreasing transportation cost by allowing for a second trailer per truck, or increasing tube pressure up to 550 bar.

In the upcoming year, the major effort for the H2A Delivery Analysis and H2A Delivery Components Model will focus on:

- Maintaining and updating the H2A Delivery Components Model.
- Analyzing early- and mid-term delivery scenarios.

Subcontractor:
 Spencer Composites Corporation (SCC), Sacramento, CA

Project Start Date: October 1, 2004
 Project End Date: September 30, 2012

Fiscal Year (FY) 2011 Objectives

- Optimize hydrogen delivery by tube trailer.
- Demonstrate strength improvements of glass fiber pressure vessels at low temperature.
- Develop materials and manufacturing for low temperature hydrogen delivery.
- Quantify performance and economics of developed pressure vessels.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Delivery (3.2) section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (F) Gaseous Hydrogen Storage and Tube Trailer Delivery Cost
- (G) Storage Tank Materials and Costs

Technical Targets

All capital cost projections are detailed to the component level for composite pressure vessels (CPVs) including manufacturing capital, labor, materials, and disposal. Costs of other trailer components, however, are much less detailed (plumbing, CPV mounting, and integration). These non-vessel costs have been estimated based on compressed natural gas trailers as 43% of the total 1,100 kg H₂ trailer cost and 33% of the 2,350 kg H₂ trailer cost.

TABLE 1. Progress towards Meeting Technical Targets for Hydrogen Delivery

Characteristic	2005 value (Table 3.2.2)	DOE Targets FY2012/2017	LLNL+SCC 2011 status
Delivery Capacity (kg of H ₂)	280	700/1,100	1,100
Operating Pressure (psi)	2640	<10,000	<10,000
Purchased Capital Cost (\$)	\$165,000	<\$300,000	<\$291,000

Notes: LLNL has also designed a 2,350 kg delivery capacity cold glass CPV trailer option that uses the entire International Organization for Standardization (ISO) 20 ft. long container volume, with same operating pressures and temperatures, and a projected cost of under \$477,000. This option cuts delivered cost estimates from \$1.01/kg-delivered to \$0.82/kg-delivered (not including forecourt storage, compression, or dispensing).

Delivery costs are based on H2A models for labor and cab, while operating pressure has been optimized (for minimum \$/kg-delivered) at 7,500 psi. We calculated refrigeration costs assuming 33% exergetic efficiency to worst case 140 K. The estimated cost of refrigeration (\$0.24/kg-delivered) is conservative based on refrigeration costs calculated by Argonne National Laboratory [1] at the gas terminal scale.

FY 2011 Accomplishments

- Designed and built multiple full-scale pressure vessels to implement trailer design capable of delivering hydrogen (over 100-mile round trip) for less than \$1/kg-delivered.
- Qualified vessel design and manufacturing processes for pressures (0 to 22,500 psi) and temperature (ambient to -100°C) required to support cold delivery mission.
- Successfully burst tested first full-scale pressure vessel (with water at ambient temperature) as the first and most significant step in the technical proof of concept.

Introduction

This project has been funded to develop the key missing component necessary for LLNL's "cold glass" delivery approach: trailer-scale pressure vessels. Other technologies can build low-temperature-capable pressure vessels, but their vessels are either much too costly or too heavy for delivery trailers. Only CPVs are light enough to carry compressed hydrogen in sufficient quantity to achieve LLNL's optimized delivery costs within the volume and mass limitations of a trailer. Meeting the capital cost requirements of a trailer payload is not enough. Our target (below \$1/kg-

delivered, not including forecourt storage, compression, or dispensing) must pay for the energy and capital required for refrigeration, plus the operating and capital costs of the trailer cab (including labor to drive and load/unload). The CPV technology LLNL is developing with partner Spencer Composites Corporation (SCC) has the potential to meet this economic target for hydrogen delivery.

When first proposed in 2007, the CPV development effort was expected to advance the manufacturing readiness level (MRL) for this technology from 4 to 8 [2]. This translates to moving the technology from proven manufacturing feasibility to manufacturing processes that operate at target cost, quality, and CPV performance. Over the course of development, it was realized that this characterization was incorrect and the development effort has been re-defined as progressing the technology from MRL 3 (manufacturing process identified) to MRL 7 (proven manufacturing processes). The change required significant pre-production materials testing, and the development process is currently on track with the first proof of CPV performance from a full-scale vessel.

Approach

The cold glass strength effect needed for the glass-fiber composite material to potentially meet cost, delivered mass, and trailer payload mass targets was demonstrated in 2007 and later through proprietary glass fiber characterization carried out by a major fiber producer. A requirement of 3,650 temperature cycles between ambient and 100 K can routinely be met by commercially available fiber, but not by economical composite matrix and CPV liner materials. A new system of plastic materials is being developed that can perform over these thermal cycles and enable the LLNL CPV design.

Full regulatory approval of CPVs sufficient to carry hydrogen on U.S. highways requires a sequence of 16 full-scale tests. Such a test project is clearly beyond the resources available for this development effort. Therefore all key technical risks of failing any of those tests are being addressed by an affordable plan of burst, cycling, and permeation tests. No regulatory approval process has yet been formulated by Department of Transportation (DOT), ISO, or American Society of Mechanical Engineers (ASME) standards organizations for low temperature CPV service, mobile or stationary, so low temperature operation risks are being addressed with subscale test articles. Testing of the articles and of small-scale tensile coupons also allows risk associated with materials process development to be reduced. However, the processes needed to manufacture composites and liners do not scale from one size to another without posing significant risk to vessel performance and cost, and therefore testing of full-scale diameter (23") vessels is required once the technology has been shown to be acceptable prior to process scale up. However, to reduce materials process development risk, testing was first

performed on small-scale tensile coupons and 3" diameter subscale vessels.

Results

The first successful burst test of a full-scale (23" diameter, length over 50" that can satisfy ASME Code X certification requirements for all greater lengths) is illustrated in Figure 1. This test was performed with pressurized water to meet permit requirements at SCC's facility in Sacramento, CA. Testing CPVs filled with compressed hydrogen over a period of weeks is planned to prove that full-scale CPVs do not permeate at maximum operating pressure.

Before conducting this successful burst test in FY 2011, we had built three full-scale vessels from 'proven' components in early 2010 that failed 'prematurely' at varying pressures of several hundred psi. These failures were all slight leaks through cracks in their liners. The form and location of those cracks was similar to cracks found and overcome in 3" subscale CPV testing. Scale up from the 3" vessels to the first 23" vessels involved the costly construction of large tooling, and was only undertaken after 3" vessel manufacture had been adjusted to avoid those earliest CPV cracks at burst pressures above 22,500 psi (the maximum anticipated burst pressure required by LLNL's proposed trailer delivery integration design). Therefore the premature failures encountered in the three full-scale 2010 burst tests came as a very unpleasant surprise.

The persistence of significant technical risks was not unexpected because of two previous kinds of failure experienced by this development project. Before the final of the three failed 2010 full-scale CPVs was built, the first attempt to cast its liner went awry in a very illuminating fashion. After succeeding in building a 51" long liner, the same materials, tooling, and process sequence was used to build a 114" long vessel, but the liner molding tool produced a horrid 200 pound lump of darkened plastic! This unexpected scale up failure came from tripling of resin mass put into the tool before it was employed for the fourth time to cast the longest liner. This problem was overcome with successive resin pours to prevent the thermoset plastic's exothermic solidification reaction from thermal runaway. The catalysis reaction that solidifies our chosen, low-temperature-stable liner plastic was well known, but its dynamics in the molding tool was the first warning that thermal control during liner casting could be tricky.

The other development problem of 2009 was overcome entirely in the 3" subscale process development effort, and was apparently fixed by resin formulation changes. Since the liner cracks that caused problems in the 3" effort looked almost identical and appeared to originate in almost the same end dome location as the cracks that failed the 2010 full-scale test CPVs, it made sense to reopen the diagnosis of those cracks. Such debugging is simply not affordable at full-scale, so no more full-scale vessels were built until the

DCPD Liner Burst Test 1/10/11

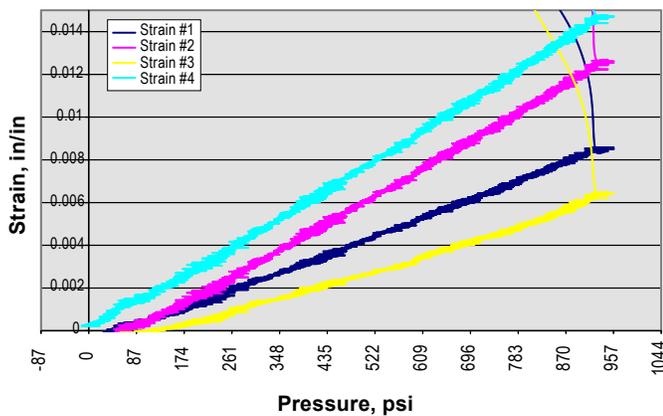

FIGURE 1. Successful Burst Test of Trailer-Scale CPV – Figure 1 shows a 23” diameter glass fiber composite pressure vessel that was burst tested with compressed water at ambient temperature. The photograph above shows the CPV after burst was declared, with its composite overwrap layer shredded. The vessel did not actually rupture, but lost most of its pressure and no fluid escaped. This is a very unusual outcome, due to the unprecedented toughness of SCC’s liner material. The middle photograph shows the bulge that formed in the unruptured liner, which accounts for an internal volume increase of roughly 3%, and is enough to explain the depressurization due to the relative incompressibility of water. The bottom figure illustrates four strain gage traces during this test, which prove this CPV’s manufacturing is adequate for designs that ‘burst’ at any pressure within the capabilities of plumbing seals.

problem was fixed in subscale articles without the earlier formulation changes. The same material that was cracking at low pressure in both early 3” and 2010 23” burst tests continues to stretch 18% in tensile tests, but something else had to be going on in particular end dome locations of liner castings for that material to crack at much lower strain. Figure 2 shows the variety of different hypotheses our team collected to explain these cracks, and the diagnosis we arrived at through skillful use of the scanning electron microscope (SEM) just in time to show dozens of SEM photographs at the 2010 annual merit review.

The internal features of our failing liners were responsible for the repeatable location of crack initiation. Defects had been built into the liner material during its casting process that were not built into the flat plaque tensile test specimens. Those defects were not visible to the naked eye, nor to an optical microscope, nor in unbroken liners – but they were visible in the SEM on the surfaces of cracks in the vicinity of crack initiation. When the liner cracking problem was first ‘fixed’ by resin reformulation, it appeared that the trouble was transient rather than built-in because almost all of the crack surface was shiny like the fracture surfaces on broken glass, indicating brittle failure. Resin additives that increased liner toughness and stretchiness (maximum elongation at tensile failure) appeared to fix it, until the problem returned at full scale.

The correct diagnosis was based on SEM imaging of the entire crack surface from the failed 23” liners. The cracks forked, with forks not left on the failure surface being those that didn’t run faster than those that formed the surface. These ‘diving’ forks were later seen on examination with low power optical microscopy, saving considerable time in the SEM. The direction that the ‘tines’ of these forks pointed must be the crack propagation direction, so the crack initiation region was localized between a single pair of forks whose tines pointed away from each other. In that region, shiny surfaces gave way to slight localized frostiness; presumably before the crack propagation ramped up to high speed and could take advantage of orders of magnitude stress concentration at its crack tip. Those frosty regions are represented by the SEM sequence that appears in Figure 3, which focuses in on the “smoking gun” feature found on the complex surface of a diving fork.

That feature is a crater sticking up into a void, but not like craters seen in geology or astronomy. New materials have new failure modes, and this one occurred when the resin was a weak gel. Earlier SEM diagnosis had already determined that the forked cracks in the vicinity of crack initiation were not running in the maximum strain energy release direction (perpendicular to local tension), but went curling around with geometries that might be seen on the surface of puddings that had dried from neglect. The crater feature in question has sharp edges, but these could not have formed when ejecta blew into the void it sticks up in. Gas erupted through the surface of a weak gel into that void, then the gel shrank to form facets on the crater. Although density

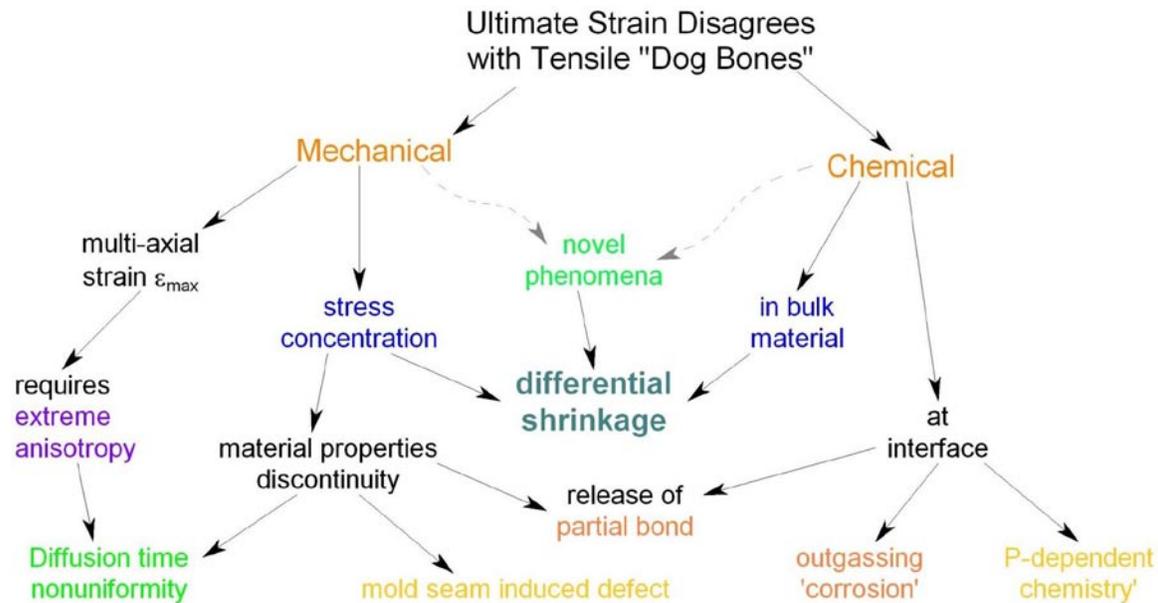

FIGURE 2. Tree Diagram of Hypotheses for Premature Liner Rupture - Figure 2 illustrates all the possibilities LLNL and SCC hypothesized to account for obscure failures observed in burst testing 3" and 21" diameter CPVs and unwrapped liners. For over two years experimental liner material formulations passed tensile testing at 8-9,000 psi ultimate stress and roughly 18% strain, yet failed when built into CPV liners at strains as low as 0.3%. These materials are not brittle, and most formulations were capable of toughness roughly 30-fold above epoxies. The materials failed as liners 'prematurely' despite passing every toughness test with an ASTM drop tower impact. Hypotheses in orange type were proven partially correct, yellow type were proven incorrect, and green type were verified. The odd conjecture shown in purple type was proven to be a result of the unprecedented solidification mechanisms of this material, while the hypothesis in teal type was found to be an unexpected part of that mechanism.

measurements have long shown a 6% densification of this resin upon solidification, how that shrinkage was distributed in space did not appear to matter. After LLNL's diagnosis, it was clear that the plastic was cracking itself just where it ran out of more liquid for a wave of catalysis to solidify.

Knowing what went wrong did not initially make it clear how to fix it. Another wave of dozens of 3" bottles became the front line for variations in the mold tool and resin pour sequence. Control was taken over where catalysis started, and care taken to never let the catalysis wave pass through liquid resin up against a solid wall, either of the mold or of previously solidified plastic. A technique was found to locate defective regions of castings without breaking them and to prepare the shards for SEM imaging, that is shown in Figure 4. But the next question was whether the project could afford to rebuild the 23" tool to incorporate these necessary improvements. The answer appeared to be no, before a real customer for such CPVs showed up in late summer of 2010. The customer could and did pay for a new tool which LLNL's liner mold fit into, but wanted CPVs built faster than SCC had any confidence they might pass ASME certification. This led to an extreme scramble to get LLNL development done on the tool the customer paid for, before the customer got its parts.

In January of 2011 the first good liner emerged from this tool to wind glass composite around, and then to burst test

into the article shown in Figure 1. That burst test vindicated the improved liner molding process, because it ended in an unprecedented CPV failure mode, which might be called burst without rupture. Just because all the water remained inside after a loud noise and a big pressure drop does not mean this mode is really safer, since gaseous contents would not have dropped in pressure with just a little midriff bulge. But the survival of the liner in that bulge region does prove that the liner remained ductile under rapid straining to over 11% strain. Since design hydrogen delivery pressures only call for 3% liner strain, the liner component that has caused this project so much trouble has been proven to operate beyond its requirements at full scale.

Further surprises were in store when the happily undestroyed vessel in Figure 1 was cut into to see how well its liner's end dome was cast. If the vessel had burst in a more normal way, the region wherein more 'defects' were found might have been lost. Instead Figure 4 shows failure surfaces that have nothing to do with the performance of the CPVs LLNL and SCC are building, and everything to do with the nature of the new material we are developing. Composites built with this material as a matrix have all the right properties, including fiber 'translation' (material tensile strength divided by raw fiber strength) over 90% and no strength loss at 77 K. Castings built with it, however, can have localized frosty regions whereat catalysis ran out

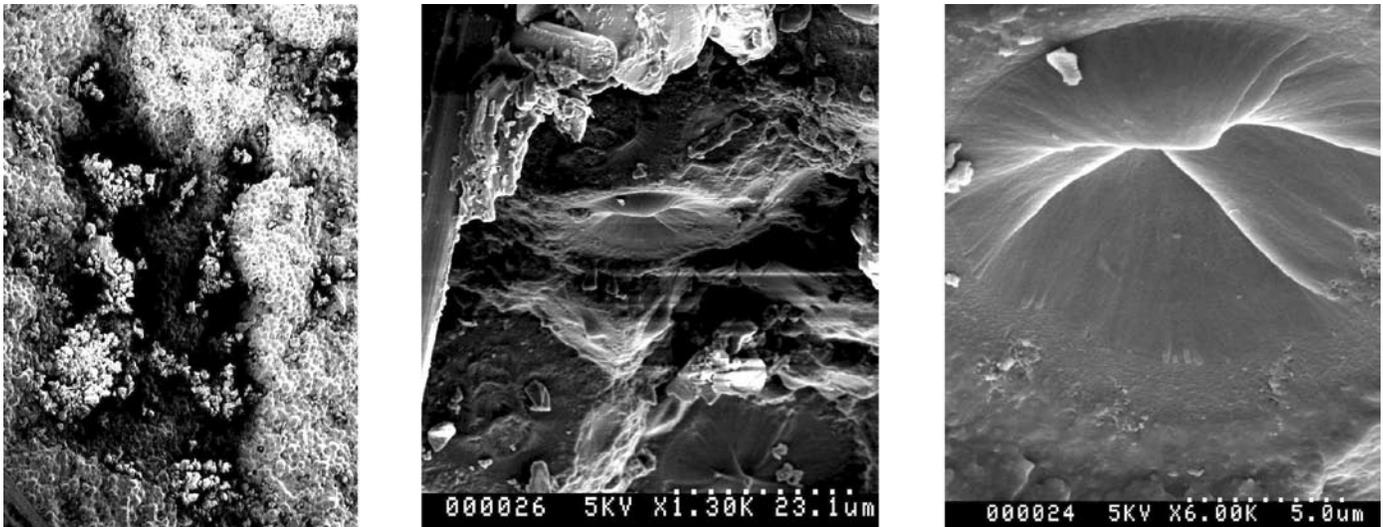

FIGURE 3. SEM Photographs of Liner Crack Surface – Figure 3 shows the “smoking gun” sequence of SEM photographs of a particular portion of the surface whereat a full scale (21” diameter) liner cracked inside of an early-2010 burst CPV. None of these features are visible in an optical microscope, and the sequence of photographs taken at the same point on the failed specimen increase in magnification from left to right. This particular spot was close to the origin of the crack that ruined this liner, causing the test CPV to leak below 800 psi and 0.7% nominal axial strain. The detective work that found the crack origin vicinity is based on forks in the cracked surface, whereat branches of the crack that did not succeed in forming part of the final separation surface dive beneath the surface on view. The origin of the crack must be somewhere between the two forks whose branches point away from that region. Looking into a fork of the crack, in the middle photograph shards of 2.7 micron glass fiber are visible which have been blown into a diving fork branch. On the wall inside that branch the odd “flying saucer” that appears centered in the micrograph at right initially resisted interpretation (since SEM views do not have darkness reflecting tilt angles as optical views do), but many attempts to view it at different angles convinced SEM operators this is a crater with sharp radial ridges.

of resin. This generation of 23’ liners just happens to have one of those regions in a ring on its outer mold line (OML, casting terminology for exterior molded surface). The 3” liners that were cracking had several such regions on their inner mold line (IML, interior surface), and that surface goes into tension when the liner inflates, whereas the OML region on the 23” liners goes into compression.

The defective regions were actually visible to the naked eye, with the aid of a flashlight, when looked at through the polished edge of the burst success liner end dome cut out segment. They appear as a tenuous frostiness, which LLNL has come to term ‘nanocracking’, since any frosty region on a cast surface has the kind of frosty surface shown in Figure 3 when examined in the SEM. Once cast into the part, the penetrant dye that visualizes these regions in Figure 4 cannot get in to detect them, but when bar shaped specimens cut with this region in the middle were broken, the dye can be used to decorate the cracks. A forked crack is visible in the left micrograph of Figure 4, which was broken in tension at extreme elongation. A much more complex swirl appears in the right hand micrograph which failed at a few percent strain in torsion.

Although stress and strain have tensor rotation properties, it turns out that failure stress and strain do not rotate like a proper 2-tensor in these materials! Material so anisotropic that shear and longitudinal failure properties are decoupled is the consequence of its rapid solidification by Grubbs catalysis. It does not matter if shear stress is

identical to tensile stresses exactly twice as large when the coordinate system is rotated by 45 degrees, because the molecular structure in nanocracked regions has almost no bonds to carry force in that direction. So an adequate solution for a 23” CPV liner is not the only fruit of these investigations: an informed strategy to design liners without bending stresses that put tension on the IML, and to design mold tooling that drives catalysis waves from IML to OML, enables progress (at customer expense) to be defect tolerant. The ability to detect defective regions before building CPVs around them, plus the advancing mass production of 3” CPVs with this technology improve the odds that reliable cold strength and inconsequential liner OML surface nanocracking can be proven before this project ends.

Conclusions and Future Directions

- First significant risk reduction test at full-scale passed with benign failure mode.
- More full-scale vessels under construction for cycling and permeation tests.
- Permeation test rig for dangerous compressed hydrogen filled, multi-week duration permeation tests under construction.
- Further quantitative proof of cold strength effect at various reduced temperatures anticipated with subscale (3”) glass fiber pressure vessels tested in expendable dewar.

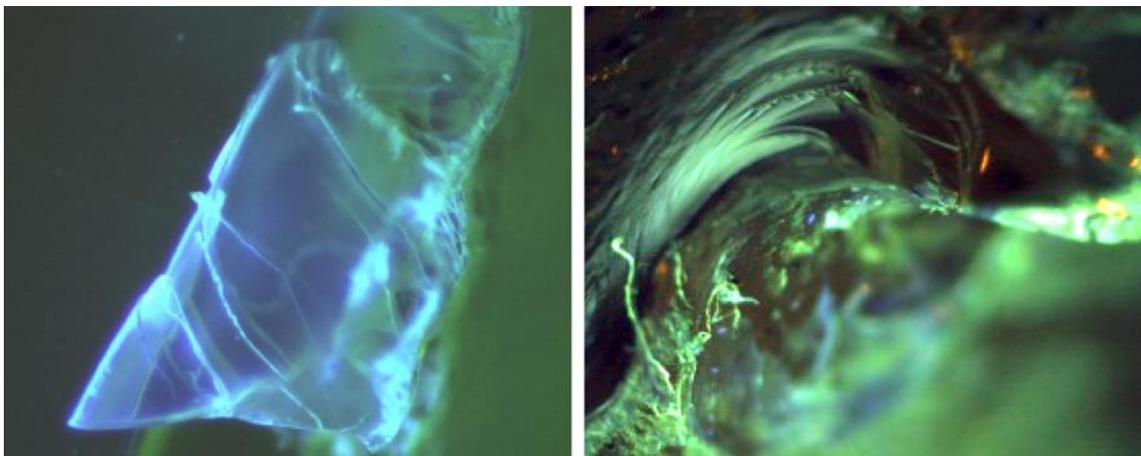

FIGURE 4. Observed Cracks in Specimens of Successful Liner – Figure 4 shows the splendid images resulting from two crude strength tests performed in a vise. These photographs are taken at low magnification with an optical microscope (commonly called a macroscope), in a combination of ultraviolet and visible illumination. SCC developed a diagnostic technique to make defective liner casting regions visible without a SEM, using a penetrating fluorescent dye. While the SEM cannot image regions likely to initiate cracks buried within cast parts, this technique cannot image defects directly on surfaces. Since the successful liner had not broken during burst testing, it made a fine vehicle to see whether defective regions could be found before they triggered cracks. This ‘experiment’ was conducted in January of 2011 by plunging an industrial vibratory cutter into the dome region of the unruptured yet burst CPV, then taking the wedge cut from the dome through a band saw to cut test specimens. The specimen at left was pulled with a vise grip pliers, and failed at over 100% strain, while the one at right was twisted and failed at several percent strain. They both failed in the millimeter-thick circumferential region where cloudy fuzziness is visible when polished edges of the wedge were illuminated by flashlight, on which the band saw cuts were centered to produce test specimens 3” long by roughly 0.3” square.

- ASME regulatory approval test program of nearly identical CPVs based on a batch of 20 full-scale (23” vessels) paid for by a private SCC customer anticipated in 2012.
- Joint DOE/DOT demonstration project possibility likely under discussion by early FY 2012 with hydrogen proponent DOT managers who currently have responsibility for certifying highway-rated pressurized containers.

Project End Date: October 1, 2012

Fiscal Year (FY) 2011 Objectives

Fiber Reinforced Composite Pipeline (FRP)

- Focused evaluation of FRP for hydrogen service applications.
- Development of data needed for life management and codification FRP technical barriers.

This project addresses the following technical barriers from the Hydrogen Delivery section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (D) High Capital Cost and Hydrogen Embrittlement of Pipelines
- (I) Hydrogen Leakage and Sensors
- (K) Safety, Codes and Standards, Permitting

Technical Targets

This project is focused on the evaluation of FRP for hydrogen service applications. Assessment of the structural integrity of the fiber reinforced piping and joining components needed for hydrogen delivery are addressed. Insights gained will support qualifications of these materials for hydrogen service including the DOE 2012 delivery targets:

- Pipeline Transmission and Distribution Cost: \$0.6 M/mile and 0.27 M/mile, respectively.
- Hydrogen Leakage: to be determined, <0.5% by 2017.

FY 2011 Accomplishments

- Multiple burst tests of FRP samples were completed to evaluate the design margins for flawed fiber piping to evaluate the consequence of third party damage to pipelines.
- Chemical exposure test of flaw samples were completed to evaluate address the influence of soil pH on FRP design margins.
- Completed initial literature review of flaw detection methodologies for FRP.

Introduction

The goal of the overall project is to successfully adapt spoolable FRP currently used in the oil industry for use in high-pressure hydrogen pipelines. The use of FRP materials for hydrogen service will rely on the demonstrated compatibility of these materials for pipeline service environments and operating conditions. The ability of the polymer piping to withstand degradation while in service, and development of the tools and data required for life management are imperative for successful implementation of these materials for hydrogen pipeline.

In FY 2009 a FRP life management plan was developed by SRNL and the American Society of Mechanical Engineers (ASME) to focus the direction for the research and testing needed to have FRP codified in the ASME B31.12 Hydrogen Piping Code. The plan also provided the tasks needed for the post construction management of FRP to insure structural integrity through end of life. The plan calls for detailed investigation of the following areas:

- System design and applicable codes and standards
- Service degradation of FRP
- Flaw tolerance and flaw detection
- Integrity management plan
- Leak detection and operational controls evaluation
- Repair evaluation

Approach

SRNL has completed the first areas of the Life Management Plan. Codes and standards for the high-pressure piping, process, and transport pressure vessels were reviewed and design margins and qualification techniques evaluated.

SRNL and Oak Ridge National Laboratory (ORNL) have collaborated on evaluating the service degradation of FRP in high-pressure hydrogen. Initial laboratory

testing indicated that there is not a degradation mechanism connected with the use of hydrogen in FRP. The codes and standard development organizations would like additional long-term data on this question to ensure the long-term life management of FRP.

SRNL has begun investigation to determine the flaw tolerance of FRP products. Creep data on glass fiber was also reviewed to evaluate the effect of creep life on the glass fiber. The results indicate that a design margin of at least 3.5 is required to address long-term creep effects for a 20+ year design life. The use of the fiberglass creep data has been effective in evaluating the effect of flaw tolerance using a short-term burst test. Multiple tests have been completed to evaluate the effect of flaw tolerance on FRP samples for FRP designed to a recognized national consensus standard were used in the evaluation. Flaws for various depths were machined into the samples and burst tests have been performed.

Tests have also been performed to evaluate the effect of chemical environment on the FRP. The purpose of the chemical exposure tests are used to determine a measure of soil pH on the FRP materials. The first series of tests measured the chemical resistance of S- and E-type fiberglass strands that are typical of those that are used to fabricate the load-bearing overwrap used for the composite pipeline segments. Type S and E glass fiberglass strands were exposed to aggressive chemical environments in order to determine bounds on the base mechanical properties of tensile strength and chemical resistance. These bounds were comparable to technical literature on the subject [1] which have not been chemically exposed. These samples were subjected to solutions of pH 2.4, 7 and 10.6 for periods of either 24 hours or 120 hours (5 days) and then subjected to tensile strength testing using an Istron 4507 Electromechanical System with a strain rate of 200 $\mu\text{m}/\text{sec}$ per ASTM 1557-03. Additionally, two flawed pipe sections were exposed to the same pH levels for 120 hours and burst tested.

Results

To address third party damage the sensitivity of FRP to flaws must be established. The flaw testing was performed over a range of flaw sizes to determine the flaw tolerance of the FRP. FRP with single layer reinforcement and multi-layer reinforcement were evaluated.

The results of the single layer FRP tests are shown in Figure 1. A reduction in burst pressure from unflawed condition to a 2-inch long flaw cutting the reinforcing layer of 75% was observed. With the 2-inch long flaw cutting the reinforcing layer the burst pressure drops below the rated pressure for the single-layer product. The single layer reinforced piping does not provide sufficient redundancy to tolerate third party damage. Following a review of the results from the piping with the single layer reinforcement, it was determined that this type of fiber-reinforced piping was not an acceptable option for hydrogen piping.

The results of the multi-layer FRP tests are provided in Figure 2. Tests were conducted for increasing flaw depths up to 40% through wall. A 28% reduction in burst pressure from the unflawed condition to a 40% through wall flaw was observed. With the 40% through wall flaw there is still a margin of approximately 3x above the rated pressure of the FRP multi-layered product. The margin on burst of 3 provides an acceptable remaining product life to detect and repair flaws in FRP systems. Additional burst tests were conducted in on FRP samples with 40% through wall flaws to determine the variability between different samples. The results of the additional tests show that the variability between the tests is low and that all tests provide an acceptable design margin. The results for increasing the flaw length and width are also shown in Figure 1. The flaw with increased length showed no additional loss in design margin above the base flaw length. The flaw with increased width showed a small additional loss in design margin above the base flaw width. Two FRP samples were exposed to the high and low pH solutions and burst tested. The results are shown in Figure 2. The failure pressure for the chemically exposed samples fell within the variability of the unexposed data.

From the flawed samples, it was observed that as the flaw depth increased the failure mode changed from a local failure to a more global failure mode. The series of photos shown in Figure 3 illustrates these failure modes. The first photo from the left shows the failure of the unflawed sample indicating a global failure of the pipe. The next three photos illustrate how the failure mode changed as the flaw depth increased. The last photo on the right shows the 40% through wall flaw. In the 40% through wall photo, the failure encompasses most of the pipe circumference. Based on this data it was determined that the 40% through wall was a reasonable upper limit to set for flaw detection.

The test results for glass fiber strands exposed to high and low pH solutions are shown in Figure 4. The red and blue curves in Figure 4 show the results for the untreated E- and S-type samples. As can be seen, mechanical failure typically occurred for the untreated samples below the 3% strain threshold, with the both samples showing

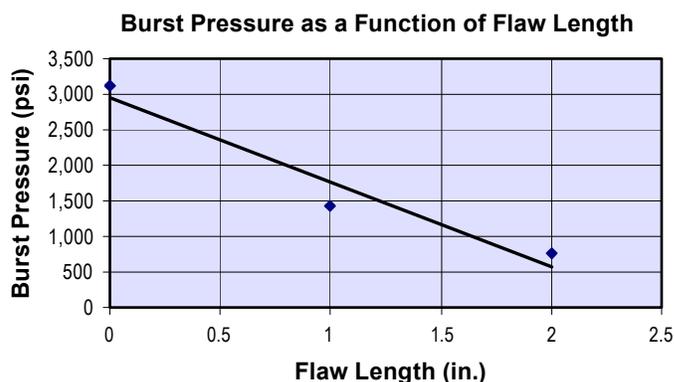

FIGURE 1. Single-Layer FRP Burst Test

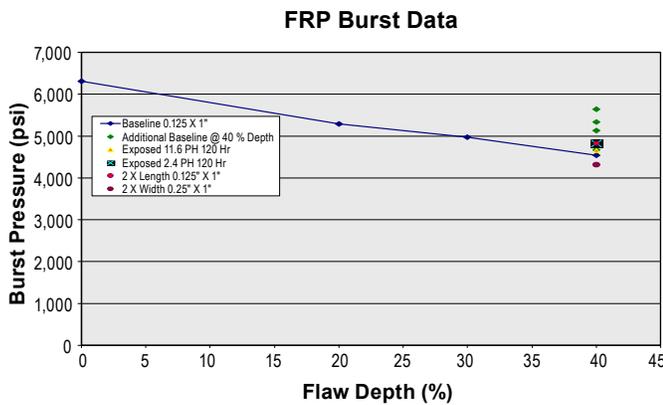

FIGURE 2. Multi-Layer FRP Flaw Tests

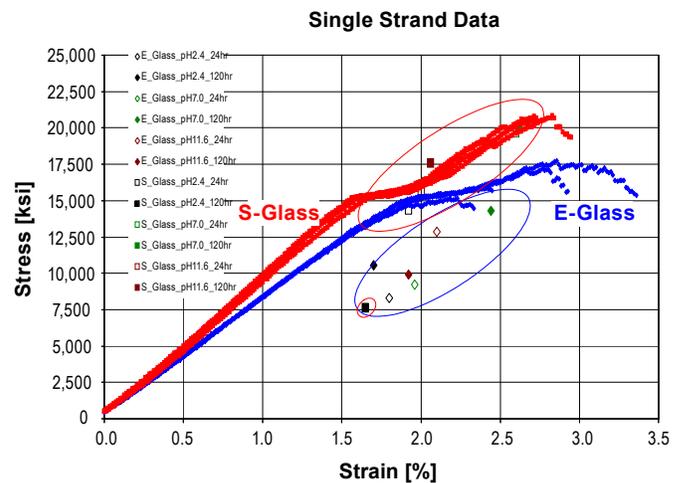

FIGURE 4. Test Results for Glass Fiber Strands

FIGURE 3. Photo Illustrating Failure Mode of FRP

reproducibility in the strain point of the initial point of failure. These tests were performed using thread grips and the samples were inspected after testing to ensure that failure occurred in a position not associated with applied stress or pinching at the grip surfaces.

Samples were taken from the same lot of fiberglass and were subjected to the chemical environments described above. The data in the blue circle provides the failure strain for the chemically exposed samples. It can be seen from a review of the chemically exposed data that the aggressive chemical environments can have a deleterious effect on their mechanical properties of the uncoated glass samples. Additional testing on chemically exposed uncoated glass sample indicated the effect of the chemical environment had resulted in corrosion of glass. Because the glass fibers are epoxy coated in the actual FRP product form, chemical exposure tests were conducted on flawed FRP samples. Two FRP samples were exposed to the high and low pH solutions and burst tested. The results are shown in Figure 2. The failure pressure for the chemically exposed samples fell within the variability of the unexposed data.

To establish a life management program the ability to detect external flaws in FRP by applying internal examination or smart pipe technology is needed for controlling failures and maintaining acceptable safety

margins. The laser profilometry method is one technique to be investigated for inner diameter examination of FRP. In FY 2011 SRNL began work on flaw detection. A literature review was begun to investigate the potential for flaw detection using the laser profilometry method. In addition, to determine the effect of small flaws on FRP geometry, a flawed sample of FRP was pressurized to the rated design pressure and the sample was monitored for swelling. The initial result indicate that for the small flaw sizes the geometry changes for the sample will be negligible. The initial review for flaw detection data points to the need for smart pipe technology or an external flaw detection scheme.

Conclusions and Future Directions

Conclusions

- FRP is an attractive technology with potential to reduce overall pipeline installation cost.
- Field case studies indicate 20-60% reduced cost over steel pipeline.
- American Petroleum Institute standard 15HR is the most relevant standard reviewed to date for the fabrication of FRP line pipe for hydrogen service. This standard can be tailored to address the need for hydrogen pipelines.

- Flaw tolerance tests show that for flaws up 40% through reinforcement and up to 2 inch length and 0.25 inch width a factor of 3X margin is maintained on rated pressure.
- The current recommendation is to develop a performance-based design specification to be included in ASME B31.12.
- Workshop to discuss next steps toward ASME codification to be held in FY 2011.
- Evaluate B31.8S (Managing System Integrity of Gas Pipelines) for changes needed to address FRP in hydrogen service.
- Develop FRP hydrogen demonstration loop project among DOE, State of South Carolina, Aiken County, SRNL, ORNL, and ASME.

FY 2011 Presentations

1. SRNL FRP Piping Project, Presentation to Hydrogen Delivery Tech Team, Detroit MI, December, 2010.
2. SRNL FRP Piping Project, Presentation to Hydrogen Delivery Pipeline Working Group, Boulder, CO, April 2011.

Future Work

- Perform long-term stress rupture test for flawed FRP samples.
- Performed additional burst testing of flawed FRP samples on aged samples.
- Recommend performance qualification tests for FRP in hydrogen service to the ASME B31.12 committee.

Contract Number: DE-FG36-08GO18062

Project Start Date: July 1, 2008
Project End Date: June 1, 2011 (request for extension to June 30, 2012)

Fiscal Year (FY) 2011 Objectives

The objective of this project is to design and develop the most effective bulk hauling and storage solution for hydrogen in terms of:

- Cost
- Safety
- Weight
- Volumetric Efficiency

Technical Barriers

This project addresses the following technical barriers from the Delivery section of the Hydrogen, Fuel Cells and Infrastructure Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (F) Gaseous Hydrogen Storage and Tube Trailer Delivery Costs
- (G) Storage Tank Materials and Costs

Technical Targets

This project has focused primarily on the design and qualification of a 3,600 psi pressure vessel and International Organization for Standardization (ISO) frame system to yield a storage capacity solution of approximately 8,500 L of water. Second phase is to perform and qualify same size container at higher pressures.

TABLE 1. Progress towards Meeting Technical Targets for Hydrogen Storage

Characteristic	Units	2010 Target	2015 Target	Status	Comments
Storage Costs	\$/kg	\$500	\$300	\$675-\$750	5,000 psi tank is expected to lower the cost
Volumetric Capacity	kg/liter	0.030	0.035	0.018	Estimated: 5,000 psi = >0.024 kg/liter 8,300 psi = >0.035 kg/liter
Delivery Capacity, Trailer	kg	700	1,100	600	Estimated: 5,000 psi = >800 kg 8,300 psi = >1,150 kg

Accomplishments

- Successful completion of design and qualification of a 3,600 psi pressure vessel.
 - Qualification testing included:
 - Hydrostatic Burst
 - Ambient Pressure Cycle Test
 - Leak Before Burst Test
 - Penetration Test
 - Environmental Test
 - Flaw Tolerance Test
 - High Temperature Creep Test
 - Accelerated Stress Rupture Test
 - Extreme Temperature Cycle Test
 - Natural Gas Cycle Test with Blow-down
- Successful completion of design and qualification of an ISO frame capable of holding four 3,600 psi pressure vessels with a combined capacity of 600 kg of hydrogen. In addition to the structure, a system for loading, unloading, and pressure relief have been designed and implemented.
 - Qualification testing included:
 - Stress Analysis
 - Dimensional Analysis
 - Stacking
 - Lifting – Top and Bottom
 - Inertia Testing
 - Impact Testing
 - Bonfire Testing
- Successful completion of a trade study was achieved with respect to use and utilization of 5,000 psi pressure vessels.

- Factors used in the study:
 - Number of Pressure Vessels per Assembly
 - Working Pressure
 - Storage Temperature
 - Module/Cylinder Cost
 - Stress Ratio – reduce weight and cost by lower carbon fiber usage

Introduction

Hydrogen holds the long-term potential to solve two critical problems related to energy use: energy security and climate control. The United States transportation sector is almost completely reliant on petroleum, over half of which is currently imported, and tailpipe emissions remain one of the country's key air quality concerns. Fuel cell vehicles operating on hydrogen produced from domestically available resources would dramatically decrease greenhouse gases and other emissions, while also reducing our dependence on oil from politically volatile regions of the world.

Successful commercialization of hydrogen fuel cell vehicles will depend upon the creation of a hydrogen delivery infrastructure that provides the same level of safety, ease, and functionality as the existing gasoline delivery infrastructure. Today, compressed hydrogen is shipped in tube trailers at pressures up to 3,000 psi (about 200 bar). However, the low hydrogen-carrying capacity of these tube trailers results in high delivery costs.

Hydrogen rail delivery is currently economically feasible only for cryogenic liquid hydrogen; however, almost no hydrogen is transported by rail. Reasons include the lack of timely scheduling and transport to avoid excessive hydrogen boil-off and the lack of rail cars capable of handling cryogenic liquid hydrogen. Hydrogen transport by barge faces similar issues in that few vessels are designed to handle the transport of hydrogen over inland waterways. Lincoln Composites' ISO Tank Assembly will not only provide a technically feasible method to transport compressed hydrogen over rail and water, but a more cost and weight efficient means as well (Figure 1).

FIGURE 1. Assembled ISO Container Without Outer Panels

Approach

In Phase 1 of this project, Lincoln Composites will design and qualify a large composite pressure vessel and ISO frame that can be used for storage and transport of compressed hydrogen over road, rail or water.

The baseline composite vessel will have a 3,600 psi service pressure, an outer diameter of 42.8 inches and a length of 38.3 feet. The weight of this tank will be approximately 2,485 kg. The internal volume is equal to 8,500 liters water capacity and will contain 150 kg of compressed hydrogen gas. The contained hydrogen will be approximately 6.0% of the tank weight (5.7% of the combined weight).

Four of these tanks will be mounted in a custom-designed ISO frame, resulting in an assembly with a combined capacity of 600 kg of hydrogen. Installing the compressed hydrogen vessels into an ISO frame offers a benefit of having one solution for both transportable and stationary storage. This decreases research and development costs as well as the amount of infrastructure and equipment needed for both applications.

The large size of the vessel also offers benefits. A limited number of large tanks is easier to package into the container and requires fewer valves and fittings. This results in higher system reliability and lower system cost. The larger diameter also means thicker tank walls, which will make the vessel more robust and damage tolerant.

Phase 2 of the project will be to evaluate using the same approximate sized vessel(s) and ISO frame at elevated pressures. The pressures that are targeted for scope are 5,000 psi and 8,300 psi. Basic design of the individual vessels will remain approximately the same size at the 5,000 psi pressure and minor changes may be needed for the higher pressure. Higher pressures are needed to accommodate goals of the project.

Results

Design and Manufacture of a 3,600 Psi Pressure Vessel

The design of the 3,600 psi pressure vessel architecture has been completed using finite element analysis to find a composite solution that resolves the internal pressure requirements and expected external loads. This design was translated into a manufacturing process that addresses the feasibility of vessel production. Several development units were fabricated and pressurized until burst to validate the proposed manufacturing process and design.

With the completed design and working manufacturing process, several additional vessels were fabricated and tested to address optimizing manufacturing issues and minimize production expenses. One of the units was fabricated and tested to ensure the highest risk associated with material availability could be addressed. By ensuring multiple

sources of supplied materials, more leverage is available during procurement and lower production costs can be realized. Another vessel was fabricated to help establish confidence with migrating to a design having a higher margin of safety. Both of these vessels were subjected to a proof cycle and hydraulic burst test. The result of the testing met the expectations predicted by the design.

Qualification of 3,600 Psi Vessel

Due to the tanks geometry and construction, there are no published standards that can be used to directly qualify the product. There do exist, however, standards to qualify small pressure vessels of similar construction. These standards were reviewed for input to determine the appropriate requirements that would apply to a vessel of this geometry and construction and include:

- ISO 11439, gas cylinders – High Pressure Cylinders for the On-board Storage of Natural Gas as a Fuel for Automotive Vehicles
- ISO 11119-3, Gas Cylinders of Composite Construction (fully wrapped non-metallic liners)
- ANSI/CSA NGV2-2007, American National Standards for Natural Gas Vehicle Fuel Containers
- American Society of Mechanical Engineers (ASME) Code Case in Work/ASME BPV Project Team on Hydrogen Tanks and Section X

All qualification vessels have successfully been fabricated and completed through the following tests:

- Hydrostatic Burst
- Ambient Pressure Cycle Test
- Leak Before Burst Test
- Penetration Test
- Environmental Test
- Flaw Tolerance Test
- High Temperature Creep Test
- Accelerated Stress Rupture Test
- Extreme Temperature Cycle Test
- Natural Gas Cycle Test with Blow-down

Qualification of the ISO Frame

A complete assembly was constructed including ISO frame, four pressure vessels, and all relevant plumbing including pressure relief system. The following tests were performed on the entire assembly:

- Stress Analysis
- Dimensional Analysis
- Stacking
- Lifting – Top and Bottom
- Inertia Testing

- Impact Testing
- Bonfire Testing

American Bureau of Shipping has successfully approved the entire ISO assembly for production including, pressure vessels, ISO frame and subsequent valves, fittings and pressure relief system.

Trade Study for a 5,000 Psi Pressure Vessel

A trade study were undertaken to evaluate potential targets that would increase utilization storage design that best meet or exceed DOE targets. Lincoln Composites existing Titan Module was used as the baseline for the studies and a gap audit was conducted.

Design Baseline

- Intermodal ISO 668 1A Frame
- Four Type 4 Pressure Vessels
 - 250 bar Working Pressure
 - Carbon Fiber, 2.35 Stress Ratio

Gap Audit

- Increase Capacity (kg of hydrogen per liter)
 - Increase pressure and/or utilization
 - From 0.018 kg to 0.03 kg of hydrogen per liter
 - From 616 kg to 700 kg hydrogen capacity at 15°C
- Decrease Cost (\$ per kg hydrogen)
 - From \$500 per kg to \$452 per kg hydrogen

Cylinder size was identified as a potential candidate for increase capacity through the increase of utilization of space. The study compared Lincoln Composites current four vessel configuration with a single large diameter vessel. Space utilization for the current Titan assembly is roughly 60% in volume while replacing it with a single, large tank would increase the utilization to 63%. However, when looking at the sheer size of a single tank, the thickness of a liner to manufacture this tank would not be very efficient and will have its limitations; i.e. pipe extrusion, and injection molding of the domes.

Lincoln Composites also looked at different scenarios of packing of pressure vessels within the current ISO frame. First scenario was to add an additional vessel down the center of the existing four vessels. This would increase the utilization of space to 68% from 60%, but the manufacturing of a small diameter tank that would fit in the available space would be difficult to achieve. This is due to the length/diameter (L/D) ratio. When this number becomes large, the tanks begin to bend due to the weight and decreased strength of the liner. Straightness is a key factor when trying to place the vessels next to each other within the frame.

This also increases the cost of the plumbing of the system. Second scenario is eight cylinders packed in a 3x2x3 matrix within the existing ISO frame. This arrangement would actually reduce the utilization from 60% to 56%. Lastly, Lincoln Composites performed a study to determine the potential to have many smaller cylinders packed within the frame assembly. Ninety-one smaller cylinders could be packed vertically with the frame. Again, the L/D ratio would increase and thus affect straightness and winding stability. If this were done, utilization would increase from 60% to 68%. However, the additional cost of plumbing this configuration would increase as well as the complexity of servicing the cylinders.

A third factor that was investigated through the study was to look at raising working pressure to increase compressed hydrogen density. By raising working pressure from 3,600 (250 bar) to 5,000 psi (350 bar) we could potentially see an increase of 33% in capacity at 15°C. Higher concentrations could be achieved at higher pressures, however cost increases need to be considered. As can be seen in Figures 2 and 3, the practical limit is 5,000 psi (350 bar). These costs are driven by several factors, i.e. higher pressures exacerbate thick-wall effects and reduced strength translation, the availability of high pressure plumbing hardware and the availability of hydrogen compressors.

Storage temperature was also investigated as a means to increase hydrogen density. As can be seen in Figure 4, with a decrease in storage temperature to -40°C, the current 3,600 psi tank could potentially see an increase of 33% in hydrogen density. With respect to a 5,000 psi tank, reducing the storage to the same temperature, -40°C, has the potential to increase hydrogen density by 61%. However, cold storage adds cost to the system.

Lincoln Composites also looked at full module costs as well as costs to manufacture pressure vessels for the Titan product line. The breakdown of costs associated with a full

bulk hauling module and individual pressure vessels are as follows:

- Module
 - Pressure vessels make up approximately 72% of the total cost.
 - Frame and hardware make up approximately 28% of the total cost.
- Pressure vessel
 - End bosses make up approximately 3% of the total cost.
 - High-density polyethylene (HDPE) liner makes up approximately 11% of the total cost.
 - Composite material makes up approximately 86% of the total cost.

As part of the cost factor associated with this study, Lincoln Composites evaluated scenarios to reduce costs in

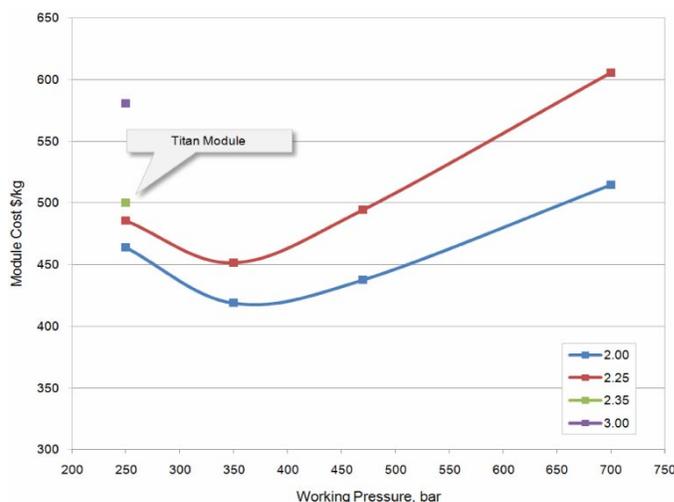

FIGURE 3. Working Pressure vs. Module Cost (\$/kg)

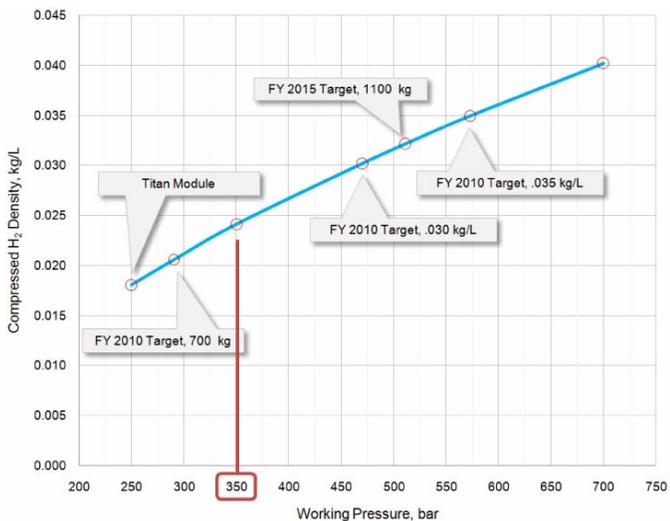

FIGURE 2. Working Pressure vs. Compressed Hydrogen (kg/L)

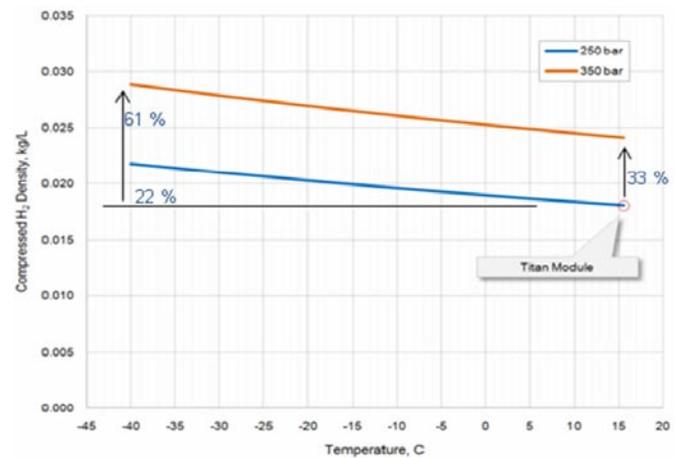

FIGURE 4. Temperature vs. Compressed Hydrogen Density (kg/L)

both the liners and the composite materials. Liner costs are associated with HDPE tubes/domes and the steel end bosses. Current construction and design of the liner shows that we are presently at minimum thickness/diameter ratio and any changes would result in difficulties in liner fabrication and filament winding of the vessel. The end bosses are constrained by the current mounting scheme and cost savings would be minimal if changes were made. As for the composite costs, the carbon fiber that is currently being used in the design contributes the lowest stress ratio of allowable fibers at 2.35. Current fiber possesses the greatest strength per unit cost. There are higher strength carbon fibers in existence but would have a 2-4 times increase in cost for a 15-40% increase in strength.

The last factor evaluated was that of reduction of stress ratio. By reducing the stress ratio, one could in turn lower the amount of carbon needed in the assembly of the pressure vessels and thus lower the cost of fiber used.

- Current Titan stress ratio is 2.35 based on compressed natural gas requirements
- ASME H2 allows for a 2.25 stress ratio
- 2.00 stress ratio is considered safe

Conclusions and Future Directions

Proposed objectives for Phase 1 of this project were completed in the fourth quarter of 2009. This includes successful completion of a large 3,600 psi pressure vessel able to contain 8,500 liter water capacity. The successful

qualification of an entire assembly into an ISO container was also completed. Lincoln Composites will continue to evaluate cost reductions in design of the vessel as well as in the manufacturing processes. Pursuant of a higher pressure vessel is underway and will continue.

Trade studies have been completed for a increased service pressure of our current 3,600 psi Titan assembly. Based on the findings of this study, the logical next step is as follows:

- 5,000 psi pressure vessel design
- 2.25 stress ratio design will fit current Titan frame
- Will see an increase from 0.018 to 0.024 kg of hydrogen per liter
- Will see a hydrogen capacity increase from 616 to 822 kg of hydrogen
- Cost per kg of hydrogen would decrease from \$500 to \$452
- Cold storage would add cost
- Adding cylinders to the assembly adds cost

Future work will involve the fabrication and testing of a 5,000 psi pressure vessel. This will show results more closely to the targets for hydrogen storage.

less than \$9 M (compressor package of \$5.4 M) for 240,000 kg/day system.

- Reduce package footprint and improve packaging design. Achieve transport delivery costs below \$1/gasoline gallon equivalent (gge) (\$2008 goal).
- Reduce maintenance cost to below 3% of total capital investment.
- Increase system reliability to avoid purchasing redundant systems.
- Maintain hydrogen efficiency (as defined by DOE) to 98% or greater.
- Reduce H₂ leakage to less than 0.5%.

Technical Barriers

This project addresses the following technical barriers from the Delivery (Section 3) of the Fuel Cell Technologies Program Multi-Year Research, Development, and Demonstration Plan [1]:

(B) Reliability and Costs of Hydrogen Compression

Technical Targets

The project has met the following DOE Targets as presented in DOE's 2007 Technical Plan for Hydrogen Delivery Projects [1] (Table 1).

Accomplishments for Phases I and II (completed from 2008 to 2010) and Phase III (in progress)

Developed computer models to aid in analysis of hydrogen compressor:

- System Cost and Performance Model
 - Suitable as a macro for DOE "HDSAM v2.0" economics model.

Fiscal Year (FY) 2011 Objectives

Develop and demonstrate an advanced centrifugal compressor system for high-pressure hydrogen pipeline transport to support DOE's strategic hydrogen economy infrastructure plan.

- Delivering 100,000 to 1,000,000 kg/day of 99.99% hydrogen gas from generation site(s) to forecourt stations.
- Compressing from 350 psig to 1,000 psig or greater. Reduce initial installed system equipment cost to

- Identifies hydrogen compressor package performance and component cost with respect to a variety of compressor-gearbox configurations.
- System Reliability and Maintenance Cost Model
 - Estimates comparative reliabilities for piston and centrifugal compressors for pipeline compressors developed.
 - Failure Mode and Effects Analysis (FMEA) for component risk and reliability assessment.
 - Estimates operation and maintenance costs for compressor system.
 - Uses Federal Energy Regulatory Commission operation and maintenance database as the basis for determining the maintenance costs for a centrifugal compressor.
- Anti-surge algorithm developed to assist in controls analysis and component selection of preliminary design (completed) and detailed design of pipeline compressor module (in progress).
- Compressor design conditions confirmed by project collaborators.
 - $P_{inlet} = 350$ psig, $P_{outlet} = 1,250$ psig; flow rate = 240,000 kg/day.
 - A six-stage, 60,000 revolutions per minute (rpm), 3.6 (max) pressure ratio compressor with a mechanical assembly of integrally geared, overhung compressor impellers.
 - Stress analysis completed.
 - Volute (compressor housing) design in progress for two-stage prototype.
 - Rotordynamics completed to verify shaft-seal-bearing integrity at operating speeds.
- Completed critical component development (compressor rotor, shaft seal, bearings, gearing, safety systems) and specifications for near-term manufacturing availability.
- Completed detailed design and cost analysis of a complete pipeline compressor and a laboratory-scale prototype for future performance lab verification testing.
- Completed a two-stage laboratory prototype compressor system to verify mechanical integrity of major components at full power ratings per stage.

Introduction

The DOE has prepared a Multi-Year Research, Development, and Demonstration Plan to provide hydrogen as a viable fuel for transportation after 2020, in order to reduce the consumption of limited fossil fuels in the transportation industry. Hydrogen fuel can be derived from a variety of renewable energy sources and has a very

high Btu energy content per kg, equivalent to the Btu content in a gallon of gasoline. The switch to hydrogen-based fuel requires the development of an infrastructure to produce, deliver, store, and refuel vehicles. This technology development is the responsibility of the Production and Delivery sub-programs within the DOE. The least expensive delivery option for hydrogen involves the pipeline transport of the hydrogen from the production sites to the population centers, where the vehicles will see the highest demand, and thus, have the greatest impact on reducing the U.S. dependency on fossil fuel. The cost to deliver the hydrogen resource to the refueling stations will add to the ultimate cost per kg or per gallon equivalent that needs to be charged for the hydrogen fuel. Therefore, it is necessary that the cost to deliver the hydrogen be as kept as low as possible, which implies that the cost of the compressor stations, their installation costs, and their efficiency in pumping the hydrogen fuel to the refueling stations must be kept low. DOE has set a target of \$1/gge (\$2008 goal).

The delivery cost target can be met if the compressor system can be made more reliable (to reduce maintenance costs), more efficient (to reduce operation costs), and be a smaller, more complete modular package (to reduce the compressor system equipment, shipment, and its installation costs). To meet these goals, the DOE has commissioned Concepts NREC with the project entitled: The Development of a Centrifugal Hydrogen Pipeline Gas Compressor.

Approach

A three-phase approach has been programmed to implement the technical solutions required to complete a viable hydrogen compressor for pipeline delivery of hydrogen. This approach is summarized in Figure 1.

The technical approach used by Concepts NREC to accomplish these goals is to utilize state-of-the-art aerodynamic/structural analyses to develop a high-performance centrifugal compressor system for pipeline service. The centrifugal-type compressor is able to provide high pressure ratios under acceptable material stresses for relatively high capacities – flow rates that are higher than what a piston compressor can provide. Concepts NREC's technical approach also includes the decision to utilize commercially available, and thus, proven bearings and seal technology to reduce developmental risk and increase system reliability at a competitive cost. Using its expertise in turbomachinery analysis, design, machining, and testing, Concepts NREC is researching the use of a material that is compatible with hydrogen and that can enable the highest possible impeller tip speeds, reducing the number of required stages while meeting DOE's goals for overall pressure ratio and efficiency. In order to minimize the development time and ensure industrial acceptance of the design for the new pipeline compressor system, Concepts NREC has assembled a project team that will assist in the advanced engineering of the compressor while also preparing an implementation

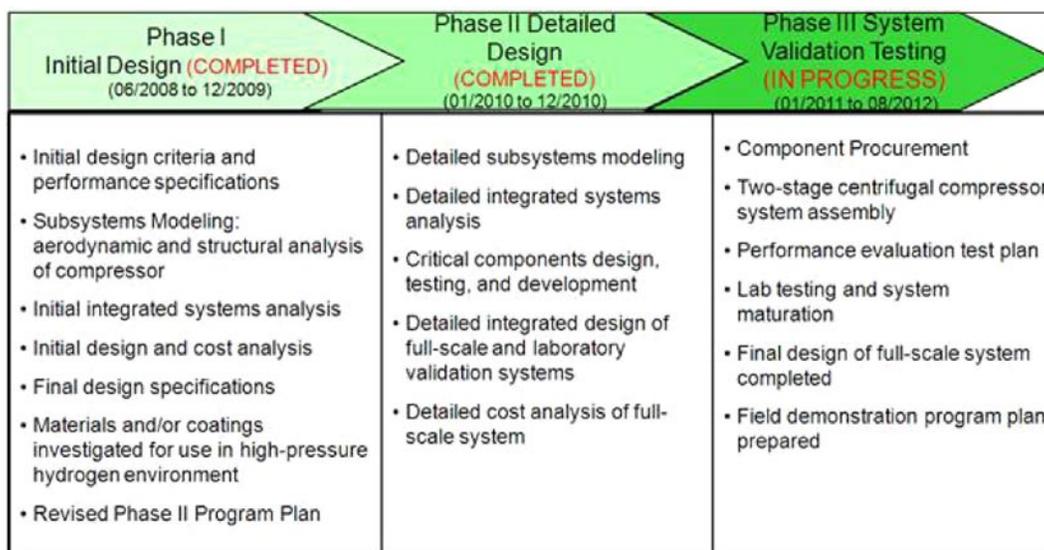

FIGURE 1. Three-Phase Project Approach

plan that can provide for near-term industrial pipeline applications.

The engineering challenge to implement this technical approach is to design a compressor stage that can achieve the highest acceptable pressure ratio and thermodynamic efficiency per stage, while also using as few stages as possible and employing the smallest diameter impeller. For centrifugal-type compressors, the pressure ratio is proportional to the square of the rotor speed (rpm^2) and the square of the radius (radius^2). Thus, even a small increase in tip speed or impeller radius results in significant increases in pressure. The aerodynamic design challenge in reducing the number of stages is to maximize tip speed of the centrifugal compressor impeller while staying within acceptable design safety levels of the strength limitations of the material, in addition to utilizing advanced diffuser systems to maximize recovery of dynamic head into static pressure. However, material stresses also increase proportionally to rpm^2 and radius^2 , and also by material density. Ultimately, the major constraint is imposed by the limitations of the maximum stress capability of impeller material. This constraint is further aggravated by the need for the material selection to consider the effects of hydrogen embrittlement on the strength of the material. The selection of a rotor material that can enable the high tip speeds to be achieved while avoiding damage from hydrogen embrittlement was selected as the major technical challenge for the project. To eliminate other more conventional challenges when developing a new compressor, the engineering directive was also to select only commercially available components that are operated within the manufacturer's design guidelines for state-of-the-art materials, loads, stresses, operating speeds, and power ratings. Principal among these components is the choice of the bearings, shaft seals, gearing, and hydrogen controls and safety instrumentation.

Concepts NREC has met all of these engineering challenges in order to provide a pipeline compressor system that meets DOE's specifications for near-term deployment.

Results

Concepts NREC has developed several computer design models that have helped to optimize the design choice for the pipeline compressor module that complies with DOE requirements. These models include:

1. Compressor Package Performance and Cost Model using algorithms to determine the relative component cost and operational risks.
2. FMEA and Engineering Reliability and Maintenance Cost Model [2,3].
3. Completed detailed mechanical integration of compressor rotor-drive shaft with gearbox.
4. Detailed design of a six-stage centrifugal compressor module.
5. Detailed design of a 2-stage laboratory prototype compressor system for testing the mechanical integrity of the major compressor components: rotor, shaft seal, bearings, and gearing.
6. Successfully machined and spun compressor rotor (60,000 rpm to operating speed).

The engineering analysis conducted in Phase I and continuing in Phase II resulted in the design of the pipeline compressor package shown in Figure 2. The complete modular compressor package is 29 ft long x 10 ft tall x 6 ft wide at the base x 8 ft wide at the control panel, approximately one-half of the footprint of a piston-type, hydrogen compressor. The packaged module can be transported to the installation site as a pre-assembled

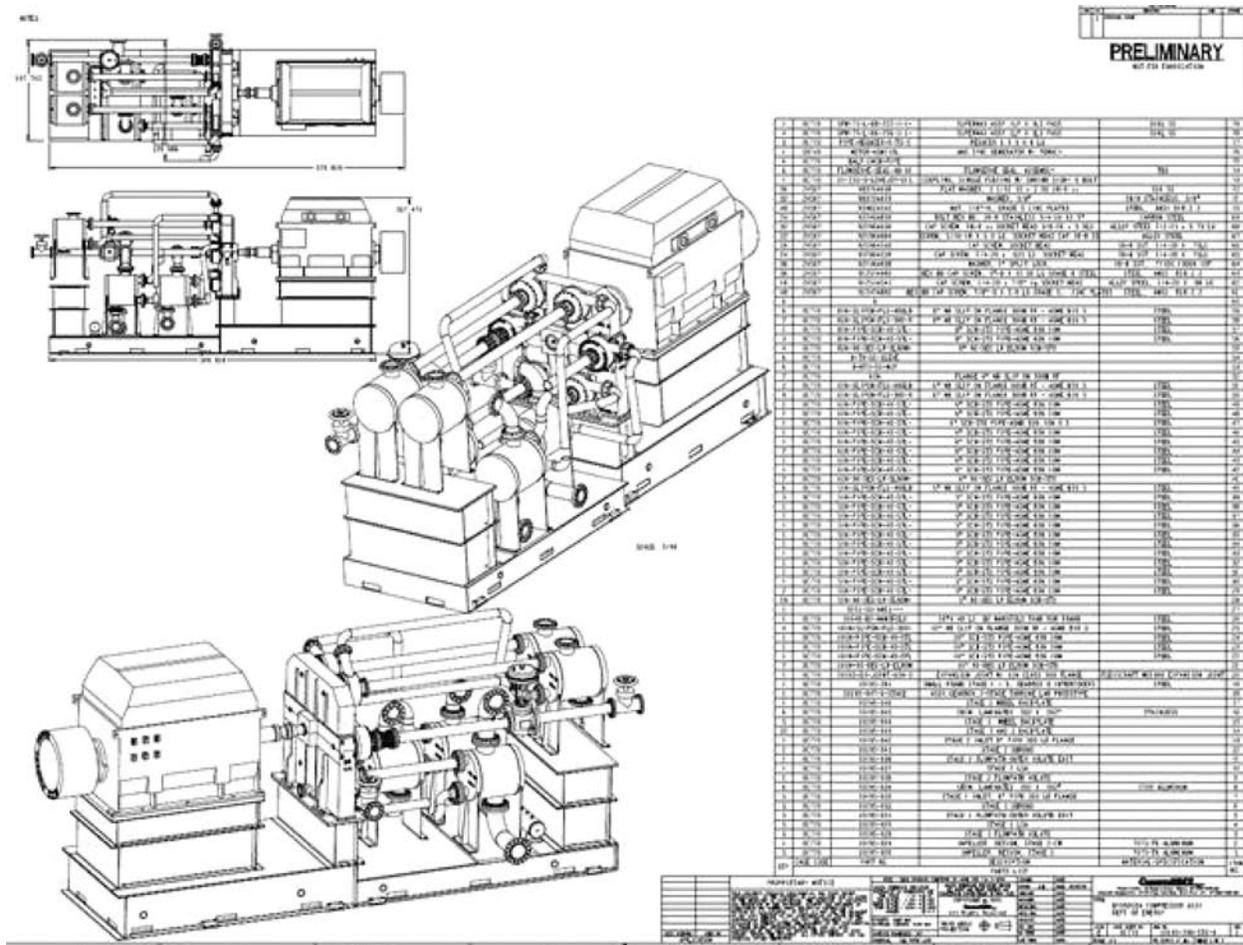

FIGURE 2. Engineering analysis and design results: pipeline hydrogen centrifugal compressor 240,000 kg/day; 350 to 1,285 psig; 6,300 kWe.

package with a minimum of final alignment, water piping and electrical power connections, and instrumentation and controls start-up.

The compressor selection uses six stages, each operating at 60,000 rpm with a tip speed of less than 2,100 ft/s. Each compressor rotor and drive shaft is 8 inches in diameter and has an overall stage efficiency of between 79.5 and 80.5%, for an overall compressor efficiency of 80.3%. The first and last stages have a slightly different length which helps to improve the rotordynamics for the last stages. Each compressor impeller is a single, overhung (cantilevered) impeller attached to a drive shaft that includes a shaft seal, bearing, and drive pinion (Figure 3) integrated with the gearbox drive. The impeller rotor is designed without a bored hub in order to reduce the hub “hoop” stresses. This requires the impeller to be mechanically attached to the high-strength steel alloy, a drive shaft with a patented design attachment system that enables the rotor to be removed from the gearbox without removing the drive shaft, and thus does not disturb the shaft seal and bearings. A gas face seal will provide the isolation of the hydrogen from

the lubricating oil. The 1,400 hp per stage can be sustained by using two tilting-pad hydrodynamic bearings on either side of a 2.5-inch-long drive-pinion gear. The face seal and bearings are commercially available from Flowserve and KMC, respectively. The pinion and bull gear is part of a custom gearbox manufactured by Artec Machine Systems representing NOVAGEAR (Zurich, Switzerland) and utilizes commercially available gear materials that are subjected to stresses and pitch line speeds that meet acceptable engineering practice.

Also shown in Figure 3 is the encasement of each compressor rotor and (pressure recovery) volute. The encasement is made of nitronic-50 steel that is designed to sustain the highest compression pressure.

The material chosen for the compressor rotor and volute is an aluminum alloy. The choice is based on its mechanical strength-to-density ratio or (S_{yield}/ρ) which can be shown to be a characteristic of the material’s ability to withstand centrifugal forces. Several grades of aluminum have a strength-to-density ratio that is similar to titanium and high-strength steels at the 140°F (max) operating temperatures that

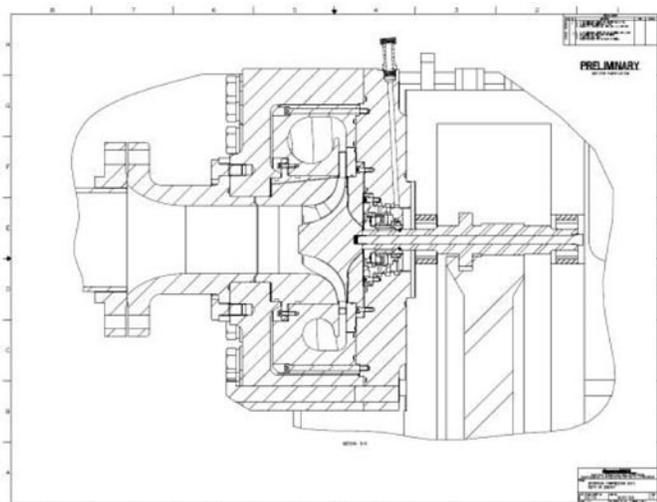

FIGURE 3. Mechanical Detailed Assembly of One of Six Stages of Pipeline Compressor

will be experienced by the hydrogen compressor. However, unlike titanium and most steels, aluminum is recognized by the industry as being very compatible with hydrogen.

Aluminum also helps to reduce the weight of the rotor, which leads to an improved rotordynamic stability at the 60,000 operating speed. A rotor stability and critical speed analysis has confirmed that the overhung design is viable. The 1st stage compressor rotor has been manufactured (Figure 3) and successfully spun to its 60,000 operating speed. A subsequent fluorescent penetrant inspection and strain measurements of the rotor after the spin test indicated no creep or micro-crack design flaws as a result of the test.

The project team includes researchers at Texas A&M, led by Dr. Hong Liang, who are collaborating with Concepts NREC to confirm the viability of aluminum alloys for this compressor application. Also assisting with a collegial collaboration of suggestions are several national laboratories, including: Sandia National Laboratories (fracture mechanics testing; Dr. Chris San Marchi), Savannah River National Laboratory (specimen “charging” with hydrogen plus tensile testing with H₂; Dr. Andrew Duncan and Dr. Thad Adams), and Argonne National Laboratory (Dr. George Fenske).

The Phase II work also completed the detailed design of a closed-loop one and two-stage prototype compressor modules. One of these modules will be selected for laboratory testing in Phase III of the project. The laboratory prototype is shown in Figure 4.

Conclusions and Future Directions

- An advanced pipeline compressor system has been designed that meets DOE’s performance goals for:
 - High reliability with 350 to 1,200⁺ psig compression of 240,000 kg/day at 98% hydrogen efficiency.

- Footprint 1/4 to 1/3 the size of existing industrial systems at projected cost of less than 80% of DOE’s target.
- Utilize state-of-the-art and acceptable engineering practices to reduce developmental risk and provide a near-term solution for the design of a viable hydrogen pipeline compressor:
 - Aerodynamic/structural analyses for acceptable material (7075-T6 and Nitronic-50) stresses in hydrogen.
 - Industrially proven bearings, seal technology, gearing, heat exchangers, and lube system.
- Aerodynamic analysis and design of a cost-effective, 6-stage centrifugal compressor and a 2-stage full-power lab prototype have been completed. The 1-stage laboratory prototype will be tested at Praxair’s facility.
- The collaborative team consists of Praxair, an industrial technical experienced user and host of lab prototype test; a materials researcher, Texas A&M; a hydrogen refueling industry consultant, HyGen; and the coordinated technical support of several national labs.
- Complete materials coating testing of specimens with Texas A&M: actual rotor forensics after high-speed testing as necessary.
- Start the procurement of major components for the laboratory testing of a prototype compressor-gearbox in Phase III; prepare test plan for lab test and coordination with Praxair.

The preliminary engineering and design of an advanced pipeline compressor system has been completed and meets DOE’s performance goals for a reliable 98% hydrogen efficiency compressor system, with a footprint one-half the size of existing industrial systems and at a projected

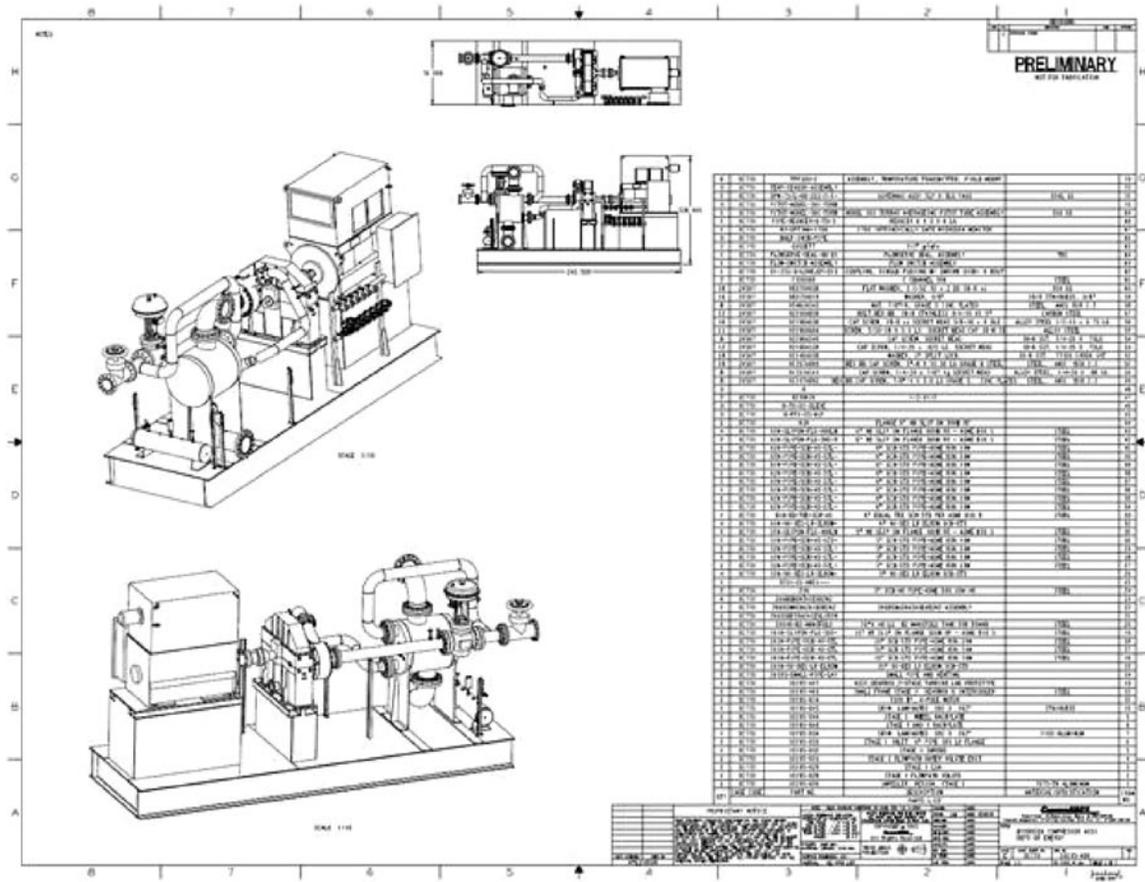

FIGURE 4. Detailed Design of a 1-Stage, Laboratory Prototype Compressor

system cost of approximately 75% of DOE’s target, and a maintenance cost that is less than the \$0.01/kWh. The detailed analysis of this pipeline compressor system is in progress in Phase II of the project. The advanced centrifugal compressor-based system can provide 240,000 kg/day of hydrogen from 350 to 1,280 psig high for pipeline-grade service. This has been accomplished by utilizing a state-of-the-art aerodynamic and structural analysis of the centrifugal compressor impeller to provide high pressure ratios under acceptable material stresses. The technical approach that has been successfully implemented includes using commercially available, and thus proven, bearings and shaft seal technology. This technical approach reduces the developmental risk and increases system reliability while maintaining a competitive cost.

The resultant design provides a compressor that not only meets DOE’s hydrogen plan for using pipeline delivery, but also a compressor package that can be used by the industrial, hydrogen gas industry where there is presently 1,200 miles of pipeline providing 9 million tons per year of hydrogen gas for industrial process chemical applications. The collaborative team that has been assembled consists of an industrial user who has experience with hydrogen as a

fuel source and as an industrial gas, a materials researcher (Texas A&M), and a consultant (HyGen Industries) with hands-on experience with the hydrogen refueling industry. This team is committed to producing the first commercially reliable hydrogen compressor for hydrogen pipeline delivery.

Future efforts include:

Phase III System Component Procurement, Construction, and Validation Testing (January 2011 to September 2012):

- Continue materials testing at Texas A&M University with hydrogen to determine effects of coatings that can be used with titanium.
- Component procurement for the 1- or 2-stage functional hydrogen compressor system.
- Assembly of the 1-stage centrifugal compressor system.
- Coordinating the integration of a laboratory prototype compressor module for testing with hydrogen.
- Conduct aerodynamic testing and assessment of mechanical integrity of the compressor system.

Patents Issued

1. Patent application filed on several innovations for centrifugal compressor design; filed March, 2010 (provision file March, 2009: SN 60/896985): “Centrifugal Compressor Design for Hydrogen Compression”.

Contract Number: DE-FG36-08GO18060

Subcontractor:
 Mitsubishi Compressor Company (MHI), Hiroshima, Japan

Project Start Date: September 25, 2008
 Project End Date: August 31, 2012

TABLE 1. Technical Targets for Hydrogen Compression

Category	2005 Status	FY 2012	FY 2017
Reliability	Low	Improved	High
Energy Efficiency	98%	98%	>98%
Capital Investment (\$M) (based on 200,000 kg of H ₂ /day)	\$15	\$12	\$9
Maintenance (% of Total Capital Investment)	10%	7%	3%
Contamination	Varies by Design		None

FY 2011 Accomplishments

- System cost analysis
- Off-design performance estimation
- Single-stage test rig design
- Manufacturing of the single-stage test rig

Fiscal Year (FY) 2011 Objectives

Demonstrate key technologies needed to develop reliable and cost-effective centrifugal compressors for hydrogen transport and delivery:

- Eliminate sources of oil/lubricant contamination.
- Increase efficiency by using high rotational speeds.
- Reduce system cost and increase reliability.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Delivery section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (B) Reliability and Costs of Hydrogen Compression
- (I) Hydrogen Leakage and Sensors

Technical Targets

This project is directed towards the design, fabrication and demonstration of the oil-free centrifugal compression technology. It will identify the key technological challenges for development of a full-scale hydrogen/natural gas centrifugal compressor. The project addresses the following DOE technical targets from the Hydrogen Delivery section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan (see Table 1).

Introduction

One of the key elements in realizing the hydrogen economy is the deployment of a safe, efficient hydrogen production and delivery infrastructure on a scale that can compete economically with current fuels. The challenge, however, is that hydrogen, the lightest and smallest of gases with a lower viscosity than natural gas, readily migrates through small spaces. While efficient and cost effective compression technology is crucial to effective pipeline delivery of hydrogen, today's positive displacement hydrogen compression technology is very costly, and has poor reliability and durability, especially for components subjected to wear (e.g., valves, rider bands and piston rings). Even so called "oil-free" machines use oil lubricants that migrate into and contaminate the gas path. Due to the poor reliability of compressors, current hydrogen producers often install duplicate units in order to maintain on-line times of 98-99%. Such machine redundancy adds substantially to system capital costs. Additionally, current hydrogen compression often requires energy well in excess of the DOE 2% goal. As such, low capital cost, reliable, efficient and oil-free advanced compressor technologies are needed.

Approach

The MiTi® team will meet sub-program objectives by conducting compressor, bearing and seal design studies; selecting components for validation testing; fabricating the selected centrifugal compressor stage, and the corresponding oil-free bearings and seals; and conduct testing of the high-speed, full-scale centrifugal compressor stage, and oil-free

compliant foil bearings and seals under realistic pressures, and flows in a hydrogen gas environment. Specific tasks include: (1) preliminary oil-free, multi-stage, high-speed centrifugal compressor system design; (2) detailed design of a full-scale centrifugal compressor stage; (3) mechanical component detailed design of the oil-free bearings, seals and shaft system needed to test the compressor stage; (4) test hardware fabrication for the single-stage compressor; (5) dynamic test; (6) compressor performance test; (7) system design refinement; and (8) project management and reporting.

Results

The design analysis of MiTi[®]'s proposed multi-stage, oil-free, hydrogen compressor was continued and refined. The proposed hydrogen compressor is a direct drive, multi-stage, double-entry, centrifugal compressor. Two system design points have been analyzed:

- Design Point 1: $P_{IN} = 500$ psig, $P_{OUT} = 1,200$ psig, Flow= 500,000 kg/day
- Design Point 2: $P_{IN} = 350$ psig, $P_{OUT} = 1,200$ psig, Flow= 240,000 kg/kay

For design point 1, the proposed system consists of nine stages operating at 56,414 rpm at relatively conservative tip speeds, affording a reasonable safety margin. This approach is referred to as the “high-margin” design. To achieve design point 2, higher relative tip speeds were used to achieve the required pressure and flow in six stages operating at 65,000 rpm. This approach is referred to as the “high-performance” design. To validate the feasibility of the two approaches, further detailed design and cost analysis have been conducted. Experimental validation and proof of concept will be performed in FY 2012 with a single-stage compressor test rig that has been designed and is presently being developed. Based on the scope of this project and funding made available for this effort, the single-stage compressor is being based on design point 1.

TABLE 2. Critical Nondimensional Parameters to Satisfy the Type 2 PTC-10 Test

Quantity	Symbol	Design Point Values	Type 2 Permissible Deviation
Specific Volume Ratio	v_i/v_d	1.072	1.018 – 1.126
Flow Coefficient	Φ	0.1253	0.120 - 0.130
Machine Mach No.	M_n	0.3266	0.141 - 0.532
Machine Reynolds No.	Re_m	$1.55e^6$	$1.55e^5 - 1.55e^7$

A detailed model of the proposed single-stage test rig is shown in Figure 1. The impeller and volute of the single-stage test rig are identical to that of a single stage within the first frame of the nine-stage system. The stage will be driven with two MiTi[®] oil-free electric motors, coupled together to produce up to 200 kW of shaft power. The test rig will be totally oil-free using MiTi[®] foil bearings and foil seals. The purpose of the single-stage testing is to validate the thermodynamic performance of the proposed centrifugal compressor design, as well as the rotor/bearing system performance under realistic speed and stress conditions expected in the nine-stage system. In order to validate the performance predictions, single stage testing will be conducted per American Society of Mechanical Engineers (ASME) performance test code 10 (PTC-10). This test code provides explicit test procedures to determine compressor thermodynamic performance with a high level of accuracy. There are two types of tests described within PTC-10; type 1 and type 2 tests. A type 1 test is one conducted with the design gas, at the design point. Under the scope of this project, testing with hydrogen is not feasible; therefore, a type 1 test will not be conducted. Since testing with all possible gases at all test conditions is often not feasible, ASME established the type 2 test based the standard design practice of compressor similitude. With this approach, key nondimensional parameters are maintained constant in testing so that thermodynamic performance of a compressor

stage in one gas would apply to other gases and at other test conditions. The critical nondimensional parameters of the test stage to be held constant (within a permissible deviation) are listed in Table 2 along with the calculated values at the design point.

In the type 2 test, a similitude gas may be substituted for the design gas as long as nondimensional parameters are kept within specified limits. For this investigation, the best similitude gas is helium. Helium is an affordable and safe alternative to hydrogen with a similarly low molecular weight. It is critical that the first compressor stage performance testing not be complicated with the issues of hydrogen embrittlement. The issues of material compatibility and

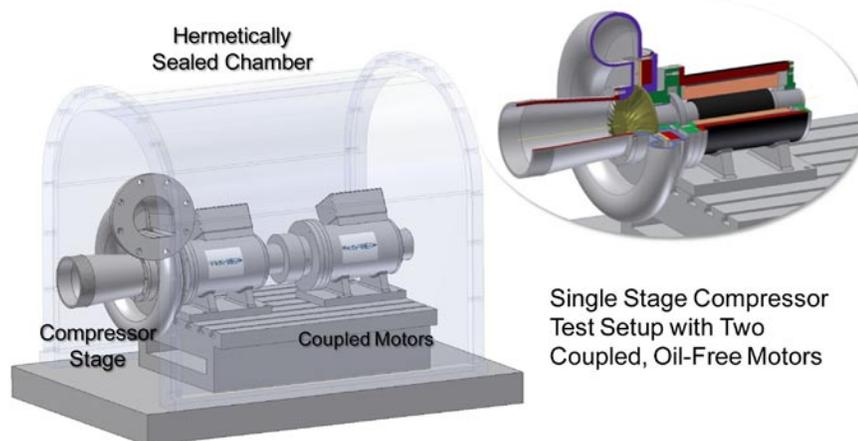

FIGURE 1. Detailed Model of the Single-Stage Compressor with Dual-Drive, Oil-Free Electric Motors

embrittlement are being addressed in a parallel effort in this project, but these two issues are not integrated at this time. The use of helium in these first compressor performance tests allows us to focus on aerodynamic and thermodynamic characterization and to establish a performance baseline so that any performance effects, due to embrittlement, will be apparent at a later time.

Presently, no single, direct-drive 200 kW drive motor capable of operating at 56,000 rpm exists. MiTi® has developed (with internal funds) the 60,000 rpm 100 kW motor. Since the objective of this project is to demonstrate the thermodynamic performance of the compressor, MiTi® has opted to couple two high speed 100 kW motors together to provide the needed drive power rather than develop a single 200 kW, direct drive motor. To assure stable operation of the proposed dual motor drive system for the single stage compressor, detailed rotordynamic analysis was performed. The finite element model of the coupled shaft system is shown in Figure 2. The compressor is rigidly attached to the shaft on the left. The two rigid shafts are connected by a flexible coupling (a proprietary technology developed by MiTi®). Each individual shaft is supported on MiTi® compliant foil journal and thrust bearings.

Appropriate stiffness and damping values for bearings were selected and rotordynamic analysis was conducted with DyRoBes® software (Eigen Technology Inc.). The analysis indicates that each individual shaft will be operating safely below its bending critical speed (Figure 3). All bending within the system will occur within the flexible coupling, as designed, and as has been demonstrated by MiTi® in numerous other applications. With design and analysis of the single stage test rig complete, manufacturing of the parts was initiated and is currently in progress.

In a parallel effort MHI is designing a single entry centrifugal compressor and a single-stage compressor for performance validation with assistance of MiTi®. The primary difference between the two approaches is related to the inlet flow. The MiTi design uses a double-entry technique, which splits mass flow evenly between two inlets at either end of the shaft. The benefit of this approach is inherently balanced thrust forces. The MHI design uses a single-entry approach that requires a balance piston to resolve excessive thrust loads. The advantage of this approach is that it allows for easy manipulation of axial clearance at all compressor impellers.

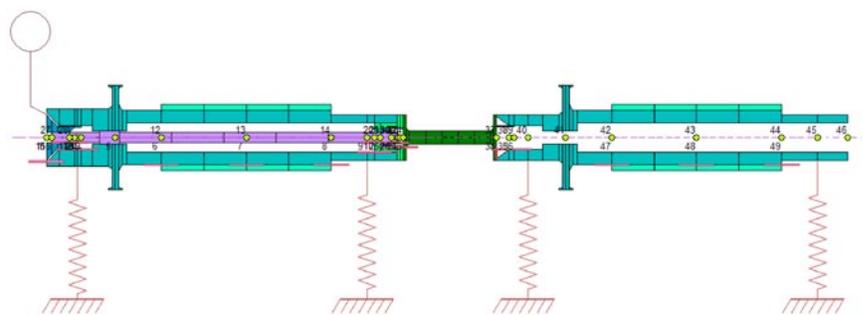

FIGURE 2. Finite Element Model of the Single-Stage Compressor And Dual-Drive System

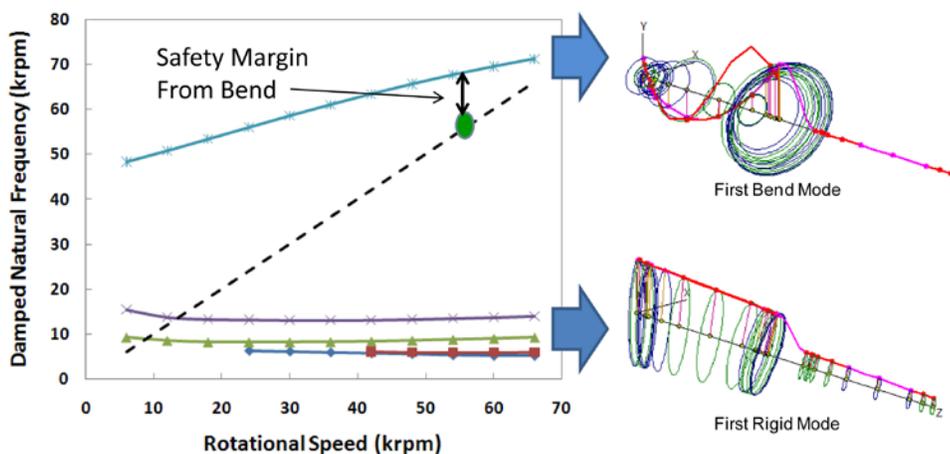

FIGURE 3. Rotordynamic Analysis of the Dual Drive Single-Stage Compressor

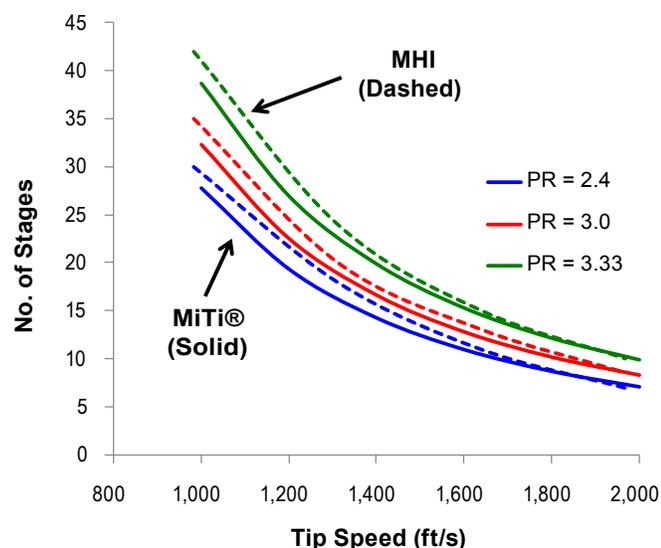

FIGURE 4. Estimation of Number of Stages Required as a Function of Tip Speed And Pressure Ratio (PR)

Despite the differences in design approaches, the overall performance of the two systems will be very similar. In Figure 4, independent results from MiTi® and MHI are presented. The number of stages required to reach a particular pressure ratio are presented as a function of tip speed. Despite the use of double- and single-entry compressor designs, the results from MiTi® and MHI correlate well, especially at higher tip speeds within the expected operating range. This is because the inlet conditions, fluid properties and design point used for each concept were identical. MiTi® and MHI both assumed similar conditions and both employ highly sophisticated, but different, software design tools.

Conclusions and Future Directions

During this reporting period, further design refinement was conducted. To demonstrate the feasibility of MiTi®'s design concept, a single-stage test rig was designed and fabrication of components was initiated. In parallel, a single-entry compressor concept is being developed with guidance from MiTi® by MHI. The following tasks are planned for the remainder of FY 2011 and FY 2012:

- Complete fabrication of single-stage compressor components for testing.
- Validate the proposed single-entry and double-entry compressor designs using performance data from the single-stage compressors.

Contract Number: DE-EE0003727

Subcontractor:
 Sustainable Innovations, LLC, Glastonbury, CT

Start Date: July 15, 2010
 End Date: July 14, 2013

- Multi-stage compression of hydrogen from near-atmospheric pressure to 6,000-12,000 psi.
- Ensure no possibility of lubricant contamination of the hydrogen from compression (DOE 2015 target).
- Reduce EHC specific energy consumption.
- Scale up EHC to a capacity of 2-4 lb/day H₂.

The ultimate goal of the project is to meet the DOE targets for forecourt compressors [1].

FY 2011 Accomplishments

- Hydrogen Pressure: reached 6,000 psi hydrogen pressure in a two-stage EHC system (Figure 1).
- Compression Efficiency: reduced specific energy consumption to <5 kWh/kg H₂ when compressing from atmospheric pressure to 2,000 psi (Figure 2).
- Hydrogen Recovery: achieved 95% hydrogen recovery in a single cell.
- Capital Cost: increased hydrogen flux from 400 to 750 mA/cm².

Fiscal Year (FY) 2011 Objectives

- Develop a solid-state electrochemical hydrogen compressor (EHC) building block capable of compressing hydrogen from near-atmospheric pressure to 2,000-3,000 psi.
- Study feasibility of an EHC multi-stage system capable of compressing hydrogen from near-atmospheric pressure to 6,000-12,000 psi.
- Increase compression efficiency to 95% (DOE 2015 target).

Technical Barriers

This project addresses the following technical barrier from the Hydrogen Delivery section (3.2) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(B) Reliability and Costs of Hydrogen Compression

Technical Targets

This project is directed at developing a solid-state EHC. The EHC is an enabling device for low-cost hydrogen delivery. Goals include the following:

- Single-stage compression of hydrogen from near-atmospheric pressure to 2,000-3,000 psi.

Introduction

With the depletion of fossil fuel reserves and a global requirement for the development of a sustainable economy, hydrogen-based energy is becoming increasingly important. Production, purification and compression of hydrogen represent key technical challenges for the implementation of a hydrogen economy, especially in the transportation sector where on-board storage of pure hydrogen may be required at

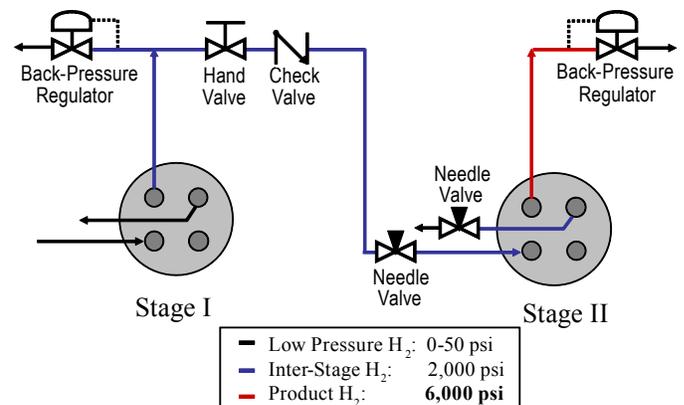

FIGURE 1. 2-Stage EHC System Concept

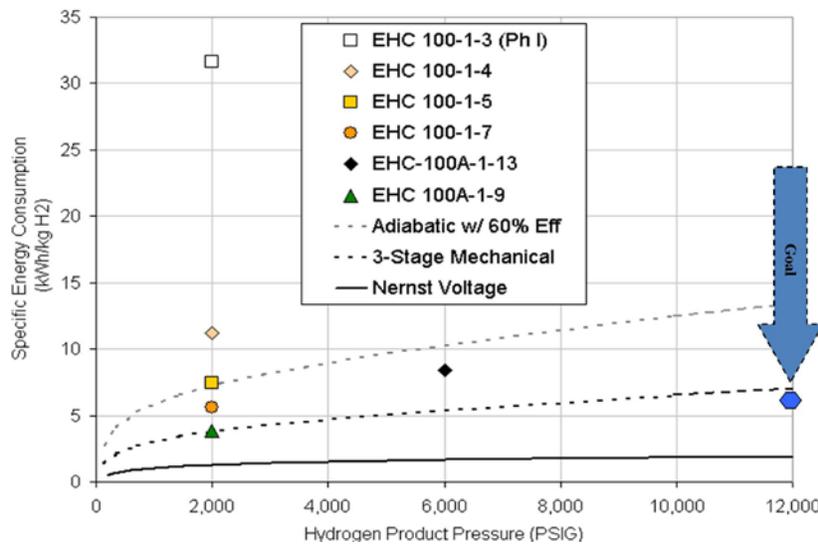

FIGURE 2. Reduction in the Specific Energy Consumption of the EHC

pressures up to 10,000 psi and compression of the hydrogen fuel up to 12,000 psi.

The level of maturity of current hydrogen compressor technology is not adequate to meet projected infrastructure demands. Existing compressors are inefficient and have many moving parts, resulting in significant component wear and therefore excessive maintenance. New technologies that achieve higher operational efficiencies, are low in cost, safe and easy to operate are therefore required. This project addresses high-pressure hydrogen needs by developing a solid-state EHC.

Approach

The approach to address the program goals consists of the following major elements:

- Increase hydrogen recovery efficiency by improving flow field design.
- Reduce capital cost by increasing the hydrogen flux.
- Reduce operating cost by improving membrane and electrode design.
- Develop a multi-stage system concept for compression to 6,000-12,000 psi.

To this end, the approach includes the design, fabrication and evaluation of improved cell architecture, and the development and demonstration of critical sealing technology to contain the high-pressure hydrogen within the EHC.

Results

A 2-stage EHC system concept was developed, in order to achieve higher hydrogen pressures using existing EHC

designs. The challenge was to design a system that can automatically respond to changes in pressure, inlet flow and current density, while maintaining stable operation in both stages. The system also needs to safely operate without attendants, in order to demonstrate continuous operation. The high level system configuration and control strategy that was developed in FY 2011 is shown in Figure 1. Atmospheric pressure hydrogen is fed to the low-pressure side of stage I. The pressurized hydrogen (inter-stage pressure) is then fed to the low-pressure side of the stage II EHC. A check valve prevents hydrogen from flowing back from stage II to stage I. The product hydrogen exits the stage II EHC at the desired high pressure. For safe operation of the laboratory system, this pressure is controlled by a back-pressure regulator. The concept was validated in the laboratory by compressing from atmospheric pressure to about 2,000 psi in the first stage, followed by compression to 6,000 psi in the second stage. Then it was operated for several weeks at a variety of inter-stage and product pressures, and at different hydrogen flow rates. This experience will provide a solid basis for designing a multi-stage system capable of reaching 12,000 psi, as shown in Figure 3. A product pressure of 12,000 psi is desirable in order to efficiently refuel hydrogen vehicle tanks with a maximum fill pressure of 10,000 psi. This pressure is needed to enable a driving range similar to gasoline-fueled vehicles, while preserving the passenger and cargo capacity of the vehicles.

A major challenge in the commercialization of the EHC is capital cost. One way to address this challenge is to increase the hydrogen flux by increasing the operating current density. This, however, could lead to a higher operating cost, due to increased specific energy consumption. The latter is proportional to the cell resistance. To lower the cell resistance, efforts were

FIGURE 3. Multi-Stage System Capable of Reaching 12,000 PSI

focused on lowering the bulk and contact resistances of key cell components, such as membrane and bipolar plates. Improvements to the cell design and materials enabled a reduction in specific energy consumption to below 5 kWh/kg H₂. This performance was obtained when compressing hydrogen from atmospheric pressure to 2,000 psi, as shown in Figure 2. The hydrogen recovery was as high as 95%. The improvements in membrane and bipolar plate materials also enabled the desired increase in current density, which leads to a higher hydrogen flux and therefore reduced capital cost. Continuous operation at 750 mA/cm² was demonstrated in a 1,000 hour test.

Conclusions and Future Directions

The feasibility of a 2-stage EHC system to increase the pressure capability has been demonstrated. Improvements

in materials have resulted in an 80% increase in hydrogen flux, which translates to a lower capital cost.

Future efforts will include further improvements in cell architecture, scale up and increase in pressure capability in a multi-stage system.

Contract Number: DE-FG36-08GO18063

Project Start Date: June 1, 2008
 Project End Date: June 30, 2011

Fiscal Year (FY) 2011 Objectives

Develop low-cost hydrogen liquefaction systems to produce 30 and 300 tons/day:

- Improve liquefaction energy efficiency.
- Reduce liquefier capital cost.
- Integrate improved process equipment invented since last liquefier was designed.
- Continue ortho-para conversion process development.
- Integrate improved ortho-para conversion process.
- Develop optimized new liquefaction process based on new equipment and new ortho-para conversion process.

Technical Barriers

This project addresses the following technical barrier from the Delivery section (3.2.4) of the Hydrogen, Fuel Cells and Infrastructure Technologies Program Multi-Year Research, Development and Demonstration Plan:

(C) High Cost and Low Energy Efficiency of Hydrogen Liquefaction

Technical Targets

TABLE 1. Technical Targets for Liquid Hydrogen Delivery

Characteristic	Units	2012 Target	2017 Target
Small-Scale Liquefaction (30,000 kg/day)			
Installed Capital Cost	\$	40M	30M
Energy Efficiency	%	75	85
Large-Scale Liquefaction (300,000 kg/day)			
Installed Capital Cost	\$	130M	100M
Energy Efficiency	%	>80	87

We are addressing the capital cost and energy efficiency targets.

Capital Cost:

- Improved process design.
- Improved process equipment.

Energy Efficiency:

- Increased equipment efficiency.
- Improved process efficiency.
- Improved ortho-para conversion efficiency with a goal of reducing energy required for ortho-para conversion by at least 33%.

FY 2011 Accomplishments

- Constructed improved test unit capable of operating over a temperature range from 77 K to about 150 K.
- Developed spreadsheet model to calculate energy requirements for hydrogen liquefaction.
- Identified problems with commercial process simulation software for modeling ortho and para hydrogen and worked with project supplier to solve the problems.
- Prepared and tested new materials for improved ortho-para conversion using recipes and equipment that produce materials similar to those that could be produced in commercial quantities.
- Developed process models for existing and proposed liquefier designs.
- Showed that overall power consumption can be reduced by about 2.5% if catalyst is used in the high-temperature heat exchanger.
- Identified a process where the demonstrated performance of the improved ortho-para conversion process is sufficient to reduce total power consumption.

- Identified a process where the performance of the improved ortho-para conversion process, even when accounting for future improvement, is unlikely to be sufficient to reduce total power consumption.
- Evaluated different compressors for small and large-scale hydrogen liquefaction.
- Calculated potential overall efficiency improvement due to improved process equipment.
- Demonstrated that the combined improvements due to using more efficient compressors (4-7%), more efficient expansion turbines (2-3%), more efficient heat exchangers (<1%), an improved liquefaction process (2%), and an improved ortho-para conversion process (3-6%) can all contribute to significantly improve efficiency and reduce power requirements, but not enough to meet the DOE goal.

Introduction

Hydrogen liquefiers are highly capital intensive and have a high operating cost because they consume a significant amount of electrical power for refrigeration. There are only a few hydrogen liquefiers in the world and only six currently operating in the U.S. These plants are not built frequently, so they have not been thoroughly optimized for today's equipment. Furthermore, many of them were built when power was much less expensive than it is today, so those plants do not have optimized efficiency.

Approach

This project focused on improving liquefier efficiency and reducing overall liquefaction cost, including reducing capital cost. The project attempted to accomplish these goals using three different aspects of an integrated approach:

- Improved process design – Develop a more efficient refrigeration process including ortho-para conversion and refrigeration using available streams and equipment.
- Improved process equipment – Integrate improvements made in process equipment since the most recent liquefier design to take full advantage of the increased capabilities and improved efficiency. Project the impact of further improvements in process equipment, including novel devices currently being developed.
- Improved ortho-para conversion process – Ortho-para conversion consumes a significant amount of refrigeration energy because it requires cooling at low temperatures. Improvements in ortho-para conversion can lead to a significant reduction in power requirements.

This project built on previous work done at Praxair, some of which was part of a project funded through Edison Materials Technology Center (EMTEC). The previous project demonstrated that the improvements in ortho-para conversion

were possible, but developing the complete optimized process design was beyond the scope of that project.

Results

The material screening test system used during the EMTEC project was recommissioned to perform additional material testing and test new materials. This system can test materials at the boiling point of the cooling fluid, such as liquid nitrogen. The system can test ortho-para conversion at pressures up to 400 psig and has the advantage of being a simple system that is excellent for preliminary screening of materials. Figure 1 shows this system. New materials work proceeded from the EMTEC project with new recipes and methods developed to provide samples with properties that more closely approximate those that would be obtained using commercial-scale materials manufacturing.

A pilot-scale system to conduct process testing on desired materials over a range of temperatures was built (Figure 2). This new test system is fully automated to allow for both remote control and material life testing. The system consists primarily of a series of pressure vessels, each of which houses a material bed. The annular space between the inside of the pressure vessel and the outside of the material bed contains a liquid coolant that can be pressurized. The ortho-para conversion process is conducted at very low temperatures (<150 K) and therefore a liquid coolant such as liquid nitrogen or liquid argon is required to achieve temperatures in this range. Each pressure vessel contains a vent line equipped with a back pressure control valve to allow for control of the liquid boiling pressure. By controlling the liquid boiling pressure, temperature can be controlled indirectly over a range of 77 K to 126 K using liquid nitrogen as the coolant and temperatures up to about 150 K using liquid argon.

This new test system was used to determine performance characteristics of the ortho-para conversion

FIGURE 1. Material Screening Test System

FIGURE 2. Pilot-Scale Test System

system. These results were used in the process model to determine the overall performance of a system using the improved ortho-para conversion process. These results are shown in Figures 3 and 4.

Modeling

Process simulations were developed for hydrogen liquefaction processes that used the improved ortho-para conversion process to compare those to processes that did not. Of the processes that did not use the improved ortho-para conversion process, it was found that adding ortho-para conversion catalyst to the high-temperature heat exchanger reduced overall energy consumption by about 2.5%.

Several different processes have been conceived that use the improved ortho-para conversion process. The modeling portion of the program compared these processes to hydrogen liquefaction processes with standard ortho-para conversion. Concept α and Concept β were evaluated. Figures 3 and 4 show the results.

The point in the center is the target based on ortho-para performance meeting the base case power target. The y-axis represents the power required for hydrogen liquefaction as a percentage of the base case power target. The x-axis shows ortho-para performance as a percentage of demonstrated performance in the laboratory. The target is based on demonstrated performance (100% of current ortho-para performance) meeting the base case power target. In this case, about 150% of the current demonstrated performance is required to meet the base case power target. Although there has been steady improvement in demonstrated performance throughout the project, marginal gains are lower than they were earlier in the project. It is unlikely that Concept α will meet the target required to be an economically viable process.

Figure 4 shows the same results for Concept β . In this case, 100% of the current demonstrated performance

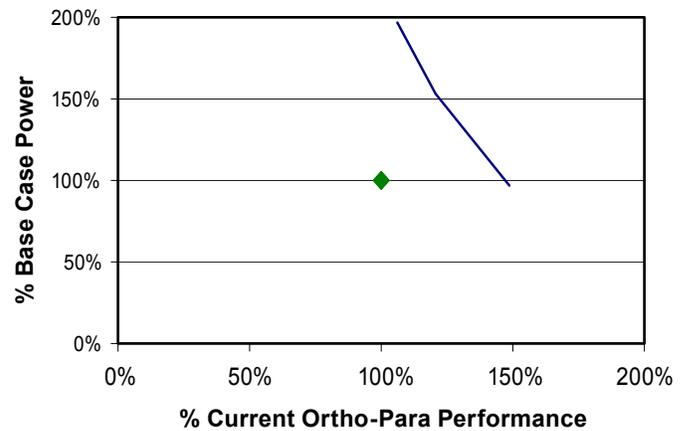

FIGURE 3. Ortho-Para Performance for Concept α

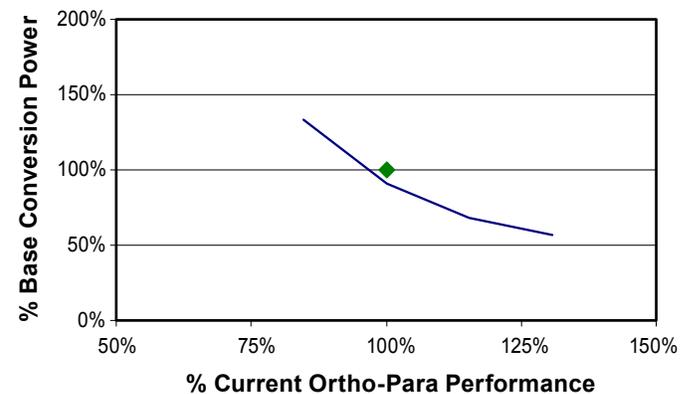

FIGURE 4. Ortho-Para Performance for Concept β

results in total power consumption below the base case power target. Concept β met the target required to be an economically viable process on an energy basis.

Process Equipment

Another way to improve the efficiency of hydrogen liquefaction is to improve the efficiency of the equipment used in the process. This includes compressors, turbines, and heat exchangers. Compression accounts for most of the power consumed by hydrogen liquefaction, so improvements in compressor efficiency can provide a significant benefit as discussed in the following. The impact of improving turbine or expander efficiency is small, but can reduce total power by about 2%. The impact of improving heat exchangers by reducing the pinch between hot and cold streams is even smaller than the impact of improving turbines.

Several different types of hydrogen compressor were evaluated. Reciprocating, screw, and centrifugal compressors were identified as being the most likely to apply to large-scale liquefaction. Metal hydride compressors were determined to be too small. Guided rotor and ionic liquid compressors were

determined to be in the developmental stage. Diaphragm compressors were unlikely to meet the capital cost target. Axial and shock wave compressors were determined to be a poor fit for a low molecular weight gas like hydrogen.

Table 2 shows some characteristics of the different types of compressor considered.

Screw compressors were expected to offer the lowest capital cost, but were also likely to have smaller capacity and lower efficiency. Reciprocating compressors offer larger size and higher efficiency, but at a higher initial cost and higher maintenance cost. Centrifugal compressors are expected to offer higher flow, lower maintenance cost, and similar efficiency compared to reciprocating machines.

Figure 5 shows the potential impact of improving compressor efficiency on the power consumption of the entire process assuming a base case with 80% adiabatic efficiency for all compressors. The main recycle compressor, which has three stages, consumes much more power than the low pressure recycle compressor, so improving its efficiency has a bigger impact on the total power. Improving the efficiency of each stage from 80 to 89%, the upper limit expected in Table 2, reduces total power by about 10%. Using an adiabatic efficiency value of 85%, closer to the middle of the range, reduces total power by about 6%.

Total Efficiency Improvement

The gains from each potential improvement discussed are additive; one does not reduce the ability to implement another. The total efficiency improvement is shown in the following:

TABLE 2. Hydrogen Compressor Options

Technology	Flow Range	First Cost	Relative Maintenance	Adiabatic Efficiency	Number of Units required	
CFM					30 tpd	300 tpd
Screw	20,000	Low	Medium	70 to 75%	2	20
Reciprocating	40,000	High	High	83 to 89%	1	10
Centrifugal	80,000	Medium	Low	80 to 89%	1	5

tpd – tons per day

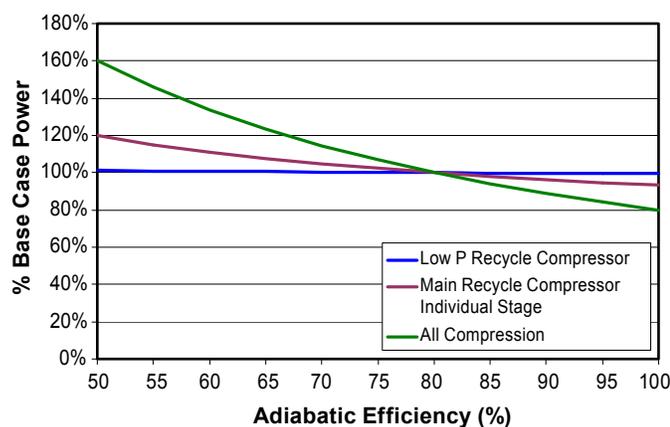

FIGURE 5. Effect of Compressor Efficiency on Total Power

Factor	Total Efficiency Improvement
Compressor Efficiency	6%
Turbine Efficiency	2%
Heat Exchanger Efficiency	<1%
Improved Liquefaction Process	2%
Improved Ortho-Para Conversion Process	5%

Total Efficiency Improvement	15%

The total efficiency improvement possible through using all of these methods is only 15%, less than the 20% goal of the project. Furthermore, each of these improvements potentially increases capital cost, making the goal of a 20% reduction in capital very unlikely to be possible for the highest efficiency process. Because of this result, the project was stopped after Phase II before completing the capital cost estimate.

Conclusions and Future Directions

- Improvements in overall process efficiency are possible through improved process equipment, improved process design, and an improved ortho-para conversion process.
- The total improvement is less than the project goal of 20%.
- Improvements are likely to add capital cost, making the other project goal of a 20% reduction in capital very unlikely.
- Ortho-para conversion performance was measured using laboratory and pilot reactors.
- The demonstrated performance is sufficient for at least one identified process concept to show reduced power cost when compared to hydrogen liquefaction processes using conventional ortho-para conversion.
- The impact of improved ortho-para conversion can be significant, but ortho-para conversion uses only about 20-25% of the total liquefaction power.
- Most of the energy used in liquefaction is for gas compression. Improvements in hydrogen compression will have a significant impact on overall liquefier efficiency.

Start Date: May 1, 2005

Projected End Date: December 31, 2011

degradation mechanisms the project's goal is to assess the reliability of the existing natural gas pipeline infrastructure when used for hydrogen transport and suggest possible new hydrogen-compatible material microstructures for hydrogen delivery. These studies meet the following DOE technical targets for Hydrogen Delivery as mentioned in Table 3.2.2 of the Multi-Year RD&D Plan:

- Pipelines: Transmission—Total capital investment will be optimized through pipeline engineering design that avoids conservatism. This requires the development of failure criteria to address the hydrogen effect on material degradation (2012 target).
- Pipelines: Distribution—Same cost optimization as above (2012 target).
- Pipelines: Transmission and Distribution—Reliability relative to H₂ embrittlement concerns and integrity, third party damage, or other issues causing cracks or failures. The project's goal is to develop fracture criteria with predictive capabilities against hydrogen-induced degradation (2017 target). It is emphasized that hydrogen pipelines currently in service operate in the absence of design criteria against hydrogen-induced failure.
- Off-Board Gaseous Hydrogen Storage Tanks (tank cost and volumetric capacity)—Same cost optimization as in Pipelines: Transmission above. Current pressure vessel design criteria are overly conservative by applying conservative safety factors on the applied stress to address subcritical cracking. Design criteria addressing the hydrogen effect on material safety and reliability will allow for higher storage pressures to be considered (2015 target).

Fiscal Year (FY) 2011 Objectives

- Mechanistic understanding of hydrogen embrittlement in pipeline steels in order to devise fracture criteria for safe and reliable pipeline operation under hydrogen pressures of at least 15 MPa and loading conditions both static and cyclic (due to in-line compressors).
- Explore suitable steel microstructures to provide safe and reliable hydrogen transport at reduced capital cost.
- Assess hydrogen compatibility of the existing natural gas pipeline system for transporting hydrogen.

Technical Barriers

This project addresses the following technical barriers from the Delivery section (3.2.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan (Multi-Year RD&D Plan):

- (D) High Capital Cost and Hydrogen Embrittlement of Pipelines
- (G) Storage Tank Materials and Costs
- (K) Safety, Codes and Standards, Permitting

Technical Targets

This project is conducting fundamental studies of hydrogen embrittlement of materials using both numerical simulations and experimental observations of the degradation mechanisms. Based on the understanding of the

FY 2011 Accomplishments

- Discovered the nature and characteristics of the hydrogen degradation mechanisms of two promising microalloyed, low-carbon steel microstructures designated as B¹ and D² hereafter. The samples were provided by the DGS Metallurgical Solutions, Inc. The mechanisms of fracture were identified by using focused ion beam (FIB) machining to lift-out sections from fracture surfaces along with transmission electron microscopy (TEM) analysis of the extracted thin foils.

¹ Steel B is a typical low carbon (0.05% by wt.) Mn-Si-single microalloy API/Grade X70/X80 capable of producing a ferrite/ acicular microstructure. The alloy was found to perform well in sour natural gas service.

² Steel D is a typical low carbon (0.03% by wt.) Mn-Si-single microalloy API/Grade X60, a predominantly ferrite microstructure with some pearlite. The alloy was found to perform very well in sour natural gas service.

- Identified the microstructure of pipeline steels through optical analysis, scanning electron microscopy (SEM), transmission electron microscopy (TEM), and identified particle composition through energy dispersive spectroscopy (EDS) for: a) laboratory specimens from Air-Liquide, Air Products, and Kinder-Morgan industrial pipelines; b) new microalloyed, low-carbon steels from Oregon Steel Mills provided by DGS Metallurgical Solutions, Inc.
- Developed a model for predicting hydrogen-induced fracture on the basis of the fracture mechanism acting at the microscale.
- Investigated the mechanism of fatigue fracture of 304 and 316 stainless steel in a hydrogen environment through FIB/TEM analysis. Unique localized martensitic lath bands were identified underneath the fracture surface.
- Augmented our modeling and simulation capabilities of transient hydrogen transport to account for the mechanical deformation and hydrogen-induced grain boundary decohesion in high strength steels. Predictions have been made of threshold stress intensities associated with subcritical crack growth.

Introduction

Hydrogen is a ubiquitous element that enters materials from many different sources. It almost always has a deleterious effect on material properties. The goal of the project is to develop and verify a lifetime prediction methodology for failure of materials used in pipeline systems and welds exposed to high-pressure gaseous environments. Development and validation of such predictive capability and strategies to avoid material degradation is of paramount importance to the rapid assessment of the suitability of using the current pipeline distribution system for hydrogen transport and of the susceptibility of new alloys tailored for use in hydrogen related applications.

We focused our effort on analyzing the fracture mechanisms of two promising steel microstructures (microalloy steels B and D) with large fracture resistance to hydrogen degradation. We also advanced our studies of the fracture mechanisms of 304 and 316 stainless steel samples fatigued in a hydrogen environment. Accounting for the identified hydrogen-induced fracture mechanisms, void growth at slip band intersection, we employ a tested model of the hydrogen-deformation interactions to develop a simulation tool for pipeline crack behavior with predictive capabilities.

Approach

Our approach integrates mechanical property testing at the microscale, microstructural analyses and TEM observations of the deformation processes of materials at

the micro- and nano-scale, first principle calculations of interfacial cohesion at the atomic scale, and finite element modeling and simulation at the micro- and macro-level.

To understand the hydrogen-induced fracture processes, we use high resolution SEM with three-dimensional (3-D) visualization and TEM studies of samples taken from just below the fracture surface by the lift-out technique using FIB machining. We investigate the interaction of hydrogen transient transport kinetics with material elastoplastic deformation ahead of an axial crack either on the internal diameter (ID) or outer diameter (OD) surface of a pipeline. Using finite element simulations of the hydrogen transport in the neighborhood of the crack tip, we explore the transient and steady state hydrogen population profiles and how their development influences the fracture processes/events.

Results

Identification and Characterization of the Fracture Mechanisms

The study of the fractured surfaces of our compact tension specimens of B and D type steels revealed several distinct morphologies (such as feathery region, ductile ridges, and featureless flat areas) which were not observed in the overload fracture of compact tension specimens in the absence of hydrogen. The feathery region and ductile ridges were analyzed (see 2010 annual progress report) using high resolution SEM, 3-D visualization, and TEM studies of samples taken from just below the fracture surface by the lift-out technique using FIB machining. The analysis suggested that hydrogen-induced fracture mechanism is governed by dislocation slip activity [1].

In order to understand the fracture processes, we further studied the featureless flat regions of the fractured surfaces. The 3-D visualization demonstrated that the featureless surfaces are not really flat but are undulating. Figure 1a shows the high resolution SEM image of the flat surfaces. The micrograph reveals that those undulations are covered with very small rounded mounds. The roughness of the surfaces is confirmed by atomic force microscopy measurements. Our TEM analysis of the lift-out sections beneath the featureless flat regions shows enormously high dislocation densities (Figure 1b). These observations demonstrably confirm that severe plastic processes control the fracture of these pipeline steels in a hydrogen environment [2].

The identification of the precise mechanism of hydrogen-induced fracture in pipeline steel materials serves all objectives of the project.

Identification and Characterization of Fatigue Mechanisms

Along with the characterization of specimens fractured under monotonic or static loading, similar analysis was carried out for 304 and 316 stainless steel samples fatigued

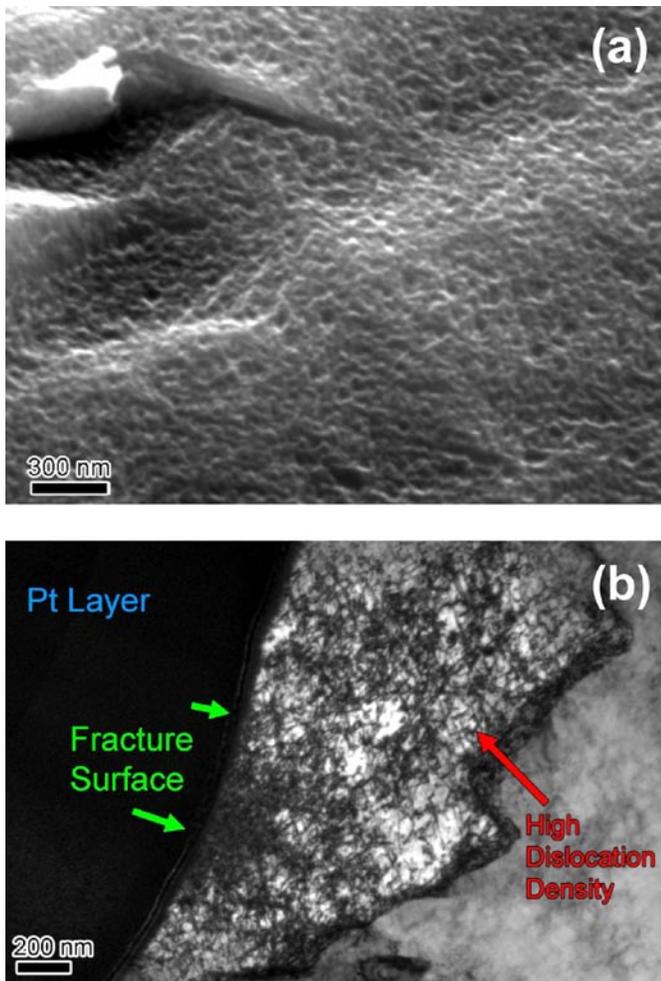

FIGURE 1. a) High-magnification SEM image of flat feature which shows that the flat surface in actuality is heavily dimpled. b) TEM micrograph showing the microstructure immediately beneath the flat features on the fracture surface. Image shows a high dislocation density suggesting that the fracture process is related to dislocation slip. The grains below the one shown have similar dislocation densities suggesting plasticity occurred not just immediately below the fracture surface.

in a hydrogen environment. Figure 2 shows the striations on the fractured surface which mark the progression of the fatigue crack with cycling. TEM analysis of sample extracted perpendicular to striations shows three sets of intersecting deformation bands (Figure 3). A large amount of plastic deformation, both in the bands and in the matrix, is visible. It appears that the bands intersect the surface at the striations, but further analysis is needed to confirm this. Diffraction analysis suggests that these bands are martensite laths which are localized closer to the crack tip with increasing hydrogen. This would suggest that with increasing hydrogen, martensite formation is localized closer to crack tip and produced in finer laths, which would be less visible to techniques such as electron backscatter diffraction. This is in agreement with the results of Mine et al. [3] who

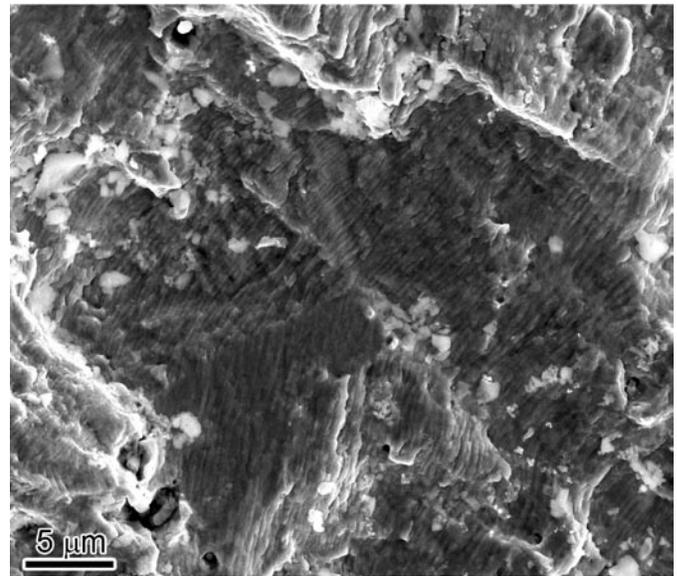

FIGURE 2. SEM image showing striations, a typical feature on fatigue surfaces, on the fracture surface of a 304 stainless steel sample fatigued under hydrogen atmosphere. A sample was extracted perpendicular to the marking and examined in the TEM.

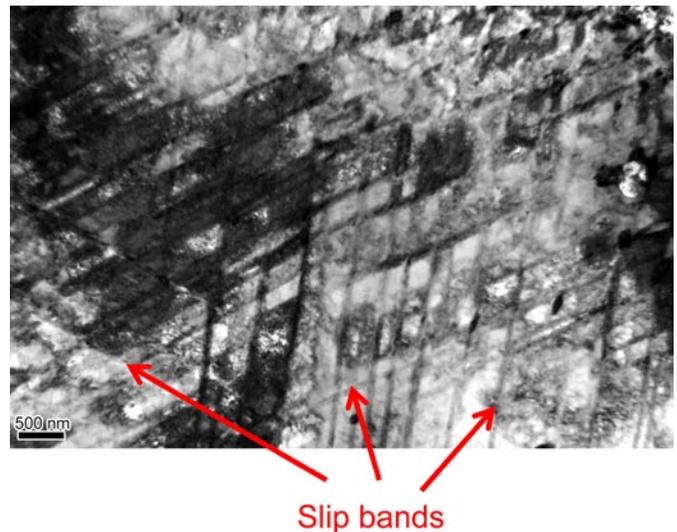

FIGURE 3. TEM micrograph showing the microstructure immediately beneath the fatigue fracture surface. The intersecting sets of deformation bands are visible. These features continue for several microns below the fracture surface.

observed the decrease in deformation induced martensite with increasing hydrogen saturation.

To further understand this phenomenon, we are investigating samples extracted by the FIB in a different way. From fatigued but unfractured specimens of the 304 and 316 steels, samples were extracted perpendicular to the polished surface and perpendicular to the crack in locations

identified to likely be similar to the striations observed on the fracture surface. This method will enable the observation of the microstructure directly ahead of the crack tip and possibly confirm that the microstructure is universal.

Micro- and Macro-Modeling and Simulation

The hydrogen-induced fracture mechanism of B and D type of steel pipelines under rising load has been identified as void nucleation and growth at slip band intersections [1]. We use a continuum mechanics description of the dislocation slip bands to investigate the conditions for a microcrack and then a void to be formed at slip band intersections in the hydrogen environment ahead of a crack tip.

We model the process by simulating the pile-up formation and interaction as shown in Figure 4. The simulation involves hydrogen-induced increased dislocation activity and interaction of dislocations with the applied load. We assume that fracture occurs when the energy of the system with a void forming at the intersection of the pile-ups is less than the energy in the absence of the void. The insertion of a void is considered energetically expensive due to the surface energy creation. We designate the stress intensity factor at which void formation occurs as a descriptor of the fracture resistance of the material to hydrogen embrittlement. This is one of the main project objectives, that is, to come up with a fracture criterion for these steels that is predicated on the underlying fracture mechanism acting at the microscale. The predictions will be compared with results obtained at Sandia Laboratories from rising load fracture toughness testing with B and D steels.

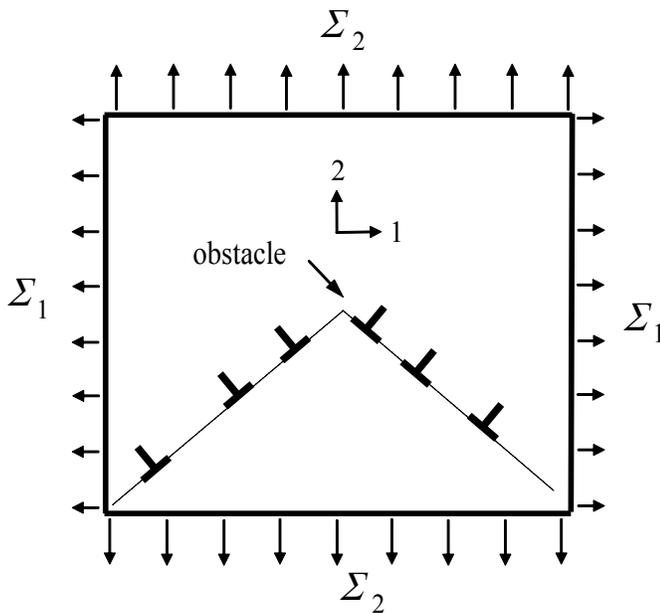

FIGURE 4. Schematic of the unit cell used for the modeling of the microcrack/void formation at the intersection of pile-ups. The cell is under applied macroscopic stress characteristic of the crack tip stress environment.

In order to understand the hydrogen/fatigue interactions, we developed a crystal plasticity constitutive model that accounts for the effect of hydrogen on the activation and operation of the slip systems. The face-centered cubic material version of the model has been implemented in the general purpose finite element code ABAQUS through a User Material subroutine. We are investigating the response of a crack whose tip is within a single grain to understand the material's response under cyclic loading. The development of a criterion for hydrogen-induced fatigue onset is also a central objective of our project.

The simulations described in this section are meeting all objectives of our project.

Conclusions and Future Directions

- In collaboration with Sandia National Laboratories, we carried out fracture testing of promising micro-alloyed, low-carbon steel microstructures. Our TEM analysis of lift-out sections beneath the fracture surface shows slip bands parallel to ridge edges, suggesting a fracture mechanism completely governed by dislocation slip. Such enhanced and confined slip activity is consistent with the hydrogen-induced localized plasticity mechanism for hydrogen embrittlement. This discovery of intense hydrogen-induced slip band formation also leads to the recognition that the coining of the term “quasi-cleavage” is misleading as it denotes cleavage events for a fracture that is controlled clearly by dislocation processes.
- In collaboration with the International Institute for Carbon Neutral Energy Research and the Institute for Hydrogen Industrial Use and Storage of Japan, we performed fatigue testing of stainless steel specimens in hydrogen environment. We analyzed the microstructure beneath the fracture surface and identified localized martensitic lath bands. This fatigue fracture testing is used for the damage tolerance assessment under cyclic pressure conditions.
- We model the discovered mechanism of failure, void nucleation and growth at slip band intersections, and implement the result in our finite element codes to simulate and predict onset of crack propagation under gaseous hydrogen transport at fixed pressure (static conditions). The results have been used to develop a fracture criterion for pipeline safe operation in terms of the hydrogen pressure, geometric, and material characteristics of the pipeline.
- We continue our collaboration with the International Institute for Carbon Neutral Energy Research and the Institute for Hydrogen Industrial Use and Storage of Japan. We participate in the annual meetings of the automobile Industry of Japan (Toyota, Honda, Nissan) on hydrogen technology standards.

Special Recognitions & Awards

1. P. Sofronis visited Japan from June 9 to June 25, 2006 as a fellow of the Japan Society for the Promotion of Science (JSPS) to collaborate on research related to hydrogen/material compatibility.
2. P. Sofronis and I. M. Robertson were invited speakers at the *International Hydrogen Energy Development Fora* organized by HYDROGENIUS at Fukuoka, Japan on January 31 – February 1, 2007, February 4-8, 2008, February 4-6, 2009, February 3-4, 2010, February 2-3, 2011.
3. P. Sofronis was elected to a fellow of the American Society of Mechanical Engineers (ASME) for his contributions to the field of hydrogen embrittlement.
4. P. Sofronis and I. M. Robertson received the 2011 Delivery Team Award from the Hydrogen and Fuel Cells Program of the U.S. Department of Energy.

Start Date: January 2005

Project End Date: Project continuation and direction determined annually by DOE

Fiscal Year (FY) 2011 Objectives

- Investigate the use of composite pipeline technology (i.e., fiber-reinforced polymer [FRP] matrix composite pipelines) for transmission and distribution of hydrogen, to achieve reduced installation costs, improved reliability and safer operation of hydrogen pipelines.
- Evaluate current composite pipeline liner materials with respect to their performance as a hydrogen barrier; consider the hydrogen permeabilities of the materials to determine the degree of improvement (if any) that is necessary, and propose a path forward based on the available liner materials and modifications or treatments.
- Assess joining methods for composite pipelines.
- Determine integrated sensing and data transmission needs pipelines to provide health monitoring and operational parameters; report on state of the art in structurally integrated sensing and data transmission.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Delivery section (3.2.4.2) of the Fuel Cell Technologies Program (FCT) Multi-Year Research, Development and Demonstration Plan:

(D) High Capital Cost and Hydrogen Embrittlement of Pipelines

Technical Targets

The long-term project objective is to achieve commercialization and regulatory acceptance of FRP pipeline technology for hydrogen transmission and

distribution. Accordingly, the project tasks address the challenges associated with meeting the DOE hydrogen delivery performance and cost targets for 2017 [1]:

- Transmission pipeline total capital cost: \$490k per mile
- Distribution pipeline total capital cost: \$190k per mile
- Hydrogen delivery cost: <\$1.00/gasoline gallon equivalent (gge)
- Transmission and delivery reliability: acceptable for H₂ as a major energy carrier
- Hydrogen pipeline leakage: <0.5% (leakage target is currently under review by the Delivery Tech Team)

FY 2011 Accomplishments

- Completed tests on aging of glass reinforcement fibers in high-pressure hydrogen, and tensile tests indicate that long-term exposures to high-pressure hydrogen has a negligible effect on the strength of the fibers.
- Began cyclic fatigue testing on FRP pipeline specimen using cyclical hydrogen pressurization to pipeline maximum allowable working pressure. Measurements of the pressure-stress relationship and hydrogen leakage rate will provide information on liner collapse resistance and crack propagation, reinforcement layer resistance to micro-cracking, crazing, crack propagation, fiber-resin interface failure, and integrity of joint sealing.

Introduction

Pipelines could be a feasible long-term solution for delivering large quantities of gaseous hydrogen over long distances and distributing it in urban and rural settings. However, there are hydrogen compatibility issues in steel pipelines, and the capital costs for pipeline installation must be dramatically reduced. Composite pipeline technology is a promising alternative to low-alloy high-strength steel pipelines from both performance and cost considerations. For instance, FRP pipelines are engineered composite pipelines that are widely used in upstream oil and gas operations and in well interventions. FRP pipelines typically consist of an inner non-permeable liner that transports the fluid (pressurized gas or liquid), a protective layer applied to the liner, an interface layer between the protective layer and the reinforcement layers, multiple glass or carbon fiber reinforcement layers, an outer pressure barrier layer, and an outer protective layer. The pipeline has large burst and collapse pressure ratings, high tensile and compression strengths, and tolerates large longitudinal and hoop strains. Thousands of feet of continuous pipe can be unspooled and trenched as a seamless entity, and adjoining segments

of pipeline can be joined in the trench without welding using simple connection techniques. The emplacement requirements for FRP pipelines are dramatically less than those for metal pipe; installation can be done in a narrower trenches using light-duty, earth-moving equipment. This enables the pipe to be installed in areas where right-of-way restrictions are severe. In addition, FRP pipe can be manufactured with fiber optics, electrical signal wires, power cables or capillary tubes integrated within its layered construction. Sensors embedded in the pipeline can be powered from remote locations and real-time data from the sensors can be returned through fiber optics or wires. This allows the pipeline to be operated as a smart structure, providing the unique advantage of lifetime performance and health monitoring.

Approach

The challenges for adapting FRP pipeline technology to hydrogen service consist of evaluating the constituent materials and composite construction for hydrogen compatibility, identifying the advantages and challenges of the various manufacturing methods, identifying polymeric liners with acceptably low hydrogen permeability, critiquing options for pipeline joining technologies, ascertaining the necessary modifications to existing codes and standards to validate the safe and reliable implementation of the pipeline, and determining requirements for structural health monitoring and embedded real-time measurements of gas temperature, pressure, flow rate, and pipeline permeation.

These challenges are being addressed by performing bench-scale tests of FRP pipelines and constituent materials to determine their long-time compatibility with hydrogen, identifying pipeline liner materials that exhibit good performance in hydrogen environments, evaluating current methods for pipeline joining with consideration of the unique requirements for hydrogen service, and assessing the state of the art in integrated sensing technologies for composite structures.

Results

We used a straightforward accelerated aging process to evaluate the possibility that hydrogen could weaken the load-bearing capability of the glass fibers that are used as reinforcement in glass fiber-reinforced pipelines being considered for hydrogen delivery. Designing a test to screen for hydrogen-induced failures in glass fibers is difficult because potential chemical incompatibilities are largely unknown and because the permeation of hydrogen into glass is typically 3 to 7 orders of magnitude smaller than it is in most polymers and metals. Previous studies of the effects of hydrogen on glasses have focused on the ability of the glasses to store hydrogen or on the tendency of hydrogen to produce attenuation centers in the glasses (e.g., as in optical fibers).

To assess possible hydrogen-induced changes in mechanical strength of the glass fibers, we measured fiber tensile strengths in boron-free e-glass fibers (Advantex® SE 1200 Type 30) before, during and after accelerated aging in a pressurized hydrogen reactor. Our accelerated aging protocol was based on the Arrhenius model for an activated process where the aging rate is proportional to $e^{-\lambda/kT}$, where λ is the activation energy, T is the aging temperature, and k is the Boltzmann constant. We aged the fibers in a 70 bar pressure of hydrogen at a temperature of 60°C, which were the maximum allowable working pressure and temperature of the FRP pipeline. There were no stressors other than high-pressure hydrogen (i.e., no oxygen, water, chemicals, ultraviolet light). From previous measurements done by others and us, we know that simply heating the fibers to 60°C for long periods of time does not degrade their tensile strength when it is subsequently measured at room temperature. We included tensile tests of untreated control specimens to compare with the specimens treated in hydrogen.

We removed fibers from the reactor at intervals of 1, 5, 11, 20, 39 and 62 weeks of exposure to perform tensile tests on fiber specimens with gauge lengths of 25 mm. We tested 30-100 fibers of both the hydrogen exposed and control groups at each interval. The distribution of tensile strength can be approximated by the two-parameter Weibull distribution

$$P(\sigma) = 1 - \exp(-L/L_0[\sigma/\beta]^\alpha)$$

where α is the shape parameter, β is the scale parameter, and L and L_0 are the fiber gauge and reference lengths. Figure 1 shows representative test results in Weibull coordinates for the shortest and longest hydrogen exposures.

Using the Weibull parameters determined from the tensile strength measurements performed at each exposure interval, we calculated survival probabilities for the hydrogen-treated and control fibers. These survival probabilities are plotted versus exposure duration in Figure 2. The large error bars in the survival probabilities are likely due to the presence of both surface and bulk flaws in the fibers. Funding and time constraints did not allow us to censor the strength data by doing fractographic analysis to identify the type of flaw in each fiber tested, which would have allowed us to separate the data by flaw type and thereby obtain Weibull distributions with straight-line slopes. Nevertheless, the survival probabilities for the treated and untreated fibers do not change qualitatively with aging, implying that there was no hydrogen-induced degradation in the fibers during the 62-week exposure duration.

Fatigue testing using high-pressure hydrogen pressure cycling is the basis for verifying that combination of hydrogen environment and pressure-induced stress does not adversely affect composite pipeline integrity and service life. The results of high-pressure cyclic fatigue tests provide information on pipeline integrity after repeated hydrogen gas pressurization-depressurization cycles [2].

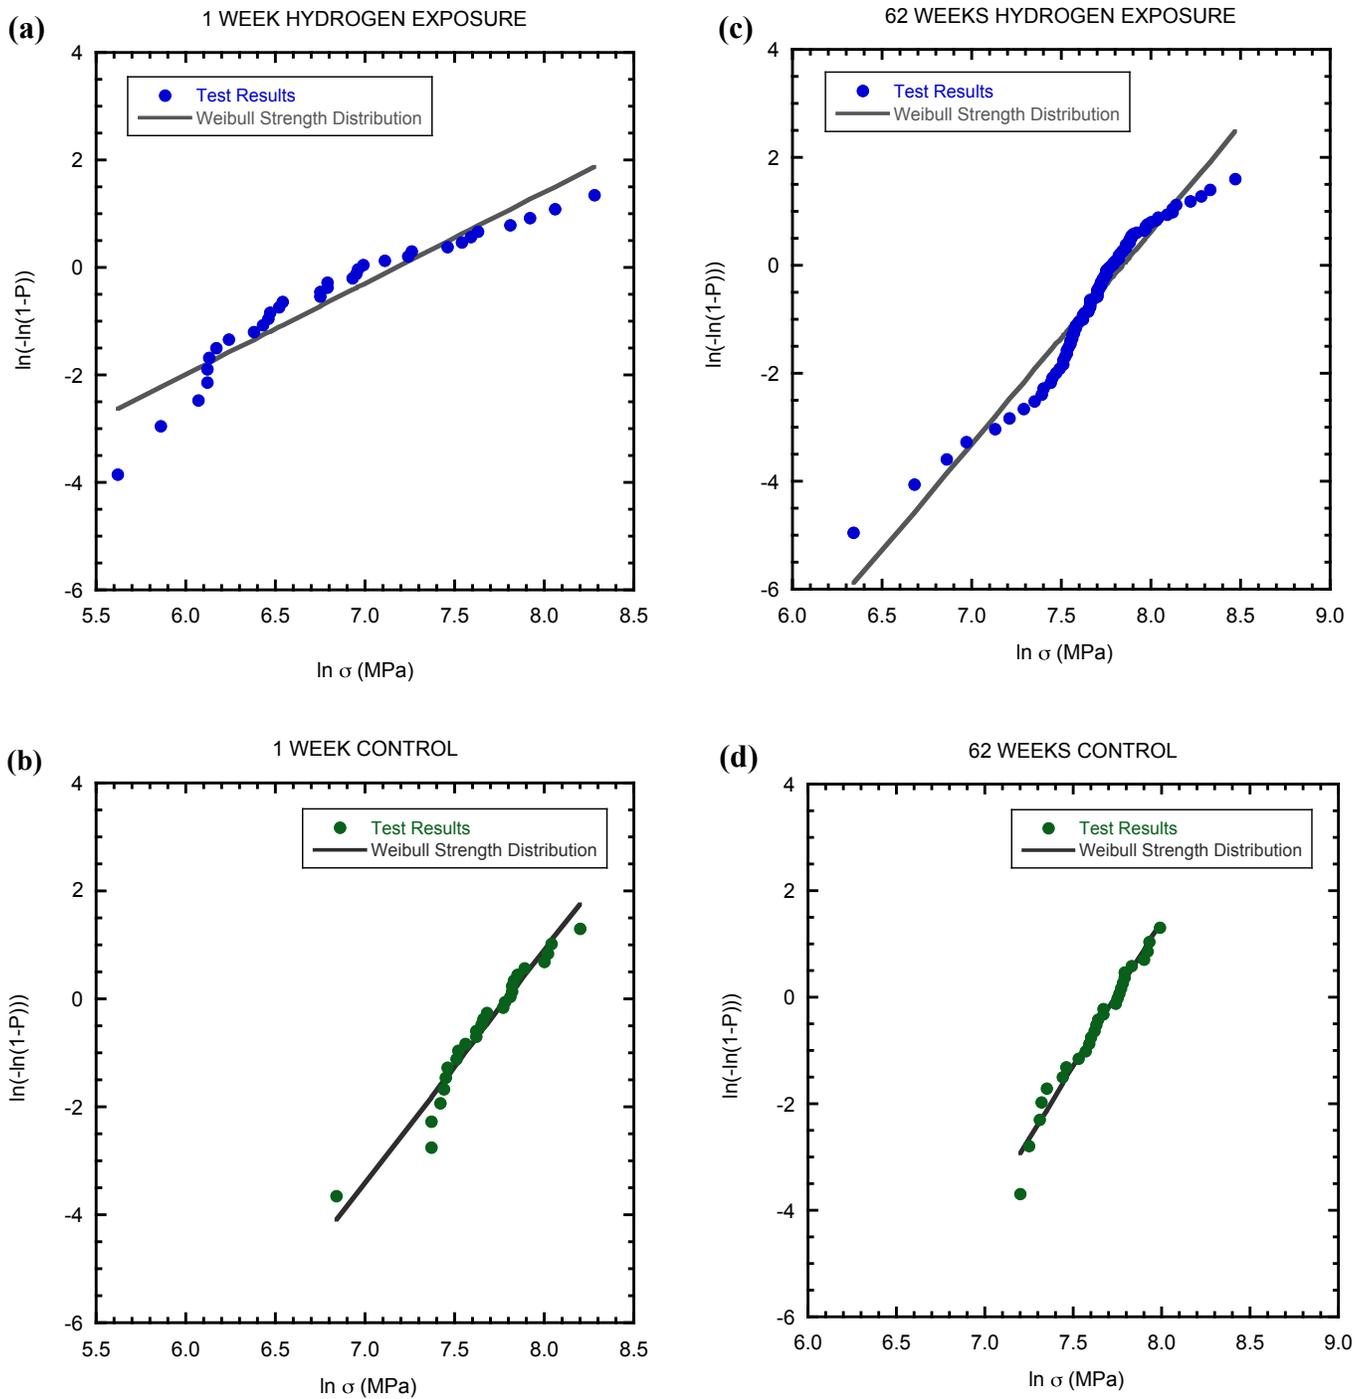

FIGURE 1. Representative test results in Weibull coordinates for fiber strengths measured following (a) 1-week and (c) 62-week hydrogen exposures. Circles are measured tensile strengths and the solid lines are the calculated Weibull distributions for the measured strengths. The corresponding tensile strength measurements for the control fibers are shown in (b) and (d).

Fatigue testing provides information that can't be derived from constant pressure testing, including liner collapse resistance (similar to blowdown testing), resistance to micro-cracking, crazing, crack propagation, fiber-resin interface failure, etc. of composite reinforcement layer, resistance to environmental stress-corrosion phenomena, and integrity

of joint attachment/joint sealing under cyclic loading. We began cyclic fatigue testing of a Fiberspar glass-reinforced polymer pipeline in this project year and are on schedule to meet the milestone for this task, but the measurement results and analysis will not be completed until near the end of the

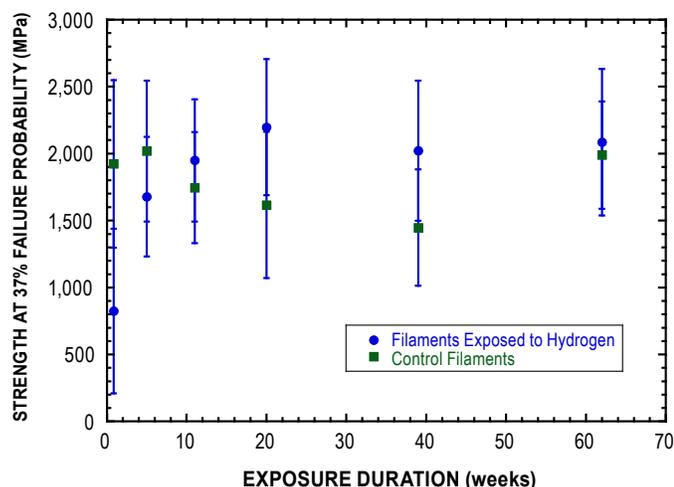

FIGURE 2. Survival probabilities of hydrogen-treated and untreated (control) fibers plotted versus accelerated aging duration. There was no statistically significant decrease in tensile strength during the 62-week exposure period.

fiscal year and will be reported in the last quarterly report of the year.

Conclusions and Future Directions

Conclusions from this year's work:

- E-glass fibers similar to those used as reinforcement in composite pipelines did not lose their tensile strength during a long-term exposure to high-pressure hydrogen gas. The intensity of the glass-fiber exposure was significantly higher than the actual exposure of fibers in the pipeline epoxy matrix and exceeded even a worst-case scenario. The conclusion reached is that e-glass should be durable in hydrogen service and the glass fibers should retain their mechanical function in a glass-fiber-reinforced pipeline during the anticipated hydrogen service lifetime.

During the remainder of this project year we expect to complete the first series of long-term stress rupture tests and report on the durability of the pipeline to further verify the expectation that composite pipelines can achieve the 2012 DOE H₂ transmission target of <\$0.90/gge H₂:

- Our plans for the next project year are (1) to participate in the codification of fiber-reinforced (composite) pipelines in the American Society of Mechanical Engineers (ASME) B31.12 Hydrogen Piping Code by helping to identify and provide data needed to guide lifecycle management of composite pipelines, and (2) to monitor the performance of composite pipeline used to store hydrogen in a hydrogen and fuel cell market transformation project demonstration project at the Hawaii Natural Energy Institute. The opportunity to monitor the field demonstration of the pipeline is uncertain and is extremely contingent on funding and scheduling constraints. Nevertheless, the FCT program will have the chance to get initial real-world field data on the use of FRP pipe for hydrogen (e.g. pressure cycling, environmental exposure, and post-use microstructural analysis), which is particularly important as we begin to work with ASME on establishing a set of codes and standards for the commercialization of FRP (composite) pipelines.

 Projected End Date: Project continuation and direction determined annually by DOE

FY 2011 Accomplishments

- Developed model of vessel fill processes.
- Calculated final fill density as a function of initial vessel conditions (temperature, T, and pressure, p).
- Completed LH₂ pump contract negotiation with Linde LLC.

Introduction

Cryogenic pressure vessels have demonstrated highest performance for automotive hydrogen storage, with weight, volume, cost, and safety advantages [1,2]. One of the outstanding challenges for cryogenic pressure vessels is refueling. Today's hydrogen storage technologies (compressed and liquid hydrogen) operate at fixed temperature. Cryogenic pressure vessels, however, drift across the phase diagram depending on the level of use. The challenge is demonstrating rapid, inexpensive refueling that minimizes evaporative losses regardless of the initial thermodynamic state of the vessel.

Approach

We have identified a promising technology for cryogenic pressure vessel refueling: a liquid hydrogen pump. This pump takes LH₂ at low pressure (near atmospheric) and delivers it as high-pressure (200-880 bar) low temperature (30-50 K) high-density (>80 g/L) hydrogen that can be directly dispensed into a cryogenic pressure vessel, even when warm and/or pressurized. In this project we plan to install a LH₂ pump in the LLNL campus and demonstrate its virtues for rapid and efficient cryogenic vessel refueling.

Results

We have developed a model for vessel fill processes in an effort to evaluate the potential for future LH₂ pump high density refueling. Based on REFPROP [3], the model considers real gas hydrogen properties and enables quick calculation of relevant thermodynamic properties.

We start by considering a simplified case: a large forecourt vessel storing hydrogen at temperature T_i and pressure p_i. This vessel fills a (relatively small) vessel onboard a vehicle. The fill process is modeled with the first law of thermodynamics for open systems [4]:

$$Q + m_i h_i = U_f - U_o + m_o h_o + W \tag{1}$$

Fiscal Year (FY) 2011 Objectives

- Demonstrate rapid refueling of cryogenic vessels.
- Refuel cryogenic vessels even when warm and/or pressurized.
- Refuel at high density (>80 kgH₂/m³).

Technical Barriers

This project addresses the following technical barrier from the Delivery section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(J) Refueling Site Operations

TABLE 1. Progress toward Meeting DOE Hydrogen Delivery Technical Targets

Pressurized LH ₂ pump				
DOE Targets for Forecourt Compressors	Units	2010 Target	2015 Target	Pressurized LH ₂ pump
Reliability	-	Improved	High	High
Compression Energy Efficiency	%	94	95	95
Installed Capital Cost	k\$(/kg/hr)	4	3	5
H ₂ Fill Pressure	Peak psi	6,250	12,000	12,000

LH₂ – liquefied hydrogen

Mechanical work W is negligible for typical (rigid) pressure vessels, and we neglect heat transfer into the vessel Q as a first approximation. Mass flow out of the vehicle vessel $m_e=0$ during refueling, and the specific enthalpy h_i of the hydrogen flowing into the vessel is calculated at the conditions of the forecourt vessel (p_f, T_f) , assumed constant due to its large relative size. The equation for the vehicle vessel therefore reduces to,

$$m_i h_i = U_f - U_o \tag{2}$$

Assuming an initially empty vessel with negligible thermal mass, the initial internal energy $U_o=0$. The final internal energy in the vehicle vessel $U_f = m_i u_f$, which leads to $h_i = u_f$, where u_f is the specific internal energy inside the vessel. From thermodynamics, $h_i = u_i + p_i v_i = u_f$. The term $p_i v_i$, frequently named flow work, explains the heating that occurs when substances are forced into a vessel.

Figure 1 shows results for the fill process of an initially empty vessel with negligible thermal mass and heat transfer. The figure shows vessel temperature and density during the fill process as a function of pressure, for forecourt vessel conditions $p_f=700$ bar and $T_f=100, 200,$ and 300 K. The figure shows that hydrogen flowing into the vehicle vessel heats substantially in the process, considerably reducing the vessel fill density. Temperature is nearly constant during the fill process, changing only slightly due to hydrogen's non-ideal behavior, especially at lower temperature. It is worth pointing out that hydrogen heats up as it flows into the vessel regardless of the value of the Joule-Thomson coefficient (negative at ambient temperature, near zero at 200 K, and positive at 100 K): vessel fill processes are not isenthalpic and therefore not controlled by the Joule-Thomson coefficient. Flow work plays the key role in understanding the process.

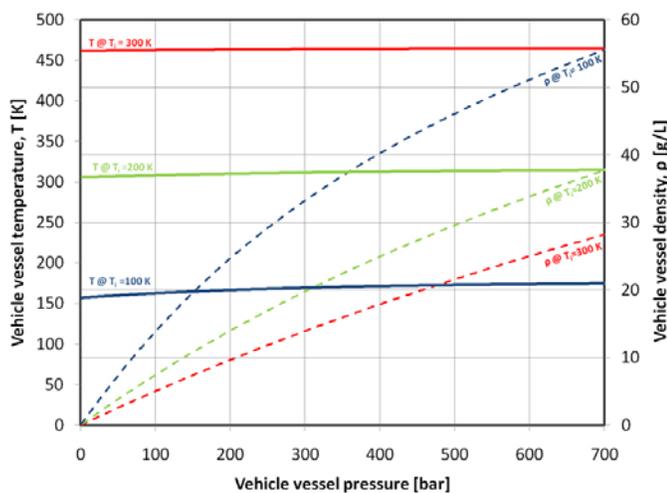

FIGURE 1. Automotive vessel temperature and density during the fill process as a function of pressure, for forecourt vessel conditions $p_f=700$ bar and $T_f=100, 200,$ and 300 K, assuming an initially empty vessel with negligible thermal mass and heat transfer.

Results in Figure 1 can be generalized by varying p_f and T_f over broad ranges. Figure 2 shows vehicle vessel temperature (blue) and fill density (red), at the end of the refueling process, when pressure equilibrium is reached with the forecourt vessel ($p=p_f$), for an initially empty vessel with negligible thermal mass, for any combination of forecourt vessel pressure and temperature (p_f, T_f) . As an example, assume that the forecourt vessel is filled with hydrogen at 100 K and 300 bar. From the figure, the vehicle vessel at the end of the fill process (when both vessels equilibrate at 300 bar) would be at 150 K and 40 g/L.

Figure 2 once again shows the considerable heating that occurs during the fill process. For an ideal gas with constant specific heat, heating is constant ($T = \gamma T_i$, where γ is the specific heat ratio c_p/c_v), and therefore temperature lines are fairly horizontal at low pressures and high temperatures. At higher pressures, deviations from ideality increase the heating. Minimum heating (minimum density losses) occurs at low temperature and pressure, where hydrogen's compressibility factor drops as hydrogen approaches liquid phase. This is observed by the 50 K blue line reaching a local maximum at ~ 50 bar.

Figure 2 also shows the exergy of the hydrogen inside the forecourt vessel (black lines). Exergy is defined as the minimum theoretical work necessary to compress and cool down hydrogen from the reference state (1 bar and 300 K) to any condition p_f, T_f in the diagram. Exergy is therefore an indication of the energy necessary for densifying hydrogen. Figure 2 shows that hydrogen compression is exergetically inexpensive compared to cooling: any level of densification from 10 to 60 g/L is achieved with minimum possible exergy by maximizing pressurization and minimizing cooling.

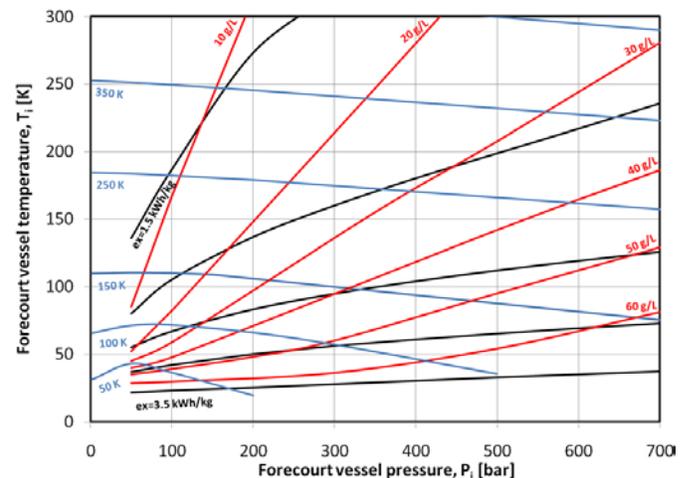

FIGURE 2. Vehicle vessel temperature (blue) and fill density (red), at the end of the refueling process, when pressure equilibrium is reached with the forecourt vessel ($p=p_f$), for an initially empty vessel with negligible thermal mass, for any combination of forecourt vessel pressure and temperature (p_f, T_f) . The figure also shows the exergy of the hydrogen inside the forecourt vessel (black lines).

Hydrogen liquefaction is well known to be exergetically expensive (3.92-3.27 kWh/kg depending on whether para-ortho hydrogen conversion is included or not [5]). Investing energy in liquefaction, however, has the virtue of minimizing station energy consumption and capital cost, because liquid hydrogen can be pressurized with little exergy input as indicated by the nearly horizontal 3.5 kWh/kg exergy line (Figure 2).

The fact that pressurizing liquid hydrogen is exergetically inexpensive enables rapid compression and efficient densification with low evaporative losses. Demonstrating the potential for this technology is the purpose of this project. While LLNL moves forward issuing the pump contract and preparing for construction, we have applied our thermodynamic model to predict expected fueling performance.

Predicting pump refueling is similar to predicting vessel refueling, and Equation (2) still dominates the process. However, delivery temperature is a function of pump performance details, and it is therefore hard to predict. For this preliminary analysis, we estimate delivery temperature assuming *isentropic* compression from the forecourt Dewar with LH₂ saturated at 3 bar and 24.6 K. While real pumps will not reach this level of performance, final vessel density may be reasonably well approximated due to the low exergetic cost of LH₂ pumping.

Modeling results are shown in Figure 3, which shows hydrogen density after refueling (when the vehicle drives away from the fueling station) as a function of hydrogen density before refueling (when the vehicle drives into the refueling station), for multiple initial vessel temperatures

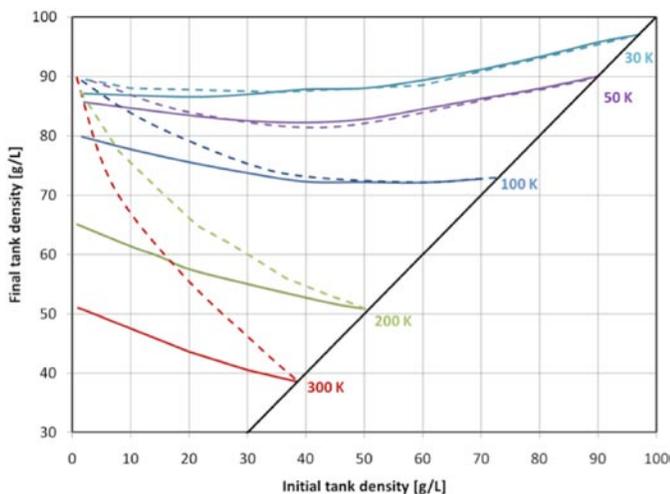

FIGURE 3. Hydrogen density after refueling (when the vehicle drives away from the fueling station) as a function of hydrogen density before refueling (when the vehicle drives into the refueling station), for multiple initial vessel temperatures (30 K, 50 K, 100 K, 200 K, and 300 K). Two sets of lines are shown: *isentropic* pump with negligible pressure vessel thermal mass (dashed); and *isentropic* pump including the vessel thermal mass, and assuming thermal equilibrium between vessel and hydrogen (solid lines).

(30 K, 50 K, 100 K, 200 K, and 300 K). Two sets of lines are shown: isentropic pump with negligible pressure vessel thermal mass (dashed); and isentropic pump including the vessel thermal mass, and assuming thermal equilibrium between vessel and hydrogen (solid lines).

Comparing dashed lines vs. solid lines in Figure 3 shows that vessel thermal mass plays a large role in fill density for warm, empty vessels. At very low temperatures (30-50 K), vessel thermal mass becomes very small, enabling high density refueling regardless of the initial fill level. An isentropic pump filling an initially cold and empty vessel may therefore enable ultimate densities beyond 85 g/L. Final densities beyond 90 g/L are obtained with very cold (30 K) nearly full vessels where the pump is essentially compressing low entropy H₂ already in the vessel.

The black diagonal line in the right of Figure 3 corresponds to a fully pressurized vessel at 700 bar. At this condition, no refueling is possible, and density after refueling equals density before refueling. Driving is necessary before refueling to reduce pressure and cool down the vessel.

In summary, the low exergetic cost of pumping LH₂ may lead to rapid and efficient refueling at high densities. Flow work is also lowest near the liquid phase (Figure 2) minimizing heating and density losses during vessel fill. Future experiments will reveal how closely real pump performance compares with the isentropic pump model.

Conclusions and Future Directions

- Rapid, low loss refueling of cryogenic vessels is possible through pressurized LH₂ dispensing.
- Modeling has revealed potential for high density refueling (85 g/L) for initially cold vessels.
- Model results need to be validated vs. future experimental results.

Project Start Date: March 1, 2004
Project End Date: September 30, 2011

Fiscal Year (FY) 2011 Objectives

- Develop and demonstrate cost-effective welding technology that can mitigate hydrogen embrittlement (HE) concerns in constructing new pipelines and converting existing pipelines for high-pressure hydrogen delivery.
- Quantify the effects of welding and joining on the resistance to HE of high-strength pipeline and other structural steels under high-pressure hydrogen.
- Develop the technical basis and guidelines to manage the weld region to ensure structural integrity and safety of hydrogen delivery systems.
- Determine the hydrogen transport behavior (such as diffusion, trapping, etc.) in steels.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Delivery section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (D) High Capital Cost and Hydrogen Embrittlement of Pipelines
- (K) Safety, Codes and Standards, Permitting

Technical Targets

This project aims at developing the scientific understanding, technical basis and cost-effective engineering solutions to control and mitigate hydrogen embrittlement in the weld region of steel pipelines and other high-pressure hydrogen delivery infrastructure systems. Insights gained from this project will be applied toward the hydrogen

delivery infrastructure that meets the following DOE 2017 hydrogen pipeline delivery technical targets:

- Capital cost: \$490K/mile for transmission, and \$190K/mile for distribution pipeline.
- Reliability/Integrity: Acceptable for H₂ as a major energy carrier.
- Cost of delivery of hydrogen <\$1.00/gasoline gallon equivalent (gge).

FY 2011 Accomplishments

- Baseline high-pressure hydrogen permeation measurements established the effects of weld microstructure, surface conditions, temperature and hydrogen pressure on hydrogen permeation, diffusion and trapping in selected pipeline steels.
- The in situ spiral notch torsion test (SNTT) and the associated finite element fracture mechanics modeling were applied to quantify the fracture toughness degradation of steel welds exposed to high-pressure hydrogen. For American Iron & Steel Institute (AISI) 4340 high-strength steel, a common material for hydrogen storage tank, preliminary testing results showed the fracture toughness of weld region in high-pressure hydrogen is as low as 25% of that in air (i.e., a degradation of 75%).
- Preliminary multi-notch tensile testing of American Petroleum Institute (API) 5L Grade X-65 pipeline steel in hydrogen showed encouraging results for the improved resistance to HE achieved by friction stir welding (FSW). Additional tests on X-65 FSW are ongoing and are expected to be completed by September-November 2011 timeframe.

Introduction

The hydrogen energy delivery infrastructure will require extensive use of steels and other cost-effective structural materials under high-pressure gaseous hydrogen exposure. For example, high-pressure (up to 3,000 psi) hydrogen pipelines are presently considered to be one of the most cost-effective and energy-efficient means to transport very large amounts of hydrogen to much of the market as is done for natural gas [1]. Under high hydrogen pressures, there are concerns about HE of steel pipelines and its potentially catastrophic consequences [2]. Concerns on HE are not limited to steel pipelines; according to a recent DOE Basic Energy Science report [3], HE needs to be addressed for a variety of hydrogen storage and delivery systems made of metallic materials that are exposed to hydrogen.

As in the case of natural gas and other energy carrier transmission pipelines, welding will be used to construct steel pipelines for high-pressure hydrogen delivery. Welding will also be widely used in fabrication of other system components for hydrogen production, storage, and delivery. However, welds in pipeline steels and other engineering materials are often the most susceptible regions to HE due to the formation of unfavorable microstructures and high tensile residual stresses. Furthermore, the weld region typically has substantially lower resistance to hydrogen crack initiation and higher crack growth rates, when compared to the baseline pipeline steel (base metal). In this regard, the weld region is oftentimes the weakest link for the structural integrity and safety of hydrogen pipelines and hydrogen delivery infrastructure. A systematic approach to deal with weld property degradation under high-pressure hydrogen exposure is critical to ensure the safe, cost-effective operation and long-term reliability of the hydrogen delivery infrastructure. Insights gained from this project will provide the scientific and technical basis for hydrogen pipelines that meet relevant DOE 2017 technical targets on total capital investment and reliability/integrity.

Approach

Currently, there exists only a limited amount of knowledge on the diffusion rate and amount of hydrogen in steels under high-pressure gaseous environment relevant to the hydrogen delivery infrastructure. Therefore, the first major effort of this project is directed toward the systematic study of (1) high-pressure H_2 permeation behavior in steels and their welds, and (2) the tolerance level to hydrogen of different steels before considerable mechanical property degradation would occur. A special hydrogen permeation testing system has been developed to test H_2 permeation and diffusion in coupon-size steel discs under high pressure (up to 5,000 psi). The effect of steel composition, microstructure, and sample surface conditions on H_2 transport behavior is studied.

As discussed earlier, the weld joint in steel pipeline is expected to be a critical region highly susceptible to HE due to the existence of unfavorable microstructure and high tensile residual stresses. Hence, the second major activity of this project focuses on generating weld property data for fracture-mechanics based pipeline design. To account for the highly inhomogeneous nature of the weld region, two special tests have been developed and validated. A tensile test is used for relative ranking of weld microstructure susceptibility to HE, while the spiral notch torsion test is used for quantifying fracture toughness degradation in steel welds.

The third major effort involves the development and validation of new welding technology for H_2 delivery steel pipelines. In particular, solid-state FSW is evaluated for improved mechanical property and reduced cost for pipeline construction and repair.

Results

The results achieved in this FY (2011) are highlighted as follows.

Quantitative Understanding of Hydrogen Embrittlement in Steel Weld Using In Situ SNTT

Although they may work for testing of base metal in hydrogen, current standard methods such as compact tension for testing hydrogen-induced mechanical property degradation have shown to be inadequate when applied to the weld due to the highly inhomogeneous microstructure and property gradients of the weld region [4]. Special, miniature and self-loading devices for in situ mechanical testing in high-pressure hydrogen were designed and fabricated previously. The FY 2011 activity is focused on fracture toughness measurement of welds exposed to a high-pressure gaseous hydrogen environment using in situ SNTT.

Figure 1 shows the in situ device for fracture toughness testing in high-pressure hydrogen. In the test, the specimen with a spiral notch is loaded in the load frame where a pure torsional load is applied to the specimen. The load frame containing the pre-stressed specimen is placed inside a high-pressure vessel. The strain gages attached to the load frame are connected to the data acquisition box via feedthroughs in the vessel cover/lid. After the assembly, the vessel is tightly sealed and is charged with hydrogen gas to the desired pressure (typically around 1,900 psi or 13.1 MPa). During the test, the strain gage readings are monitored for the variation of torsional load on the specimen, which is an indicator for hydrogen-induced cracking initiation. As the hydrogen permeation in steel can be slow at room temperature, the specimen is immersed in H_2 and tested for

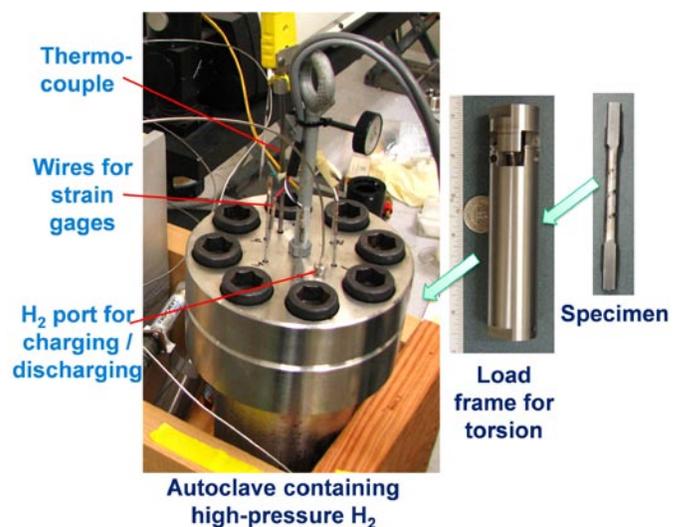

FIGURE 1. Special, in situ testing apparatus for measuring fracture toughness degradation of materials exposed to high-pressure hydrogen

one to three days to ensure sufficient time for hydrogen to diffuse to the crack tip.

As shown in Figure 1, the compact size and self-loading mechanism employed in the in situ SNTT device make it possible to accurately measure mechanical property degradation in high-pressure hydrogen without the use of a dedicated mechanical testing system. This minimizes the capital cost of the testing system and allows cost-effective study of the effect of weld microstructure and its inhomogeneity on HE resistance.

The steel studied using in situ SNTT is AISI 4340 high-strength steel, a material commonly used for hydrogen storage tank. Simulated weld heat-affected zone (HAZ), which is the most critical region to HE, is prepared using a Gleeble[®] thermal-mechanical system. Each specimen is subject to a heating and cooling cycle mimicking that encountered in practical welding condition. Using Gleeble to produce simulated weld specimens eliminates the need for fabricating a 4340 steel weld and machining specimens from the weld, which can be costly and time-consuming. After heat-treatment in Gleeble, the simulated weld specimens are cyclic-fatigued in air to induce sharp crack tips before testing in hydrogen.

Figure 2(a) shows the surface appearance of a fractured specimen after exposure to hydrogen at 1,900 psi. Figure 2(b) is the scanning electron microscope (SEM) image of fracture surface near the notch root, where primarily intergranular fractures (i.e., brittle) are observed. As it locates just underneath the surface directly exposed to hydrogen, the region near the notch root is likely saturated with hydrogen. The tensile stress field in front of the notch

tip further enhances the hydrogen diffusion. The presence of hydrogen severely deteriorates the local microstructure resistance to HE, thus resulting in a brittle fracture. Figure 2(c) is the SEM image of fracture surface away from the notch root. Both dimples (ductile) and intergranular fractures (brittle) are observed, indicating a mixed ductile and brittle fracture behavior. Detailed microstructure analyses of this region is ongoing to understand the extent of hydrogen embrittlement there.

The preliminary testing results obtained on fatigue pre-crack specimens show that the fracture toughness of 4340 steel weld HAZ drops from $38.7 \text{ ksi}\cdot\sqrt{\text{in}}$ in air to only $9.6 \text{ ksi}\cdot\sqrt{\text{in}}$ in gaseous hydrogen at 1,900 psi. The measured fracture toughness values are consistent with those reported in the literature [5]. Exposure to high-pressure hydrogen results in significant reduction in fracture toughness for the 4340 steel weld HAZ. Such hydrogen embrittlement is indeed severe, though not unexpected. The 4340 steel relies on a martensitic microstructure for its high strength. The martensitic microstructure and associated high carbon content make 4340 steel prone to HE [5]. On the other hand, new generation pipeline steels often utilize micro-alloying for improved strength and favorable microstructure for HE resistance.

Cost-Effective FSW of Pipeline Steel for Improved HE Resistance

Figure 3(a) is a snapshot of FSW of X-65 steel pipe sections. The resulting pipe girth weld is shown in

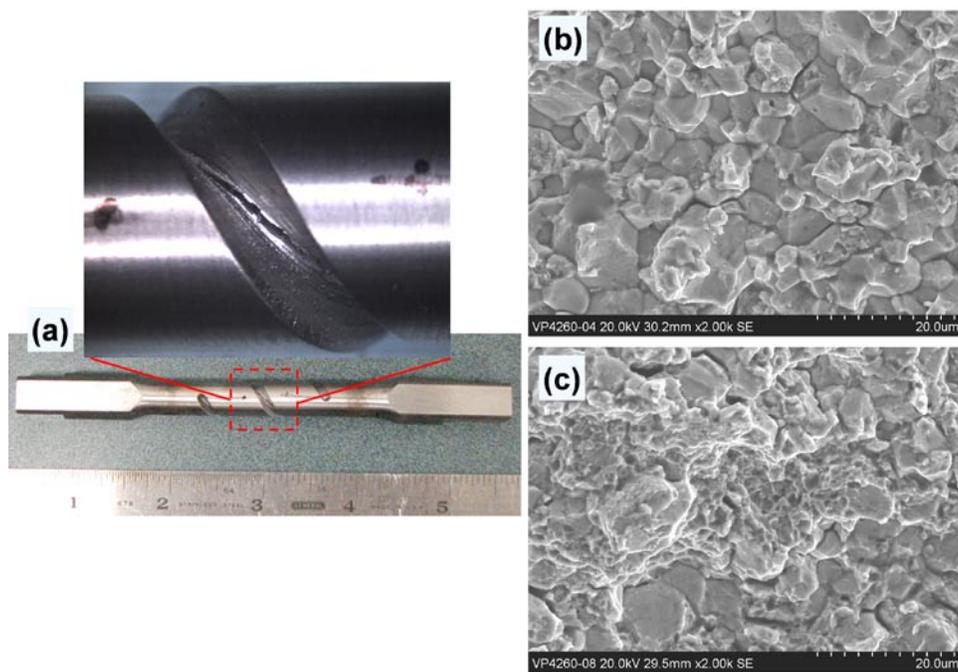

FIGURE 2. (a) Surface appearance of a fractured sample after hydrogen exposure, (b) SEM image of fracture surface near the notch root, and (c) SEM image of fracture surface away from the notch root

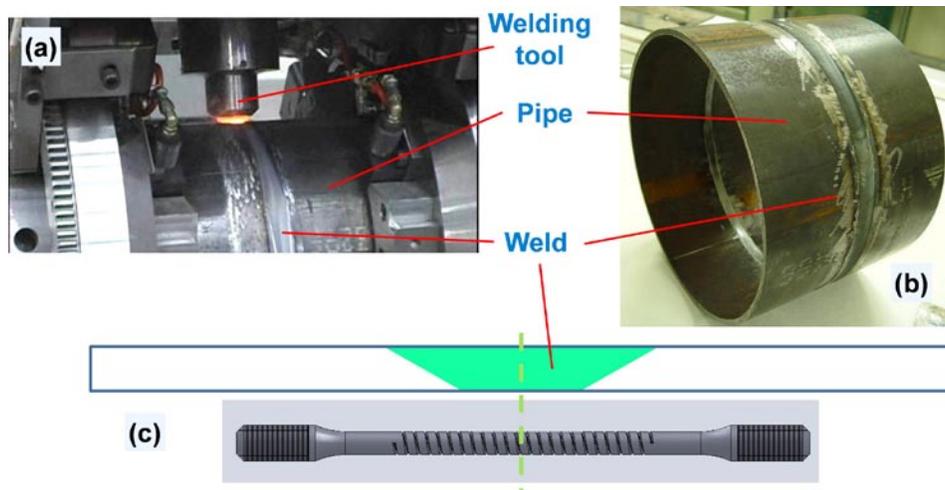

FIGURE 3. (a) Snapshot of FSW of X-65 steel pipe sections, (b) resulting pipe girth weld, and (c) schematic drawing of multi-notch tensile specimen

Figure 3(b). Previous studies on FSW of pipeline steel demonstrated considerable improvement of weld toughness and strength over the conventional arc weld in air [6]. In FY 2011, the in situ multi-notch tensile test is applied to study the resistance to HE of friction stir weld exposed to high-pressure hydrogen. Figure 3(c) is a schematic of the transverse cross-section of friction stir girth weld from which the multi-notch specimen is machined. The helical notch samples various weld regions including the stir zone, thermo-mechanically affected zone, HAZ and base metal. During testing, the notched sample is put into a load frame similar to that shown in Figure 1, where a tensile load rather than a torsional load is applied to the sample. The tensile load frame is placed inside the pressure vessel, charged to the desired hydrogen pressure, to measure the threshold tensile load for crack initiation in hydrogen.

It is noted that the multi-notch tensile test gives a qualitative ranking of microstructure sensitivity to HE. It is used because the notched samples can be readily machined from the relatively thin X-65 pipe (wall thickness = 0.24 in., or 6.1 mm). Nevertheless, such tests can provide insights into the relative performance of friction stir welds over conventional arc welds.

Preliminary tests have shown some encouraging results, as the friction stir weld sample exposed to hydrogen does not fracture at a load that is 70% of the fracture load in air. Additional tests on X-65 FSW are ongoing and are expected to be completed by September-November 2011 timeframe.

Improving Capability of Testing Apparatus

Since the current testing apparatus directly utilizes the regular hydrogen cylinder for pressuring, the maximum pressure is thus limited to about 1,900 psi. A new hydrogen charging system capable of maintaining or varying H_2 pressure up to 10,000 psi has been designed and assembled. The schematic drawing of the charging system is shown in Figure 4. The system will enable the study of the effect of hydrogen on material properties under very high pressures that are relevant to hydrogen production, delivery, and storage infrastructure.

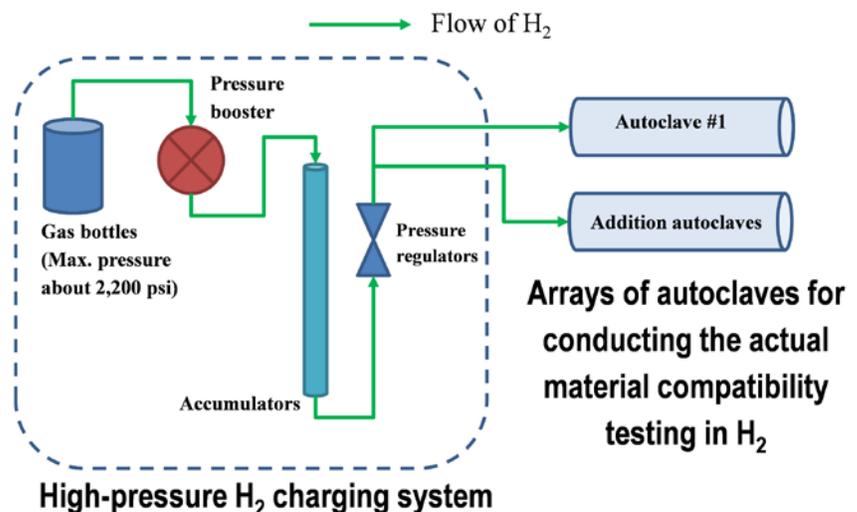

FIGURE 4. Schematic of a hydrogen charging system capable of maintaining or varying pressure up to 10,000 psi

Conclusions and Future Directions

- Demonstrated in situ SNTT for cost-effective and accurate measurement of the fracture toughness degradation in steel welds exposed to high-pressure hydrogen. The quantitative knowledge provides the technical basis for managing the weld region, i.e., the weakest link for the structural integrity and safety of hydrogen delivery infrastructure.
- Preliminary results showed FSW of pipeline steel could result in favorable microstructure with superior properties compared to the conventional arc welding.
- For the duration of FY 2011, we plan to complete (1) the study on HE resistance of X-65 steel pipe FSW, (2) the microstructure characterization of fracture surface of 4340 steel weld exposed to H₂, and (3) the assembly of high-pressure hydrogen testing system.
- At the discretion of DOE, future direction may include the application of special in situ testing methods and apparatus to study hydrogen-induced property degradation in other important materials and their welds relevant to hydrogen infrastructure.

Project Start Date: October 1, 2006
 Project End Date: September 30, 2011

Fiscal Year (FY) 2011 Objectives

- Develop advanced materials and coatings for hydrogen pipeline compressors.
- Achieve greater reliability, increased efficiency, and lower capital investment and maintenance costs in hydrogen pipeline compressors.
- Research existing and novel hydrogen compression technologies that can improve reliability, eliminate contamination, and reduce cost.

Technical Barriers

The project addresses the following technical barrier from the Hydrogen Delivery section (3.2.4.2) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(B) Reliability and Costs of Hydrogen Compression

Technical Targets

This project is directed toward the study of fundamental mechanisms associated with the tribology of hydrogen pipeline compressors (friction, wear, and degradation). The goal of the research is to identify materials and engineered surface treatments that provide low friction and wear resistance required to achieve the energy efficiency and reliability targets for pipeline compressors. Accordingly, the project tasks address the challenges associated with meeting the DOE hydrogen delivery performance and cost targets for 2017 in Table 1.

TABLE 1. Hydrogen Delivery Performance and Cost Targets for 2017

Technical Targets for Hydrogen Delivery		
Category	FY 2012 Targets	2010 Status
Reliability	Improved	Low
Energy Efficiency	98%	< 98%
Total Capital Investment	\$12M	> \$15M
Maintenance	7%	> 10%
Contamination	Varies	Unknown

FY 2011 Accomplishments

- Prior year accomplishments have been in the nature of finding a low-friction coating that can stand up to the conditions of unlubricated sliding in H₂. These tests were initially conducted with a modified in-house tribometer that could operate at room temperature.
- Candidate materials that were obtained in-house and from commercial companies were studied in detail and the general nature of each was characterized with the room-temperature tribometer.
- The design specifications and procurement of new high-temperature hydrogen tribometer was started in 2008, and the installed machine was accepted in 2010.
- The leading materials were found to be thin film carbon coatings, particularly hydrogenated carbon known as near-frictionless coating (NFC) 7, which shows very small wear in tests.
- Other counterface materials studies were MoS₂, carbon fiber, iron boride, sp³ diamondlike carbon (DLC), Ni-poly-tetrafluoroethylene (PTFE), and carbon-carbon.
- Initial tests using the new elevated tribometer found the NFC7 carbon functioned to 300°C, but apparently has a temperature limit of 400°C in H₂ gas.

Introduction

Compressors are critical components used in the production and delivery of hydrogen. Current reciprocating compressors are costly, are subject to excessive wear, have poor reliability, and often require the use of lubricants that can contaminate the hydrogen (used in fuel cells).

The primary objective of this project is to identify – and develop as required – advanced materials and coatings that can achieve the friction, wear, and reliability requirements for dynamically loaded components (seal and bearings) in high-temperature, high-pressure hydrogen environments prototypical of pipeline and forecourt compressor systems.

The DOE Strategic Directions for Hydrogen Delivery Workshop identified critical needs in the development of advanced hydrogen compressors – notably, the need to minimize moving parts and to address wear through new designs (centrifugal, linear, guided rotor, and electrochemical) and improved compressor materials. The DOE is supporting several compressor design studies on hydrogen pipeline compression, specifically addressing oil-free designs that demonstrate compression in the 0-500 psig to 800-1,200 psig range with significant improvements in efficiency, contamination, and reliability/durability.

One of the designs by Mohawk Innovative Technology, Inc. (MiTi[®]) involves using oil-free foil bearings and seals in a centrifugal compressor, and MiTi[®] identified the development of bearings, seals, and oil-free tribological coatings as crucial to the successful development of an advanced compressor. MiTi[®] and Argonne have developed potential coatings for these rigorous applications; however, the performance of these coatings (as well as the nickel-alloy substrates) in high-temperature, high-speed hydrogen environments is unknown at this point.

Approach

The approach that is being undertaken is to evaluate the tribological performance of candidate seal and bearing materials under consideration by compressor manufacturers and provide data required to select the optimum seal and bearing material/coating configuration for a 300-kg/min centrifugal compressor and high-pressure, low-flow positive displacement compressor. This effort will include a) evaluating the effects of a hydrogen environment on the mechanical properties of Ni alloys, b) evaluating the feasibility of coating suitable substrates with Argonne's NFC and outside vendor coatings, c) establishing the requirements and testing needs for NFC and a series of foil seal coatings, and d) evaluating foil seal and bearings under conditions prototypic of the proposed MiTi[®] hydrogen compressor.

The research uses facilities and expertise at Argonne – notably the ability to deposit advanced high-performance coatings (e.g., NFC), to test and evaluate coatings under extreme conditions, and to characterize and understand friction, wear, and surface degradation phenomena that determine component lifetime and reliability.

Different contact stress/sliding speed regimes were identified, depending on compressor design:

- Positive displacement – high contact stress, low sliding speed
- Axial flow compressors – high speed, low contact stresses
- Centrifugal compressors – intermediate speeds and contact stresses

Based on the range of contact stresses and sliding speeds anticipated for these compressors, we will replicate lab conditions to encompass nominal contact stresses

between 2 and 1,500 psi, with sliding speeds from 0.1 to 10 m/s. Operating temperatures up to 500°C due to working-gas adiabatic heating and flash/asperity heating can add an additional 500 to 750°C (depending on load, speed, thermal properties, and friction) to the temperature of near-surface asperities. The coating deposition is focused on NFC and commercial coatings based on conventional solid lubricants. The substrates chosen are stainless steels, nickel alloys, and Cr-Mo steels.

Results

New Test Machine

In the past year, the main focus was the acceptance and first tests using a new high-temperature test rig, which is shown in the photograph in Figure 1. The test machine exhibited deficiencies in operation which were repaired under warranty. Further deficiencies in the pressure control system were overcome in June 2011. Because the prescribed tests call for a low pressure sliding condition the machine needed to be modified from pin-on-disk to thrust washer configuration.

Continuing Tests to Evaluate Materials

In FY 2011, the FY 2011 milestones were largely met. Milestone 1 required a satisfactory acceptance test demonstrating 2,000 rpm operation for 4 h in 0.9-bar H₂ gas at 500°C with continuous measurement of friction, wear,

FIGURE 1. Photograph of new high-temperature hydrogen test machine in open position for loading of test specimens.

temperature, and sliding distance. This milestone was met 100%. Figure 1 shows a photograph of the test machine installed and operational. Milestone 2 was to complete durability testing of a NFC7 compressor foil bearing material and demonstrate a coefficient of friction that meets the desired compressor design requirements of < 0.1 under 14 kPa load, over a temperature range of 100–500°C, and in 99.999% H₂ gas. This milestone was met 90% by obtaining room temperature, 100°C, 200°C, 300°C tests, on compressor foil-bearing material producing coefficients of friction < 0.1 , at 5.6 kPa load, in 99.999% hydrogen. Figure 2 shows that the coefficient of friction is below 0.1 at all test temperatures up to 300°C, meeting the target value. However, this was not the case at 400°C for which the coefficient of friction jumped to unacceptably high values. Figure 3 shows

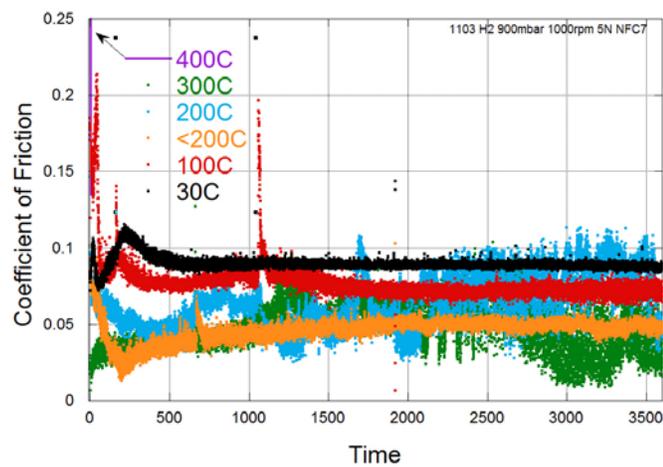

FIGURE 2. Graph showing coefficient of sliding friction as a function of test time for the NFC7 material sliding in H₂ gas against Hastelloy X at various indicated temperatures.

post-test images of the test coupons and reveals adequate durability for the NFC7 material at test temperatures up to 300°C, but failure at 400°C. Milestone 3 was to complete ball-on-disk tests on the test materials from inventory (N3FC, NFC6, MoS₂/graphite, X-750, boride, carbon composite) at temperatures up to 400°C for durations up to 12 hours or to point where materials fail. This was 10% completed by completed using the room temperature test rig in early part of FY 2011.

Most Recent Results

Table 2 shows the most recent tabular results for the most recent thrust washer tests, omitting those not run in H₂ gas. Most tests, except for those terminated early due to extreme wear, were for up to two hours duration with a 50% duty cycle, 50s on and 50s off at speeds up to 6,000 rpm. Typical results for a nickel-PTFE film are shown in Figure 4.

Conclusions and Future Directions

Longer-duration room-temperature testing was performed on existing (NFC6) and new (proprietary DLC and Argonne NFC7) materials, with excellent results for the latter. Final problems with the new elevated temperature tribometer were worked out, and initial tests showed the limitation of carbon-based materials may be 400°C. We will finish up testing of promising materials at typical in-service temperatures. The knowledge that is being gained will also be directly applicable to unlubricated forecourt compressors. The original goal of “Large Compressors: Transmission, Terminals, Geological Storage” is being broadened to include the section “Forecourt Compressors: Forecourt,” and discussions have been started with two manufacturers of non-centrifugal hydrogen compressors who have products in the field that are exhibiting the need for frequent scheduled

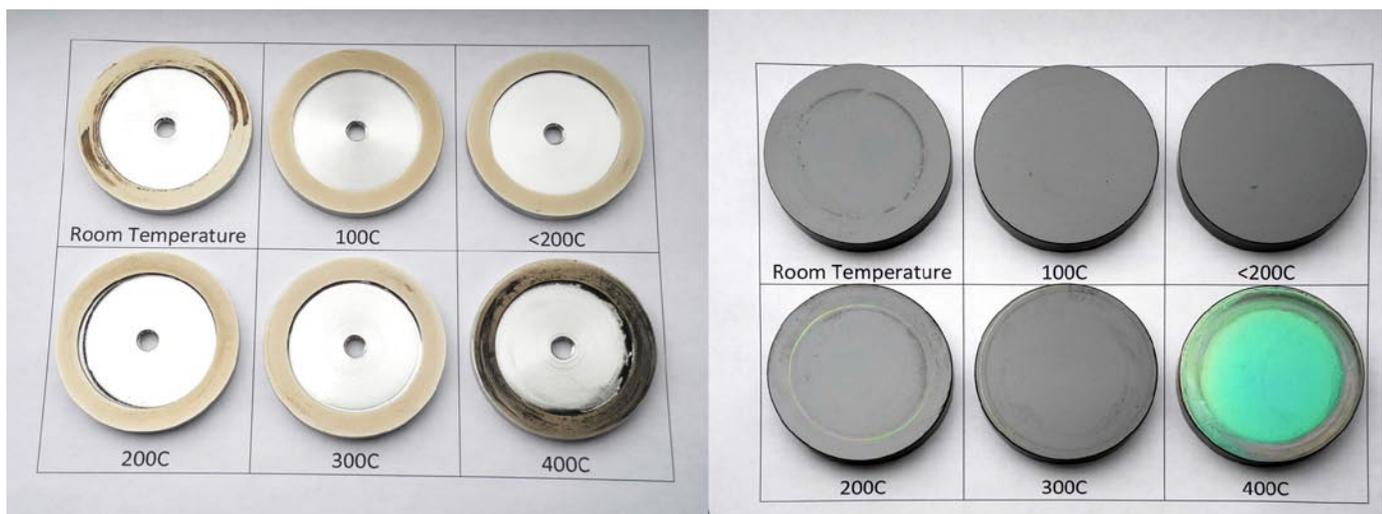

FIGURE 3. Photographs of worn thrust-washer test pairs (stationary bottom samples coated with NFC7-right, rotating Hastelloy X top samples-left) after 1 hr sliding at indicated test temperatures in H₂ gas.

TABLE 2. Most Recent Results From Thrust-Washer Tests

Rotating Face	Stationary Counterface	Environment	Friction	Wear Face	Wear Counterface
MK MoS ₂	X750	Hydrogen	Medium 0.4	High abrasion	Low
Fe/Mo/Boride	316ss	Hydrogen	Med high 0.6	Low abrasion	Low

and unscheduled maintenance. This revised goal will involve conducting longer-term sliding tests on materials used in forecourt compressors for “bone dry” use (e.g.,

polyether ether ether ketone and carbon-tetrafluoroethylene instead of nickel alloys, as has been done so far). We will continue nanoindentation studies to elucidate the possible relationship of surface mechanical properties to tribology friction and wear. This research leverages facilities and expertise at Argonne used to develop advanced materials and coatings for dry sliding conditions – notably the ability to deposit advanced high-performance coatings, test and evaluate coatings under extreme conditions, and characterize and understand friction, wear, and surface degradation phenomena that determine component lifetime and reliability. Concurrently we will to initiate discussions with point-of-delivery compressor users and manufacturers to obtain and examine failed forecourt compressor parts from reciprocating compressor partner to identify failure mechanisms and possible remedies.

Contract Number: DE-FG36-08GO18064.A000

Project Start Date: June 1, 2008
Projected End Date: May 31, 2012

Fiscal Year (FY) 2011 Objectives

This project has several well defined objectives intended to experimentally demonstrate highly efficient hydrogen liquefiers. These include:

- Develop validated engineering design data for active magnetic regenerative liquefiers (AMRLs) for liquefied hydrogen (LH₂) (or liquefied natural gas) to meet or exceed DOE's liquefaction targets for both capital and energy efficiency.
- Analyze, design, fabricate, and test AMRL prototypes to experimentally demonstrate this technology and answer numerous questions such as how to design optimized layered magnetic regenerators with bypass flow of the heat transfer fluid.
- Validate the high figure of merit (FOM) predicted by our unique numerical simulation model used to analyze and design AMRL prototypes.
- From June 2009 through May 2011 our focus has been to analyze, design, fabricate, and test our first AMRL prototype with a target of spanning from ~290 K to ~120 K with a high FOM.

Technical Barriers

This project addresses the following technical delivery barrier from the Hydrogen Delivery section of the Fuel Cell Technologies Multi-Year Research, Development and Demonstration Plan, i.e.,

- (C) High Cost and Low Energy Efficiency of Hydrogen Liquefaction

Technical Targets

Conventional hydrogen liquefiers at any scale have a maximum FOM of ~0.35 due primarily to the intrinsic difficulty of rapid, efficient compression of either hydrogen or helium working gases (depending on the liquefier design). The novel approach of this AMRL project uses solid magnetic working refrigerants cycled in and out of high magnetic fields to execute an efficient active regenerative magnetic liquefaction cycle that avoids the use of gas compressors. Numerical simulation modeling of high performance AMRL designs indicates certain achievable designs have promise to simultaneously lower installed capital costs/unit capacity and to increase thermodynamic efficiency from a FOM of ~0.35 toward ~0.5 to ~0.6. Results from experimental prototypes should support the design and deployment of hydrogen liquefier plants that meet the DOE 2011 hydrogen production and delivery targets:

- Delivery cost of LH₂ at <\$1.00/kg.
- \$40 MM capital cost for a turn-key plant with a capacity of 30 te/day.
- Operational efficiency of a complete liquefier plant of 75% as defined by DOE and commensurate with a liquefier FOM of ~0.6.

FY 2011 Accomplishments

- Successfully completed the design, fabrication, and test of the dual Gd magnetic regenerators, two pneumatic drives, and the heat transfer fluid subsystems of our reciprocating active magnetic regenerative refrigerator (AMRR) prototype.
- Mechanically and electrically integrated all eight subsystems of our first AMRR prototype into an operational system interfaced to the LabVIEW data acquisition and control program.
- Experimentally demonstrated the first cooling curves of our AMRR and begin to measure its performance under a variety of different operational parameters such as cycle frequency, magnetic field strength, heat transfer fluid flow rate, amount of bypass flow of the heat transfer fluid while measuring work input, temperature span, cooling capability as a function of cold temperature as a function of the amount of bypass flow of the heat transfer fluid for ~290 K to ~240 K temperature span.
- Began to analyze results to compare measured performance data against our numerical process

simulation calculations of this specific reciprocating dual regenerator AMRR prototype.

- Began to incorporate lessons learned from first prototype into the design of the second AMRL prototype with a rotary configuration with the objective to span from ~290 K to ~20 K and produce LH₂ with a FOM of ~0.5.

Introduction

AMRL technology promises cost-effective and efficient liquefaction of hydrogen because it eliminates the compressors, the largest source of inefficiency in Claude-cycle liquefiers. However, as with any innovative technique, many questions have to be investigated and understood before commercial applications happen. Since the mid-1970s, magnetic refrigeration technology for applications above 1 K beyond research laboratory use has been investigated with increasing understanding of magnetic cycles, magnetic refrigerants from ~4 K to ~300 K, and practical magnetic refrigeration prototype designs. The seminal patent on the ‘active magnetic regenerator’ was issued in 1982. The principle of operation this unique refrigeration cycle is illustrated as an AMRR in Figure 1. Only in the last ~15-20 years have there been significant engineering efforts on two commercial applications of magnetic refrigeration: those with small cooling power (~100 W), non-chlorofluorocarbon refrigeration near room temperature using permanent magnets and much larger capacity cryogenic liquefiers for hydrogen and natural gas (~100s of kW of refrigeration).

The AMRL project funded under this DOE award is an extensive engineering effort to analyze, design, fabricate, and test innovative natural gas and hydrogen liquefier prototypes. Successful demonstration of AMRL prototypes will answer a few key design questions and provide a proven knowledge base to enable use of advanced liquefiers for various hydrogen infrastructure projects that cost-effectively provide

LH₂ energy storage/delivery for gaseous hydrogen produced by several sources including electrolysis at intermittent wind or solar energy plants. The AMRL technology readily scales up or down in capacity so it could be scaled to reach DOE’s target of 30 te/day and down to a vehicular refueling station size of ~2-3 te/day where gaseous hydrogen continuously produced via steam methane reformation, or high temperature fuel cells, or electrolysis could be liquefied, stored and supplied as LH₂ and/or compressed hydrogen produced from liquid hydrogen (LCH₂).

Approach

During the past year our focus has been to complete the design, fabrication, integration and testing of our first AMRR prototype with the objective of spanning from ~290 K to ~120 K with multi-layer regenerators and bypass flow of the heat transfer fluid. We have demonstrated the initial results toward this objective. The experimental results will validate our numerical simulation mode and guide the design of the AMRL prototype spanning from ~290 K to ~20 K.

Results

The completed three-dimensional mechanical design of the first laboratory-scale AMRR prototype with dual regenerators reciprocating in and out of a 7 Tesla (T), large bore superconducting magnet is illustrated in Figure 2. It includes the various components of the eight subsystems required to execute the AMRR cycle. This prototype is designed to operate between ~290 K at the hot end and cold end temperatures down to as low as ~120 K. The design required numerous calculations of the thermodynamics, heat transfer, fluid dynamics, structural loads, and many related items. One of the more challenging design features was the support of the 4 K superconducting magnet that has to be structurally capable of withstanding large magnetic forces between the magnetic materials in the dual regenerators and the magnetic field of the magnet. The center access tube through the magnet is insulated from the magnet to enable the dual regenerators to operate between ~290 K and ~120 K.

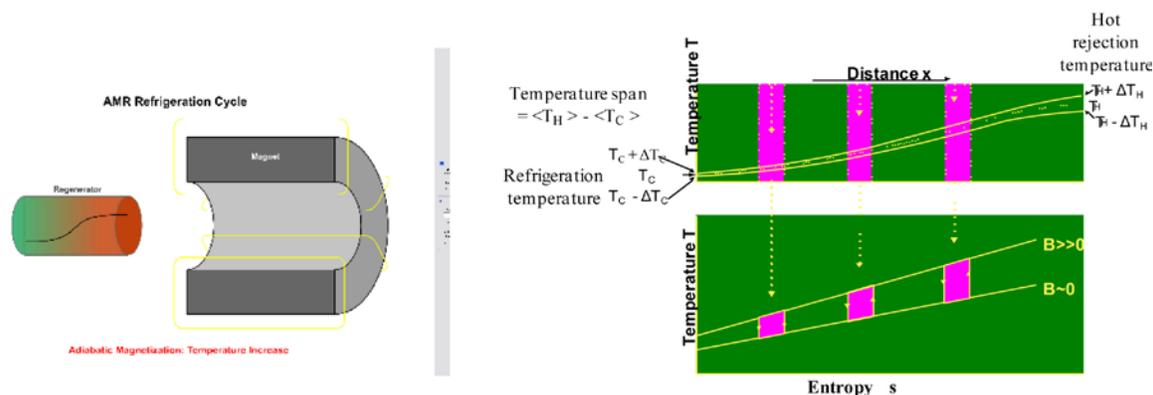

FIGURE 1. Active Magnetic Regenerative Liquefier

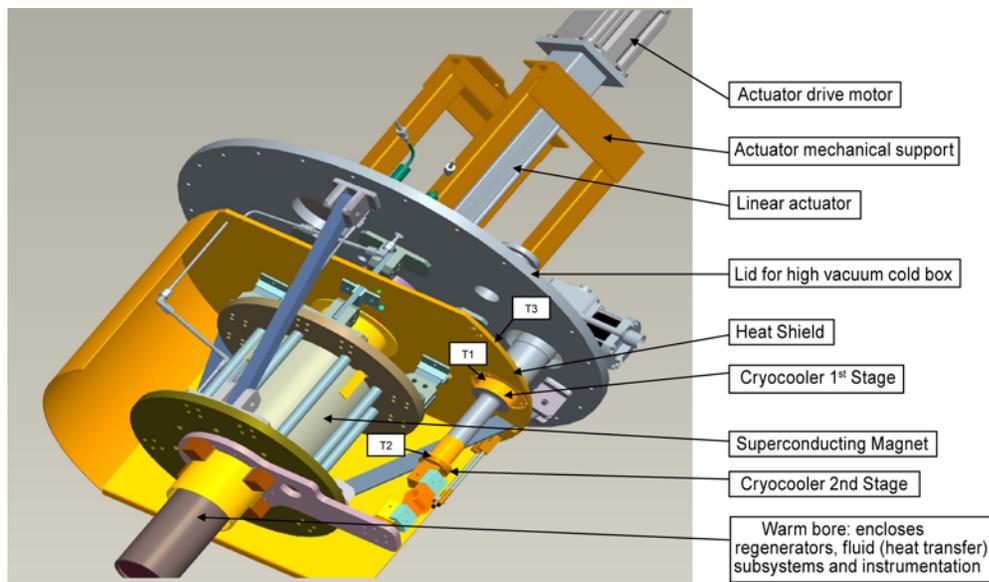

FIGURE 2. Reciprocating AMRR Prototype Design

The dual magnetic regenerators must be strong enough to react large magnetic forces and simultaneously be integrated with the pneumatically actuated mechanical drive mechanism and the helium heat transfer fluid subsystem pressurized to ~250 psia. The heat transfer fluid couples the heating and cooling of the magnetic regenerators to the hot heat sink and the cold heat exchanger between the dual regenerators. Figure 3 illustrates the resultant design of the two identical magnetic regenerators and the heat transfer fluid piping including the path for controlled bypass flow of the cold helium heat transfer fluid. Numerous sensors to measure temperature, helium flow rates, magnetic field strength, etc. are also integrated into these subsystems during the fabrication steps. All these sensors had to have vacuum-tight seals to insure that the high pressure helium did not leak into the high vacuum within the cold box during the AMRR operation. These sensors had to operate at high enough frequency to provide time resolution throughout the entire AMRR cycle. They were connected through high speed modules of a Compact-DAQ LabVIEW control and data acquisition computer.

Figure 4 presents the drive motions as a function of time from the pneumatically-actuated reciprocating drive of the dual magnetic regenerators and the drive motion of the pneumatically actuated positive displacement pump moving the heat transfer fluid as desired. Note that the two reciprocating motions are trapezoidal in time and out of phase with one another as required to properly execute the AMRR cycle.

Figure 5 illustrates a simplified piping and instrumentation diagram (P&ID) for the heat transfer fluid subsystem. It can be used to understand the relatively complex reciprocating flows of the heat transfer fluid during the AMRR operation. Figure 6 shows a photograph of the

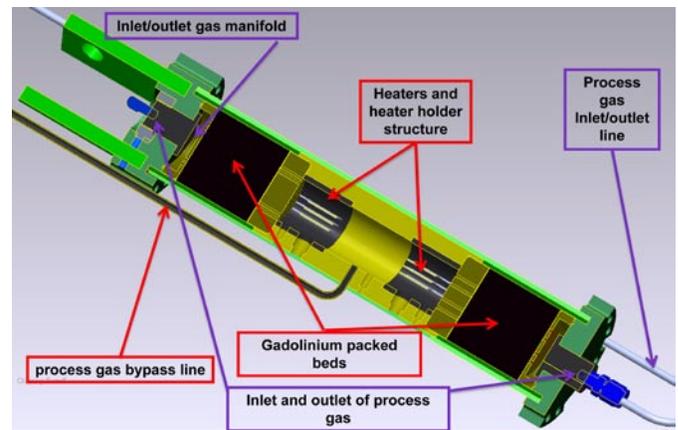

FIGURE 3. Dual Magnetic Regenerator Design Integrates Numerous Subsystems

FIGURE 6. Heat Transfer Fluid Subsystem Components

heat transfer fluid subsystem components including the brazed plate frame, counter-flow heat exchangers to couple the hot helium heat transfer fluid to the cold refrigerant from the vapor compression cycle chiller used to ensure a stable hot temperature of the heat transfer fluid during an experimental run of the AMRR. The chiller is located in the center of this photograph.

The initial cooling results from our first AMRR prototype were obtained on May 10, 2011 shortly before the poster was presented at the Annual Merit Review. The test results were not available for this report.

Conclusions and Future Directions

Heracles/Prometheus has made excellent progress and completed the design, fabrication, assembly and initial demonstration of cooling in its first AMRR prototype. All subsystems of the first lab-scale prototype were designed, built, and successfully tested. The initial measurements with the LabVIEW data acquisition program include the temperature span, cold cooling power, hot heat rejection temperature, operating frequency, total heat transfer fluid flow rate, bypass flow, applied magnetic field, etc. The recently obtained initial results spanning from ~ 292 K to ~ 240 K are very encouraging but have yet to be analyzed. The operational AMRR prototype enables us to experimentally answer key questions such as the best recipe for multiple layers of different magnetic refrigerants in one or more integrated regenerators with varying amounts of bypass flow of the heat transfer fluid. Our performance simulation model predicts that ~ 10 - 15 % of bypass flow should significantly improve the thermodynamic performance but the proof is in the pudding, i.e., measured results from an operational AMRR prototype. To our knowledge, these results will be the first such results for cryogenic liquefiers. We expect to use new insights and knowledge from the experimental results from the first AMRR prototype to validate our performance simulation code, and use that model to guide the design a rotary-type multi-stage AMRL prototype. This larger AMRL prototype should be capable of spanning from ~ 290 K to ~ 20 K to make ~ 25 kg/day of LH_2 . This will be the world's first AMRL to make LH_2 . The technical and financial report obligations for this project are completed when due.

FY 2011 Publications/Presentations

2. Several papers are being planned based on the impressive test results of our first AMRR prototype using Gd spheres.

IV. HYDROGEN STORAGE

IV.0 Hydrogen Storage Sub-Program Overview

The Hydrogen Storage sub-program supports research and development (R&D) of materials and technologies for compact, lightweight, and inexpensive storage of hydrogen. In Fiscal Year (FY) 2011, the sub-program continued to focus on R&D of low-pressure, materials-based technologies and engineered systems applicable to both stationary and transportation applications. Materials projects are focused in three main areas: metal hydrides, chemical hydrogen storage materials, and hydrogen sorbents. Additionally, increased efforts were directed at reducing the cost of compressed gas storage systems (i.e., physical storage) as a near-term commercialization pathway. The storage portfolio currently comprises projects involving 39 universities, 13 companies, and 14 federal laboratories and involves work in hydrogen storage materials discovery; materials-based system engineering; advanced high-pressure tank R&D; and system performance and costs analyses.

Goal

The sub-program's goal is to develop and demonstrate viable hydrogen storage technologies for transportation and early market fuel cell applications such as stationary power, backup power, and material handling equipment.

Objectives¹

For light-duty vehicles, the key objective is to allow for a driving range of more than 300 miles (500 km), while meeting packaging, cost, safety, and performance requirements to be competitive with current vehicles. Although automakers have made progress in demonstrating some vehicles able to travel more than 300 miles on a single fill, using high-pressure tanks, this driving range must be achievable across different vehicle models without compromising space, performance, or cost. The sub-program's 2017 intermediate targets for transportation applications will allow some hydrogen-fueled vehicle platforms to meet customer performance expectations, while the ultimate targets are intended to facilitate the introduction of hydrogen-fueled propulsion systems across the majority of vehicle classes and models. Advanced storage materials and concepts will be needed to meet the 2017 and ultimate targets.

In pursuit of high level goals and targets for hydrogen storage, there are many requirements for achieving technical success, including improvements in volume, weight, cost, durability, cycle life, and transient performance. The full set of detailed hydrogen storage targets for light-duty vehicles can be found at: http://www1.eere.energy.gov/hydrogenandfuelcells/storage/pdfs/targets_on-board_hydro_storage.pdf. These targets are based on the requirements of the application—not the current status of the technologies—and they account for differences in vehicle architecture between conventional vehicles and fuel cell vehicles.

FY 2011 Technology Status

On-board hydrogen storage approaches under investigation include: high-capacity metal hydrides; high surface-area sorbents; chemical hydrogen storage carriers; low-cost and conformable tanks; compressed/cryogenic hydrogen tanks; and new materials or processes, such as conducting polymers, spillover materials, metal organic frameworks (MOFs), and other nanostructured materials (Figure 1). There are two principal classes of on-board storage systems: “on-board reversible” systems that can be refueled onboard the vehicle from a hydrogen supply at the fueling station and “regenerable off-board” systems involving materials that are not easily and quickly “refilled” or regenerated with hydrogen while onboard the vehicle. On-board reversible systems include physical storage systems, such as compressed/cryogenic tanks, as well as on-board reversible material systems such as metal hydrides and high-surface-area sorbents. Regenerable off-board systems include chemical hydrogen storage materials and certain metal hydrides where the temperature, pressure, kinetics, and/or energy requirements are such that the processes must be conducted off the vehicle.

The current projected storage system gravimetric and volumetric capacities are shown relative to the 2017 targets in Figures 2 and 3. On a routine basis the sub-program has system capacity projections made for the

¹ Note: Targets and milestones are under revision; therefore, individual progress reports may reference prior targets.

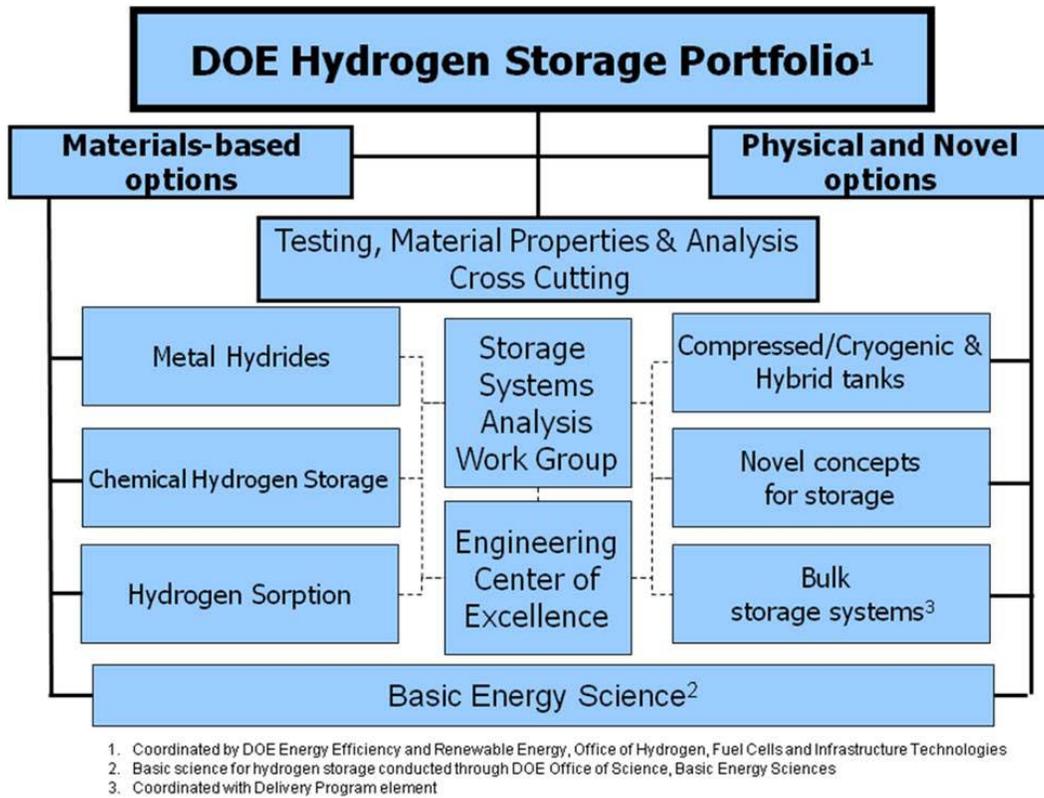

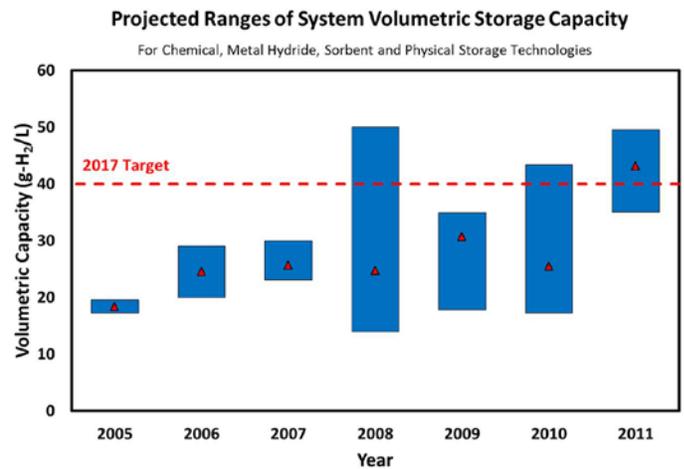

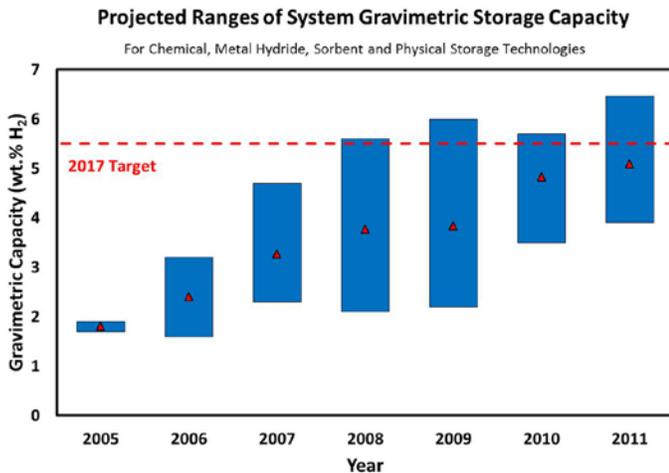

FIGURE 1. Structure of the DOE Hydrogen Storage Activities

Based on analyses using the best available data and information for each technology analyzed in the given year.

Based on analyses using the best available data and information for each technology analyzed in the given year.

FIGURES 2 AND 3. Status of projected hydrogen storage system gravimetric and volumetric capacities versus 2017 on-board system targets. Note that all systems were sized to provide 5.6 kg of useable hydrogen and that the plotted data points are the average value for all systems analyzed during each year while the bars correspond to the range of maximum and minimum values obtained for the year. Also note that systems with predicted capacities exceeding the gravimetric targets do not necessarily meet all other targets.

various on-board hydrogen storage technologies under development. Analytical models use the best available data for the technologies to project the gravimetric and volumetric capacities of complete storage systems that meet the required operational specifications. The capacity projections are periodically revised as new and more complete data become available and when improvements to system models are developed. Confidence

in the accuracy of the projection improves with the maturity of the technology; for instance, there is higher confidence in projections for relatively mature compressed gas systems than for much less mature complex hydride systems. The range bars shown in Figures 2 and 3 represent the ranges of volumetric and gravimetric capacity projections conducted for all the on-board storage technologies during the given year. The point within the bars is the average (mean) capacity for the technologies analyzed within the given year.

FY 2011 Accomplishments

Hydrogen Storage Materials

In FY 2011, the sub-program's materials-discovery projects developed a number of new materials and improved the performance of other materials. Key accomplishments in FY 2011 include: characterization of high surface area sorbents with specific surface areas greater than 6,000 m² per gram and excess hydrogen sorption capacities exceeding 8% by weight at 77 K; demonstration of cycling of Mg(BH₄)₂ at hydrogen capacities greater than 12% by weight under high temperature and pressure conditions; demonstration of alane slurry with 60% capacity by weight and with kinetics exceeding non-slurried alane; and determination that thermal stability of ionic liquids is dominated by choice of cation.

- Metal Hydrides
 - Brookhaven National Laboratory demonstrated 6 wt% hydrogen capacity from a slurry of alane, with desorption kinetics projected to meet the DOE targets at temperatures of ~100°C.
 - Demonstrated reversibility of greater than 12 wt% for Mg(BH₄)₂ under high pressure and temperature (950 bar and 400°C) conditions (University of Hawaii).
 - Demonstrated 2.5 wt% reversibility between Mg(BH₄)₂ and the triborane (Mg(B₃H₈)₂) under moderate pressure and temperature (100 bar and 200°C) conditions (University of Hawaii).
 - Demonstrated that nano-confined NaAlH₄ undergoes a single step desorption to NaH, Al, and H₂—i.e., it does not decompose through the Na₃AlH₆ phase as does bulk NaAlH₄, with a measured $\Delta H^\circ=47 \text{ kJ mol}^{-1}$ and $E_a = 47\text{-}53 \text{ kJ mol}^{-1}$ (Sandia National Laboratories).
- Chemical Hydrogen Storage Materials
 - Partially identified cation/anion selection rules for ionic liquid performance (thermal degradation) resulting in desirable liquid fuel range, and identified ionic liquids with good thermal stability (Los Alamos National Laboratory/University of Pennsylvania).
 - Experimentally determined the energetic landscape of several favorable carbon-boron-nitrogen (CBN) materials and provided a direct comparison with results from the high-level computationally predicted values (University of Oregon).
 - Synthesized the parent six-membered fully charged fuel and partially charged parent BN-indole material system for the CBN materials (University of Oregon).
 - Formulated N-H, N-tBu, and N-Me materials as liquids at around 80°C (University of Oregon).
- Hydrogen Sorption Materials
 - A highly stable porous polymer network (PPN-4) was synthesized and independently validated at Southwest Research Institute® with a Brunauer-Emmett-Teller (BET) surface area of 6,460 m²/g and 8.3 wt% excess hydrogen adsorption capacity at 77 K and 55 bar (Texas A&M University).
 - Demonstrated spectroscopic evidence that appears to support the spillover effect, through observation of C-H bonds via both diffuse reflectance infrared Fourier transform spectroscopy measurements where Pt-C showed a unique stretch that was tentatively assigned to spillover hydrogen atoms and neutron scattering that revealed apparent hydrogen wagging modes which correlated to those energies predicted by theory (National Renewable Energy Laboratory).
 - Manufactured boron-substituted carbon by deposition and thermolysis of B10H14, resulting in a high-surface-area (BET surface area greater than 2,100 m²/g), high-boron-containing (8.6 wt% boron) material that achieved a ~30% increase in hydrogen excess absorption relative to the carbon precursor (on a per-surface-area unit basis) due to the increase in the average binding energy provided by the substituted boron.

System Engineering

In FY 2011, the Hydrogen Storage Engineering Center of Excellence (HSECoE) completed a baseline assessment of storage system models for reversible metal hydrides, cryo-sorbents, and both solid- and liquid-phase off-board regenerable chemical hydrogen storage material systems. The HSECoE assessed these models against the full set of DOE on-board storage targets. The Hydrogen Storage Simulator, which couples the onboard storage system model with fuel cell power plant and vehicle performance models, was run through various drive cycles to vary the hydrogen demand required from the storage system. The comparison of storage system performance against the DOE storage targets was factored into the decision to continue cryo-sorbent and liquid-phase chemical hydrogen storage material systems into Phase II of the HSECoE. Work on solid-phase chemical hydrogen storage will not be continued, due to the difficulties involved in moving solid material onto and off the vehicle rapidly enough to meet the refueling-time target. In addition, the HSECoE will not continue work on reversible metal-hydride storage materials, because these materials require elevated temperatures for charging and discharging and/or have high sorption enthalpies. While there are complex hydride materials that could allow a system to meet the system gravimetric target, the additional hydrogen that is required to be consumed to provide the sorption temperatures and energy means that the systems cannot meet DOE performance targets for onboard vehicle use.

- Conducted a status assessment of complete, engineered, materials-based hydrogen storage systems to meet the DOE 2010 and 2017 on-board hydrogen storage targets. The assessments were used as a basis for go/no-go decisions for continuing or not continuing engineering development of systems into Phase II of the HSECoE for the material classes. A decision was made to continue development of sorbent and fluid-phase chemical hydrogen storage systems and not to continue development reversible metal hydride and solid-phase chemical hydrogen storage material systems in Phase II of the HSECoE.
- Completed a unified model utilizing the MATLAB[®]/SimuLink environment that incorporates the performance demands and requirements of a vehicle powered by a fuel cell and those of a fuel cell with the hydrogen storage system, including thermal management (HSECoE).
- Demonstrated that expanded natural graphite, when added at levels as low as 5% weight fraction, effectively improves the thermal conductivity of compacted metal hydrides and simplifies heat-exchanger design (United Technologies Research Center).
- Obtained a 4X improvement in excess volumetric capacity with only ~15% reduction in gravimetric capacity for compacted MOF-5 versus powder MOF-5 (Ford).
- Validated kinetic models for ammonia borane by pressure composition isotherm measurements and larger-scale testing (Pacific Northwest National Laboratory).
- Demonstrated ability to scrub borazine and diborane from hydrogen released from ammonia borane to meet fuel cell quality specifications (Los Alamos National Laboratory).

Compressed and Cryogenic Tanks

In FY 2011, the sub-program increased its efforts on reducing the cost of compressed hydrogen gas storage tanks by initiating new efforts on low-cost, high-strength carbon fiber. Inexpensive storage vessels for compressed hydrogen gas are considered the most likely near-term hydrogen storage solution for the initial commercialization of fuel cell electric vehicles, as well as for other early market applications. Carbon fiber composites can currently contribute as much as 75% or more to the overall cost of tanks. A topic on “reducing the cost of high-pressure hydrogen storage tanks” was included in the FY 2011 Small Business Innovation Research solicitation, and two projects were selected—a project by Quantum Fuel Systems Technologies Worldwide, Inc., addressing advanced high-pressure tank manufacturing techniques and a project by Applied Nanotech, Inc., addressing alternative glass fibers and lightweight, high-strength carbon nanotube reinforced composites for tanks. Additionally the Hydrogen Storage sub-program supported an effort (co-funded with the DOE Vehicles Technology Program) at Oak Ridge National Laboratory to investigate the use of low-cost textile-grade fibers made from polyacrylic nitrile with methyl acrylate comonomer as precursors for high-strength carbon fiber production.

In February 2011, DOE held two workshops to identify strategies and R&D needs for lowering the cost of high-pressure hydrogen storage systems and to identify R&D needs and technical pathways for continued development of cryogenic storage, including both cryo-sorbent and cryo-compressed systems. The input garnered from these activities will aid in identifying key challenges, priorities, and needs for both compressed and cryogenic hydrogen storage systems and in development of future solicitations for R&D in these areas.

- Demonstrated the ability to melt-spin PAN precursor fibers with the target denier (for fibers 10 to 20 microns in diameter) with a one-step spinning/drawing process (Oak Ridge National Laboratory).

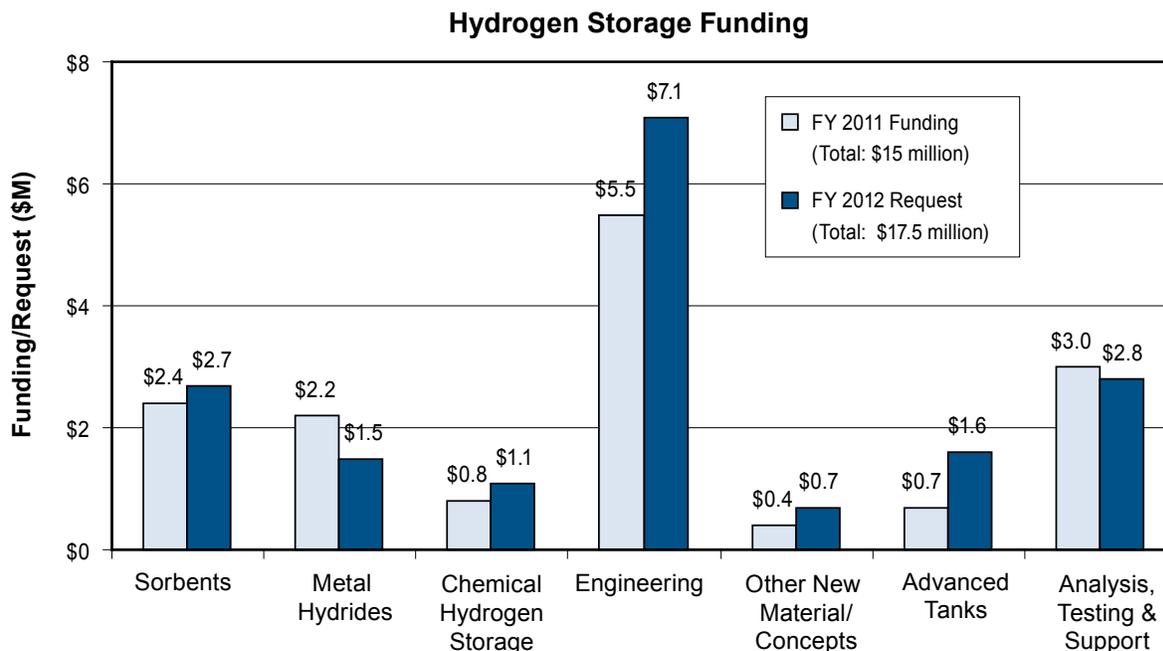

Testing, Materials Properties, and Analysis Cross-Cutting

In FY 2011, the Hydrogen Storage sub-program enlisted the National Renewable Energy Laboratory (NREL), Sandia National Laboratories (SNL), and the Pacific Northwest National Laboratory (PNNL) to carry out hydrogen storage needs assessments for non-automotive, early market applications. NREL and SNL were asked to identify the key early market applications for fuel cells where hydrogen storage presents a critical barrier for commercialization. They were also asked to determine the hydrogen storage needs for those applications and to perform gap analyses between the needs and current technologies. PNNL was asked to perform technology readiness level and manufacturing readiness level assessments of the applications and of hydrogen storage technologies these applications will require. These laboratories have gathered input (through workshops, interviews, and other activities) from stakeholders including end-users, integrators, and technology developers. The results from these assessments will be used by the sub-program to develop hydrogen storage targets, R&D plans, and future funding opportunity announcement topics for key early market applications.

- Performed system-level analysis of four hydrogen storage approaches (AX-21 and MOF-5 sorption, AB in ionic liquids, and alane), addressing capacity, charge/discharge rates, greenhouse gas emissions, safety, and cost, in addition to analysis of off-board regeneration (Argonne National Laboratory).
- Conducted and updated independent cost assessments of hydrogen storage systems using: MOF-177 sorption (\$16/kWh), AX-21 sorption (\$18/kWh), liquid hydrogen carriers (\$16/kWh), and 350-bar (\$15/kWh) and 700-bar (\$19/kWh) high-pressure tanks. All of these analyses were conducted assuming systems with capacities of 5.6 kg of useable hydrogen. Also completed preliminary on-board cost assessments for 350 and 700 bar compressed single-tank systems at different manufacturing volumes—costs for the 350-bar system ranged from \$15–\$29 per kWh, and costs for the 700-bar system ranged from \$19–\$36 per kWh (TIAX, LLC).
- Three sections (Introduction, Capacity, and Kinetics) of the Best-Practices Document on the Characterization of Hydrogen Storage Materials were completed with two more sections (Thermodynamics and Cycle-Life Properties) 95% complete.
- Performed independent capacity validation of three storage materials: 1) polyether ether ether ketone-derived carbon provided by State University of New York, 2) microporous carbon provided by the National Renewable Energy Laboratory, and 3) porous polymer network provided by Texas A&M University (Southwest Research Institute[®]).

Budget

The President's FY 2012 budget request includes \$17.5 million for hydrogen storage—compared with the FY 2011 congressional appropriation of \$15 million. In FY 2012, the Hydrogen Storage sub-program will continue to focus on materials discovery, system engineering for materials-based storage technologies, R&D to lower the cost of high-pressure storage systems, and systems analysis. The sub-program will also initiate activities focused on hydrogen storage for early market applications.

FY 2012 Plans

The technology portfolio for Hydrogen Storage emphasizes materials R&D to meet system targets for on-board and early market applications. While a focus on light-duty vehicle applications will continue, increased emphasis will be placed on new materials and novel concepts to meet performance requirements for early market applications. In FY 2012, goals and objectives for hydrogen storage for early market applications will be developed. The increased emphasis on developing lower-cost physical storage technologies will be strengthened. Specifically, the sub-program will use the Small Business Innovation Research program and coordinate with other efforts (e.g., DOE Vehicle Technologies Program, Defense Advanced Research Projects Agency, etc.) on development of approaches to produce low-cost carbon fiber for composite cylinders. System engineering and analysis will continue through the HSECoE and Argonne National Laboratory. Coordination with basic science efforts, including theory, characterization, and novel concepts, will continue during FY 2012. The sub-program will also coordinate with the National Science Foundation and Advanced Research Projects Agency–Energy through activities such as workshops and joint meetings.

Project Start Date: October 1, 2011
Project End Date: Project continuation and
direction determined annually by DOE

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan in descending order of impact:

- (A) System Weight and Volume
- (E) Charging/Discharging Rates
- (P) Understanding Chemisorption

Technical Targets

This project includes both fundamental studies of the sorption kinetics in the mixed metal amide, LiH/Mg(NH₂)₂ system, as well as new materials discovery in the mixed amide/borohydride system. Insights gained from these studies will be applied toward the design of storage systems that meet the following DOE 2010 and 2015 hydrogen storage targets (see Table 1 for values):

- System Gravimetric Capacity and Volumetric Density
- Charging/Discharging Rates
- Fuel Purity
- System Fill Time
- Minimum Hydrogen Delivery Rate

FY 2011 Accomplishments

- Majority of desorption products appear to be comprised of a mixture Mg₃N₂ and LiMgN while absorption products

Fiscal Year (FY) 2011 Objectives

- Determine the sorption kinetics for the transition metal catalyzed 2LiH+Mg(NH₂)₂+MgH₂ system under the full spectrum of temperatures and pressures required for hydrogen storage system design.
- Explore the effect of catalyst loading on both charge and discharge reaction pathways and kinetics as well as ammonia release.
- Identify reversible hydrogen storage compounds in the mixed metal/mix amide-borohydride system.

TABLE 1. Technical Targets for Onboard Hydrogen Storage Systems for Light-Duty Vehicle Applications using LiMgN System¹

¹ Values were determined from the average between the 2nd, 3rd and 4th isothermal absorption cycles for each system with the 1st cycle was excluded.

² Long fill times account for 2-step reaction, which accounts for approximately 60–80% H₂ absorbed.

³ Assumed 80 kW fuel cell for reported data,

TBD – to be determined

are comprised of MgH_2 , LiH , $\text{Mg}(\text{NH}_2)_2$ (confirmed by Raman spectroscopy) and unreacted Mg_3N_2 .

- All chemical dopants tested thus far, while significantly increasing desorption rate in the first cycle, have been shown to have no effect on sorption kinetics after the third cycle.
- A characteristic charging time (τ_{80}) of 30 minutes, calculated for the isothermal charging results, is faster than those presented for this material elsewhere in the literature.
- Processing methods have been shown to greatly affect sorption kinetics and capacity with high energy processing leading to formation of NH_3 and loss of capacity (6.66 wt%) while lower energy processes minimizing NH_3 release and resulting in higher capacities (8.0 wt%) and sorption kinetics.

Introduction

In an effort to identify and synthesize a reversible metal hydride material capable of meeting the 2015 hydrogen storage technical targets, researchers are investigating various metal hydrides/catalyst combinations. To date, the most promising in situ reversible compound stemming from the Metal Hydride Center of Excellence is $2\text{LiH}/\text{MgH}_2/\text{Mg}(\text{NH}_2)_2$ [1,2]. This compound resides among a series of similar compound stoichiometries ranging from Li:Mg ratios of 1:1 through 4:1 [1-7]. It has been found that the greatest hydrogen absorbing material is $2\text{LiH}+\text{Mg}(\text{NH}_2)_2+\text{MgH}_2$ which decomposes to LiMgN plus 8.1 wt% H_2 [1] with a calculated enthalpy of desorption of 32 kJ/mole H_2 . This composition has been reported to be reversible under fairly moderate conditions (160°C – 220°C for dehydriding, 160°C and 2,000 psi for rehydriding) [1]. This study of the LiMgN system used an autoclave-type high pressure charging apparatus and thermo-gravimetric analysis (TGA) measurements to confirm hydrogen storage capacities. The work reported in this investigation was designed to compliment the work of Lu *et al.* [1], by thoroughly measuring the isothermal kinetic hydrogen charge and discharge rates and further optimizing the kinetics through compositional adjustments.

Approach

$\text{LiH}/\text{Mg}(\text{NH}_2)_2$

The previously identified LiMgN material was studied by ball milling the precursor LiNH_2 and MgH_2 materials with the various modifiers to ensure a well-mixed and controlled initial state in terms of particle size. Material for this study was Frisch milled with a ball mass to material mass ratio of 30:1, following the work of Lu [1]. A Seivert's apparatus was used to measure the isothermal kinetics of

hydrogen charge and discharge. The hydrogen uptake was monitored by the drop in the hydrogen pressure in the system while hydrogen release is monitored by the rise in hydrogen pressure. The present studies are intended to provide a detailed understanding of the isothermal kinetics of charging and discharging of the material, and the effects of materials synthesis and chemical modifications to these rates. The parameters that are explored in the current study are charge and discharge temperature, charge pressure, and the composition of the modifiers used to activate the material.

The gravimetric capacities were determined from the average of the lowest and highest weight percent of hydrogen absorbed into the 1:1 $\text{LiNH}_2:\text{MgH}_2$ mixtures. The desorption weight percents were not included due to the lack of composition data for the off-gas stream. The following equation shows the calculations used to convert weight percent to $\text{kg}_{\text{H}_2}/\text{kg}_{\text{media}}$:

$$\text{wt}\% \rightarrow \frac{\text{gH}_2}{\text{g}_{\text{media}}} \rightarrow \frac{\text{kgH}_2}{\text{kg}_{\text{media}}}$$

where g_{H_2} is the average weight of hydrogen absorbed during recharge and g_{media} is the weight of the loaded sample prior to discharge. The volumetric capacity of the metal hydrides was calculated from the gravimetric capacity and the powder packing density of the hydrogen storage materials. The following equation shows the series of calculation used to convert weight percent hydrogen to volumetric capacity in kWh/L.

$$\text{wt}\% \rightarrow \frac{\text{gH}_2}{\text{g}_{\text{media}}} \times \rho_{\text{media}} \rightarrow \frac{\text{gH}_2}{\text{mL}} \rightarrow \frac{\text{kgH}_2}{\text{L}}$$

where ρ_{media} is the packing density of the powder. The material used in the determination of the density for the $\text{LiNH}_2:\text{MgH}_2$ mixture was a three gram sample of 1:1 $\text{LiNH}_2:\text{MgH}_2$ milled for 2 hours using a planetary mill with a ball mill ball mass to sample mass ratio of 30:1 (for every one gram of sample, 30 grams of ball mill balls were added to the vial prior to milling). A 10 mL graduated cylinder was then gradually packed with small quantities of the milled powder with the mass and volume occupied of the powder recorded at each interval. The powder was packed via tapping the bottom of the cylinder and by inserting a plunger to pack the top of the powder. This reduced the number of layers within the powder. The average powder packing density was determined to be 0.554 $\text{g}_{\text{media}}/\text{mL}$.

Mixed Amide/Borohydrides

The synthesis of materials was accomplished by ball milling one component metal borohydride ($\text{Ca}(\text{BH}_4)_2$, $\text{Mg}(\text{BH}_4)_2$) with another metal amide (LiNH_2). This is also extended for metal amides ($\text{Ca}(\text{NH}_2)_2$, $\text{Mg}(\text{NH}_2)_2$) with lithium borohydride (LiBH_4). These precursors such as LiNH_2 , LiBH_4 , and $\text{Mg}(\text{BH}_4)_2$ are available commercially

through Aldrich, with others such as $\text{Mg}(\text{NH}_2)_2$ and $\text{Ca}(\text{NH}_2)_2$ prepared by the ammoniation of Mg and Ca inside a high pressure reactor. Once the desired metal hydrides are ball milled, powder X-ray diffraction (XRD) was used as the initial screening tool. Furthermore, thermo-gravimetric analysis, in conjunction with mass spectroscopy, was used to verify mass loss vs. temperature and identify the gas decomposition products as a function of temperature. Fourier transform infrared, Raman and nuclear magnetic resonance were used to verify investigate the characteristics of new formed compounds.

Results

$\text{LiNH}_2/\text{MgH}_2$ Kinetics

Previously, we reported the charge and discharge profiles for precursor materials LiNH_2 and MgH_2 in a 1:1 mole ratio with 1.5 mol% TiCl_3 , VCl_3 , ScCl_3 , NiCl_2 , or TiN added dopant. From TGA-residual gas analysis (RGA) data, the initial hydrogen desorption temperature began between 105°C and 120°C, depending on the dopant composition, which is lower than the 135°C release temperature for the unmodified material. Compositional additions also greatly affect ammonia release. Mixtures with TiCl_3 , VCl_3 , ScCl_3 and NiCl_2 released ammonia at temperatures lower or equal to the unmodified material, approximately 230°C. The sorption profiles were measured using a Sievert's apparatus under isothermal conditions. A standard discharge condition of 260°C into a nominal 1 bar back pressure for ~6 hours was selected, along with a standard charge condition of 180°C under a nominal 100 bar pressure for 6 hrs. These conditions were selected to reach maximum charge and discharge capacities in a single work day and were used to compare differing compositions, dopants etc.

Previous MHCoe work [1,2] on this material indicated the presence of a LiMgN phase which was not definitively confirmed in this study. Instead, a Mg_3N_2 or partially substituted $(\text{Li,Mg})_3\text{N}_2$ phase was detected using powder XRD analysis. Other researchers have observed the presence of alternate discharge products in this system as well [3]. After cycling, no discernable kinetic affect remained from the additions. It is concluded that once the metathesis reaction between LiNH_2 and the halide modifiers is complete, the added metallic species are no longer active in the sorption cycle. This work has highlighted the requirement of cycling these materials to reach a steady-state operating chemistry to evaluate the effectiveness of potential additives as kinetic aids.

In order to investigate the effect of various modifiers, material was prepared to the stoichiometric composition of $\text{LiNH}_2:\text{MgH}_2$ (1:1) with 1.5 mol% vanadium oxide (V_2O_5) or iron oxide (Fe_2O_3) via Spex milling. A mixture containing 4 mol% potassium hydride (KH) was also investigated based on literature reporting an increase in kinetics of the 2:1 $\text{LiNH}_2:\text{MgH}_2$ system with the addition of KH [4]. To

determine the onset of hydrogen and ammonia release, the samples were heated in the TGA at a rate of 5°C/min from 30°C to 400°C while the off-gas composition was determined from a connected RGA (Table 2).

TABLE 2. Summary of TGA/RGA Decomposition Data of the As-Milled Samples Without and Without and With Modifiers

No Modification	8.2	9.3	240	345	285°C
1.5 mol% Fe_2O_3	7.45	6.9	225	330	270°C
1.5 mol% V_2O_5	7.36	7.2	220	325	270°C
4 mol% KH	7.82	11.2	230	290	No ammonia detected

With the addition of oxide modifiers, the theoretical hydrogen capacity drops from 8.14 wt% to 7.45 wt% and 7.36 wt% for Fe_2O_3 and V_2O_5 respectively. The measured weight loss of the Fe_2O_3 modified sample was 6.9 wt% and 7.2 wt% for the V_2O_5 modified sample, which are both reasonably close to their respective theoretical capacities, indicating that the dehydrogenation process was complete without significant NH_3 release. The differences from theoretical weight capacity is attributed to the possible releasing hydrogen during the milling process. However, the KH-modified sample lost a total of 11.2 wt%, which is significantly more than the system's theoretical hydrogen content. Unlike the oxide modified samples, during the decomposition of the KH-modified sample there was no detectable release of ammonia. The addition weight loss can be attributed to the release of nitrogen gas. Desorption mechanisms for these systems are not well understood at this time.

The impact of the transition metal oxides and potassium hydride additions on average bed dis(re)charging rates were investigated with a discharge condition of 200°C into a nominal 1 bar back pressure for ~6 hours followed with a standard charge condition of 180°C under a nominal 100 bar pressure for 6 hrs. The bed recharge rates were calculated on a mass-specific basis, determining from data the quantity of hydride bed that would be required to store 5 kg of hydrogen. The bed discharge rates are not included in the values reported in Table 2 due to the lack of information on the off-gas composition, especially the concentration of ammonia and nitrogen.

As seen from Figure 1, the discharge rate was dependent on the dopant composition and cycle. Initially, the oxide modified samples showed a slight improvement over the unmodified system during the first two desorption cycles. However, after the third desorption, both samples demonstrated a continual decrease in desorption rate while the unmodified sample began to increase its rate. The reduction in discharge kinetics over four cycles can potentially be attributed to exposure to high temperatures which led to significant coarsening of the particles resulting in lowered kinetics [5]. The potassium hydride modified sample showed significantly worse discharge rates than the other samples. This indicates potential interference

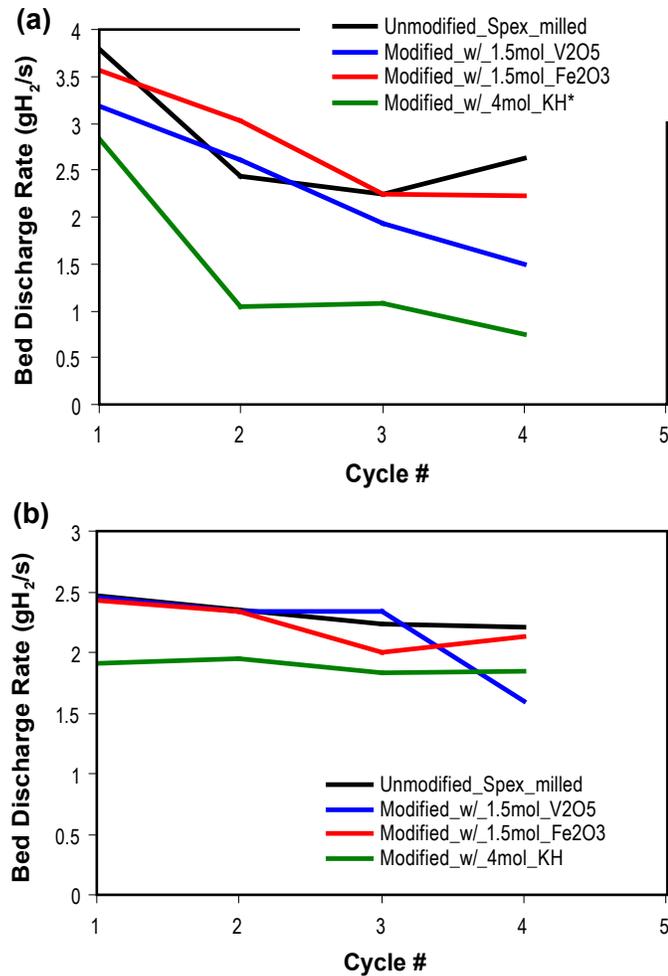

FIGURE 1. (a) Bed discharge (top) and (b) recharge (bottom) rate for unmodified (black), Fe₂O₃ (red), V₂O₅ (blue), and KH (green) modified samples. The cycling conditions are listed in the previous paragraph. (*Note: The KH sample was discharged into a smaller volume [1,030 mL] than the oxide and unmodified samples [1,190 mL] due to the use of a different pressure-concentration-temperature.)

of the modifier in the discharge reaction pathway, thus hindering the release of hydrogen from the system. An in situ diffraction study is needed to fully understand the interactions between the modifiers and the LiMgN system.

Unlike the discharge rates, the rate of recharging was not as dependent on composition of the modifier. However, the potassium hydride modified samples showed the slowest recharging rate, further indicating possible interference in the complex reaction pathway of the LiMgN system.

Mixed Amide/Borohydrides

Figure 2 shows the TGA results of Mg(NH₂)₂, LiBH₄, and various mixtures of Mg(NH₂)₂/LiBH₄. The unmodified samples show a much higher onset of decomposition with

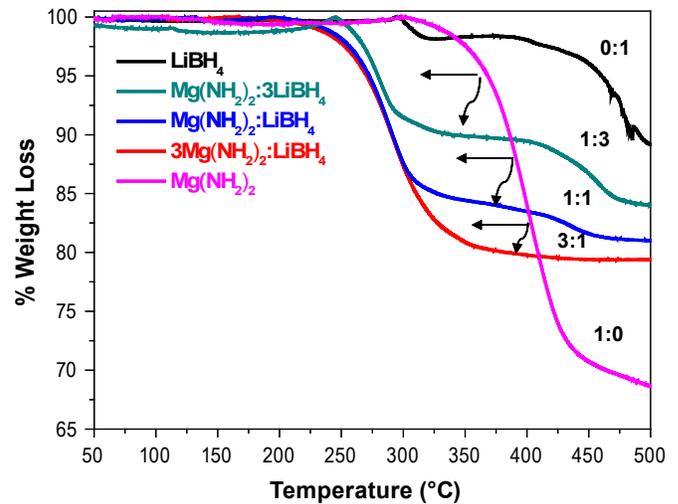

FIGURE 2. TGA Results for Mixed Mg(NH₂)₂/LiBH₄ Mixtures

respect to the mixtures. The addition of more Mg(NH₂)₂ resulted in a single decomposition similar to the starting amide material. This was also true for 3LiBH₄:Mg(NH₂)₂, which had a 2-step decomposition reaction, but at a significantly lower temperature than pure LiBH₄. These samples were characterized using mass spectroscopy and XRD. From mass spectroscopy, the addition of LiBH₄ reduces the release of ammonia and increases the amount of hydrogen released. Similar results were found with the previously reported Ca(NH₂)₂/LiBH₄ systems, but the initial decomposition of the mixtures occur at a higher temperature. Isothermal Sievert's measurements were also conducted to evaluate the mixture's cyclic characteristics compared to their respective starting materials.

Conclusions and Future Directions

LiMgN

- Desorption at 260°C and above leads to the loss of essential nitrogen.
- The addition of Fe₂O₃ and V₂O₅ modifiers significantly reduced the amount of ammonia emission during the initial decomposition.
- V₂O₅ modified mixture showed faster sorption kinetics than the Fe₂O₃ mixture.
- Discharge rate of a hydride bed with transition metal oxide dopant at 200°C is a third of the 2010 DOE technical target of 3 g H₂/s.

Mixed Amide/Borohydrides

- Mixtures of Mg(NH₂)₂ with LiBH₄ have shown a decrease in the dehydrogenation temperature and an increase in the amount of hydrogen released.

The direction for future research is as follows:

- Couple experimental results with *ab-initio* calculations to identify kinetic enhancing mechanisms in complex metal hydride systems.
- Investigate the role of additional additives, which have been identified in other studies, on the kinetics.
- Study the role of ammonia release during cycling of modified LiNH_2 : MgH_2 .
- Determination of the transformation mechanism in LiNH_2 : MgH_2 using Raman and infrared spectroscopy and neutron diffraction.
- Long-term cyclability studies to determine degradation in hydrogen capacity.
- Regeneration of $\text{LiH/Mg}(\text{NH}_2)_2$ using mix H_2/N_2 and H_2/NH_3 gas feeds for prolong cyclability.
- Further investigate the sorption characteristics of the LiBH_4 modified LiMgN system.

Project Start Date: September 1, 2008
Project End Date: July 31, 2013

Fiscal Year (FY) 2011 Objectives

The objective of the project is to discover novel mixed hydrides for hydrogen storage, which enable the DOE 2010 system-level goals. Our goal is to find a material that desorbs 8.5 wt% H₂ or more at temperatures below 85°C. The research project will combine first-principles calculations of reaction thermodynamics and kinetics with material and catalyst synthesis, testing, and characterization. We will combine materials from distinct categories to form novel multicomponent reactions. Examples of systems to be studied include mixtures of complex hydrides and chemical hydrides and novel multicomponent complex hydride materials and reactions.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (P) Lack of Understanding of Hydrogen Physisorption and Chemisorption
- (A) System Weight and Volume
- (E) Charging/Discharging Rates

Technical Targets

This study is aimed at fundamental insights into new materials and the thermodynamic and kinetic aspects of H₂ release and reabsorption from them. Insights gained from these studies will be applied toward the design and synthesis of hydrogen storage materials that meet the following DOE 2010 hydrogen storage targets:

- Specific energy: 1.5 kWh/kg
- Energy density: 0.9 kWh/L

FY 2011 Accomplishments

- Synthesis and characterization of two predicted promising hydride mixtures: 5LiBH₄ + 2Mg(BH₄)₂ and Mg(BH₄)₂ + Mg(NH₂)₂.
- Prediction of new previously-unknown MgBNH₆ compound, stable with respect to Mg(BH₄)₂ + Mg(NH₂)₂.
- Proposed new metal-carbon catalyst: Tested on NaAlH₄, and applied to Mg(BH₄)₂ + Mg(NH₂)₂; Effective catalyst - lowers desorption temperature of both reactions, and reduces formation of NH₃ in the latter case.
- Predicted new CaB₂H₆ product in decomposition of Ca(BH₄)₂.
- Predicted structure of AlB₄H₁₁ polymeric compound.
- Found new low-energy decomposition product of amidoborane reactions; found stability trends in ammonia-borane reactions to tailor ΔH to choice of metal cation.
- Extended prototype electrostatic ground state (PEGS) and grand-canonical linear programming (GCLP) to apply to nano-confined materials. Explored nano NaAlH₄ and LiBH₄ reactions.
- Developed predictive models of kinetics of mass transport. Application to NaAlH₄ and extension to borohydrides (in progress).

Introduction

The 2010 and 2015 FreedomCAR/DOE targets for hydrogen storage systems are very challenging, and cannot be met with existing materials. The vast majority of the work to date has delineated materials into various classes, e.g., complex and metal hydrides, chemical hydrides, and sorbents. However, very recent studies indicate that mixtures of storage materials, particularly mixtures between various classes, hold promise to achieve technological

attributes that materials within an individual class cannot reach. Our project involves a systematic, rational approach to designing novel multicomponent mixtures of materials with fast hydrogenation/dehydrogenation kinetics and favorable thermodynamics using a combination of state-of-the-art scientific computing and experimentation. Specifically, we focus on combinations of materials from distinct categories to form novel multicomponent reactions.

Approach

We use the accurate predictive power of first-principles modeling to understand the thermodynamic and microscopic kinetic processes involved in hydrogen release and uptake and to design new material/catalyst systems with improved properties. Detailed characterization and atomic-scale catalysis experiments elucidate the effect of dopants and nanoscale catalysts in achieving fast kinetics and reversibility. And, state-of-the-art storage experiments give key storage attributes of the investigated reactions, validate computational predictions, and help guide and improve computational methods. In sum, our approach involves a powerful blend of: 1) H_2 storage measurements and characterization, 2) state-of-the-art computational modeling, 3) detailed catalysis experiments, and 4) in-depth automotive perspective.

Results (Selected Examples)

Reaction Pathway Characterization for $Mg(NH_2)_2$ - $Mg(BH_4)_2$

We have performed initial characterization experiments of the reaction pathway for the $Mg(NH_2)_2$ - $Mg(BH_4)_2$

mixture. In particular, we have collected new in situ X-ray diffraction (XRD) and quenched Fourier transform infrared (FT-IR) data (Figure 1) toward characterization of the 2-step hydrogen desorption pathway which releases a total of ~11 wt% when heated to 550°C. From these new data, we propose that the first hydrogen release step (room temperature to 300°C and ~7 wt%) involves consumption of an amide reactant and formation of a product phase that involves boron-nitrogen bonding (infrared data). The second hydrogen release step (>300° and 4 wt%) involves decomposition of the B-N phase from step 1 and the formation of Mg and MgB_2 (infrared and XRD data). More experimental data and on-going computational studies are needed to determine the specific experimental and computational pathways from potential reactant hydride formation through complete dehydrogenation.

Facilitating Dehydrogenation of Complex Hydrides Using a Novel Metal-Carbon Catalyst

We have demonstrated that our metal-carbon catalysts are effective for facilitating dehydrogenation of solid-state hydrides, using $NaAlH_4$ as a model compound. The catalyst, comprised of metal nanoparticles and carbon support, serves multiple functions including nano-compartment of hydride, sites for nucleation, and hydrogen transport.

For low-melting point hydrides such as $NaAlH_4$, mixing the hydride with carbon materials such as activated carbon with high surface area and highly porous structure can significantly lower the dehydrogenation temperature (>100°C). The effect of carbon is mostly due to the nanostructuring of the hydride. As $NaAlH_4$ melts and diffuses into micropores of carbon, $NaAlH_4$ is confined into a

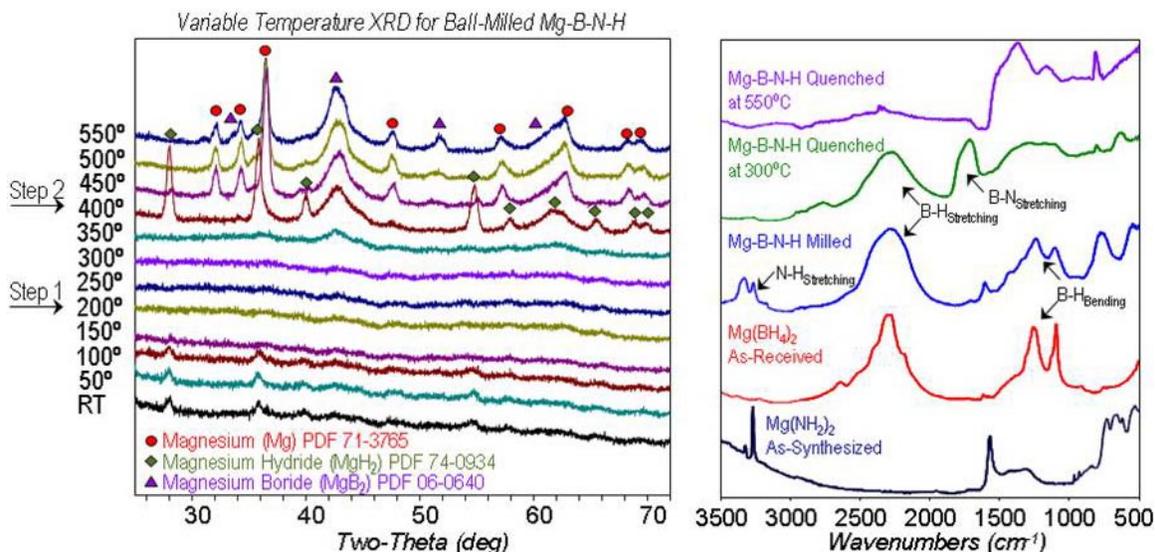

FIGURE 1. (a) In situ XRD data for ball-milled $Mg(NH_2)_2$ - $Mg(BH_4)_2$ mixture (heating rate 1°C/min) (b) FT-IR data for ball-milled $Mg(NH_2)_2$ - $Mg(BH_4)_2$ comparing reactants ($Mg(NH_2)_2$, navy) and $Mg(BH_4)_2$, (red) with ball-milled mixture (blue) and quenched samples at 300°C (green) and 550°C (purple).

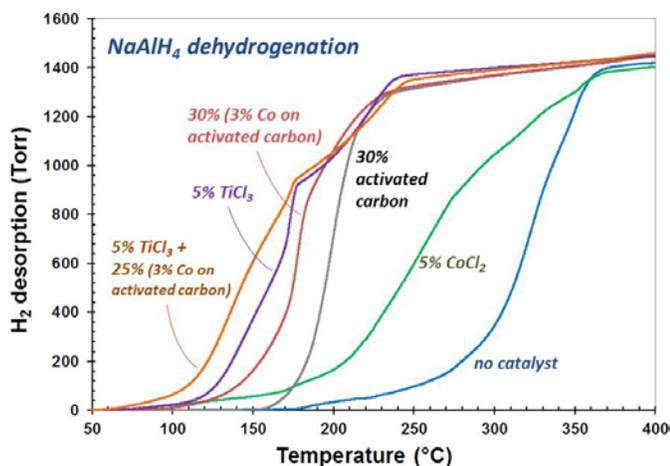

FIGURE 2. The Dehydrogenation of NaAlH_4 using Different Catalysts

nano-size region and starts to dehydrogenate at a lower temperature as a result.

Adding a small amount of transition metal such as cobalt on the carbon can further enhance the catalytic effect. Mixing with such cobalt-carbon catalyst, NaAlH_4 starts to dehydrogenate below its melting point. This enhanced effect could be attributed to hydrogen spillover facilitated by metal nanoparticles—the hydrogen atoms dehydrogenated from hydride migrate to hydride-carbon surface and recombine on the metal surface to desorb into gas phase. The cobalt-carbon catalyst can catalyze NaAlH_4 dehydrogenation below 130°C . Typically it can only be done by using Ti-based catalysts, which catalyzed the reaction through forming Ti-Al intermediates to facilitate hydrogen transportation. However, unlike Ti-based catalysts deactivate due to TiAl_3 formation after several dehydrogenation–rehydrogenation cycles, cobalt-carbon catalysts do not interact with hydride to form intermediates and catalyze the dehydrogenation under a different working principle. As a result, we observed synergistic effect from combining cobalt-carbon and TiCl_3 catalysts for NaAlH_4 —dehydrogenation starts even below 100°C (Figure 2).

As shown in Figure 3 and 4, the evidence of NaAlH_4 dehydrogenated below its melting point when catalyzed by a cobalt-carbon catalyst was provided by in situ XRD study of NaAlH_4 dehydrogenation from room temperature to 450°C . As can be seen in Figure 3, NaAlH_4 without catalyst melted at 222°C and no diffraction pattern can be detected (flat line). The subsequent diffraction patterns indicate the dehydrogenation began at a temperature above the melting point. In contrast, NaAlH_4 catalyzed by cobalt-carbon catalyst started to dehydrogenate at a temperature as low as 192°C and resulted in phase transformation of NaAlH_4 as can be seen in Figure 4.

Using PEGS to Help Deduce Amorphous Hydride Structures: The Polymeric Structure of $\text{AlB}_4\text{H}_{11}$ (collaboration with Ji-Cheng Zhao at Ohio State University)

The group of Prof. Zhao at Ohio State University synthesized the $\text{AlB}_4\text{H}_{11}$ compound through the reaction $2\text{Al}(\text{BH}_4)_3 + \text{B}_2\text{H}_6 \rightarrow 2\text{AlB}_4\text{H}_{11} + 4\text{H}_2$. The H_2 reversibility of the new compound is observed at mild conditions: 200°C and 90 bar H_2 , but its amorphous structure is unknown.

The PEGS method has been proved to be effective in the prediction of most “simple” complex hydrides with well-known anion geometries, like $\text{Mg}(\text{BH}_4)_2$. For the current $\text{AlB}_4\text{H}_{11}$ stoichiometry, the structure of the $[\text{B}_4\text{H}_{11}]^{3-}$ anion geometry structure is presently unknown. Therefore, in the PEGS simulations, we split the $\text{AlB}_4\text{H}_{11}$ into different small known fragments, $\text{Al} + [\text{BH}_4] + [\text{BH}_3] + 2[\text{BH}_2]$ or

$[\text{AlH}_4]+3[\text{BH}_2]+[\text{BH}]$. Surprisingly, after the PEGS and density functional theory (DFT), the fragments of B except $[\text{BH}_4]$ bond together to form a larger B cluster. In the low-energy structure at one formula unit (fu), it contains Al, $[\text{BH}_4]$ and $[\text{B}_3\text{H}_7]$ clusters, and they form a $-\text{Al}[\text{BH}_4]-[\text{B}_3\text{H}_7]-$ polymer chain, which is consistent with the experimental evidence (e.g., nuclear magnetic resonance and other measurements performed at Ohio State). Comparing the theoretical phonon density of states (pDOS) calculations and experimental neutron vibration spectra, we find that our pDOS is in overall agreement with the experimental peaks.

Subsequently, experiments confirmed our PEGS prediction that there are two kinds of B clusters, $[\text{BH}_4]$ and $[\text{B}_3\text{H}_7]$, but also suggest two kinds of Al environments that our initially predicted structure doesn't have, since we only performed calculations of one formula unit (and hence, only one Al atom). Therefore, we believe the two anion groups ($[\text{BH}_4]$ and $[\text{B}_3\text{H}_7]$) are correct and implement these into the PEGS code, and increased the cell size to two formula units. At 2 fu, a new low-energy $\text{AlB}_4\text{H}_{11}$ structure is predicted, which is ~ 400 meV/fu lower than the previous one. In this new structure, it still shows the $-\text{Al}[\text{BH}_4]-[\text{B}_3\text{H}_7]-$ polymer chain, and Al clearly has two kinds of surroundings. Its pDOS is in excellent agreement with the experimental neutron vibration spectra. The PEGS predicted $\text{AlB}_4\text{H}_{11}$ structure is therefore in excellent agreement with all the experimental data obtained. PEGS has previously been shown to provide accurate predictions of complex hydrides with well-known anion geometries. However, in this work, we extend the method and successfully apply it to cases where the anion geometry is unknown.

Computational Studies of Finite Size Effects in Lithium Borohydride Nanoclusters

Reducing the size of the bulk solids to the nanoscale regime is one approach that may allow for engineered equilibrium pressures and reaction kinetics that are more suitable for on-board hydrogen storage. First principles calculations on MgH_2 nanoparticles, for example, indicate that significant lowering of the desorption enthalpy is possible with decreasing cluster size [1]. Recent experimental work has demonstrated considerable changes in kinetics for hydrogen storage materials when incorporated in nanoporous frameworks. These frameworks include high surface area carbon aerogels [2,3], block-copolymer-templated highly ordered carbons [4], and metal-organic-frameworks (MOFs) [5].

In collaboration with Profs. Eric Majzoub from University of Missouri, St. Louis and Feng-Chuan Chuang from National Sun Yat-Sen University in Taiwan we are addressing the intrinsic reaction thermodynamics and decomposition pathways of gas-phase lithium borohydride clusters in the few nanometer size regime; such clusters can be synthesized in nanopores of high-surface-area carbons and MOFs, and are currently under investigation in the Northwestern group. We have recently generalized the

GCLP method to determine thermodynamically preferred decomposition pathways in finite-size systems, which allows us to obtain the phase diagram of small, free clusters of complex hydrides [6]. In the case of $(\text{NaAlH}_4)_n$ clusters with $n \leq 8$ we found that decomposition pathways of free-standing clusters are drastically different from those of bulk sodium alanate, favoring hydrogen release in a one-step reaction leading to the formation of mixed $(\text{AlNa})_n$ nanoclusters. We also predicted nanocluster analogues of bulk destabilized reactions between simple hydride (NaH and AlH_3) and complex hydride (NaAlH_4) nanoclusters. It is of considerable interest whether similar phenomena can be found in materials with higher hydrogen content than sodium alanate.

Using the recently developed PEGS method and genetic algorithm in conjunction with DFT calculations, we predict the structures of small clusters of LiBH_4 and its decomposition products (Li , B , Li_nB_n , LiH) with up to 12 Li and B atoms. A few representative structures are shown in Figures 5, 6 and 7. Just like the case for the bulk LiBH_4 compound, our preliminary results indicate that the decomposition pathway of LiBH_4 nanoclusters with $N \geq 6$ involves the formation of closoboranes based on $(\text{B}_n\text{H}_n)^{2-}$ anions. The calculated decomposition enthalpies are shown in Figure 8 as functions of the cluster size. These results demonstrate that lithium borohydride nanoclusters have higher enthalpies of hydrogen release than bulk materials, suggesting that any destabilization observed in recent experiments must come due to strong interaction effects with

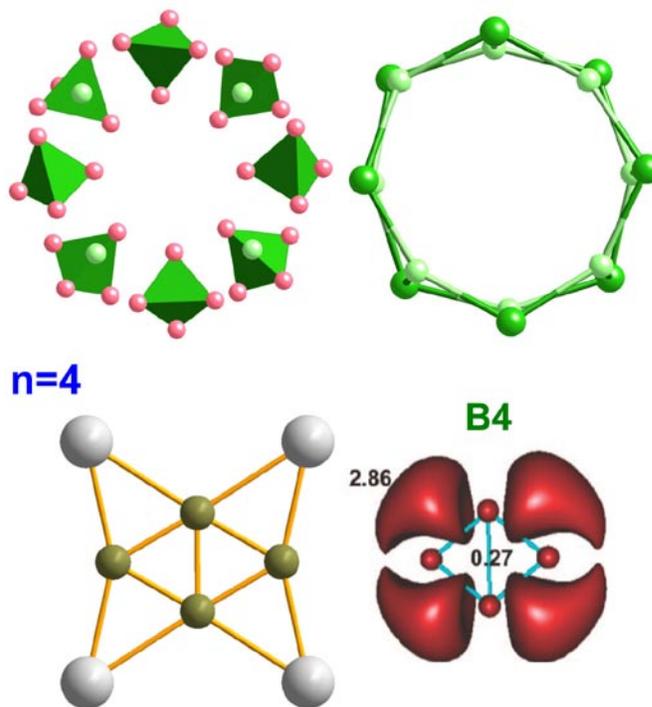

FIGURE 5. Top: Structure of $(\text{LiBH}_4)_8$ cluster found using PEGS and DFT. Bottom: structure of Li_4B_4 cluster found using genetic algorithm.

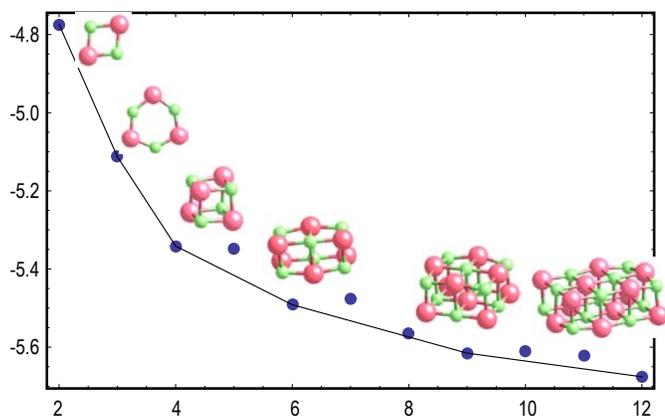

FIGURE 6. Energy of LiH clusters versus cluster size. Inset figures show the clusters that lie on the convex hull.

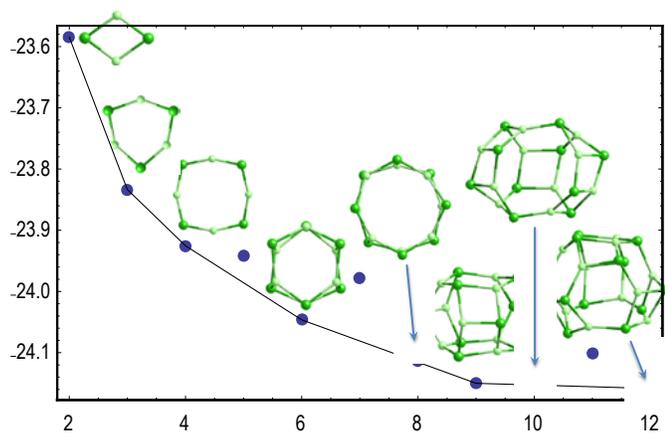

FIGURE 7. Energy of LiBH₄ clusters versus cluster size. Inset figures show the clusters that lie on the convex hull. Only Li and B atoms are shown.

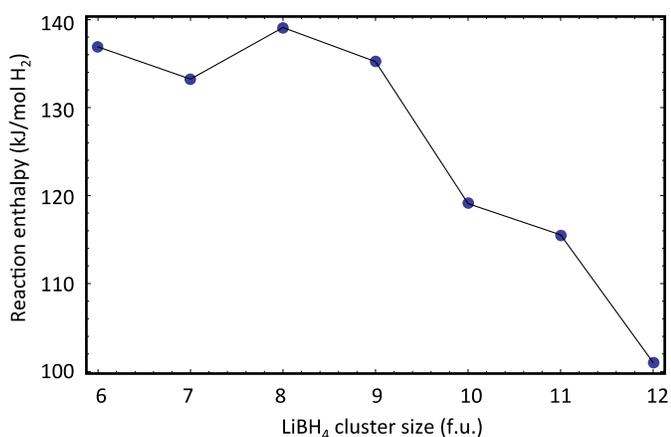

FIGURE 8. Calculated Decomposition Enthalpies of LiBH₄ Clusters as Functions of Cluster Size

the porous support. These results are in marked contrast to earlier DFT-based findings for metal nanoclusters, which suggested destabilization with decreasing size and the appearance of new decomposition pathways. We are currently in the process of refining the structures of B_nH_m nanoclusters using genetic algorithms. Inclusion of B_nH_m may yet change the preferred decomposition pathways and somewhat alter the preliminary conclusions reached so far.

Conclusions and Future Directions

- Experimentally characterize storage properties/reactions of (NH₄)₂B₁₂H₁₂ and other predicted reactions; elucidate decomposition pathway for Mg(BH₄)₂+Mg(NH₂)₂ mixture.
- Extend experimental catalyst studies to other predicted promising materials; explore optimal morphology of carbon/metal catalysts.
- Direct computational efforts to focus on kinetics, defects, diffusion/mass transport in promising predicted reactions.
- Continue some computational exploration for: novel BH₄/NH₂ compounds and reversible reactions, and mixed metal borohydrides.

Project Start Date: April 1, 2005
Project End Date: September 30, 2011

Technical Targets

The work on this project is currently exclusively devoted to materials that have demonstrated available hydrogen capacities of 7-17 wt% hydrogen. We have developed a system for the full reversible dehydrogenation of $\text{Mg}(\text{BH}_4)_2$ to MgB_2 that has shown a record, >12 wt% reversible hydrogen capacity but requires further development to meet kinetic performance targets within the target temperature. We have also developed a highly efficient method of the direct hydrogenation of LiH/Al to Ti-doped LiAlH_4 (7 wt% hydrogen capacity, rapid dehydrogenation at 120-150°C) at moderate pressure and room temperature that has been estimated to have a well-to-tank energy efficiency that approaches 60% and thus approaches DOE targets.

Accomplishments

We have provided the first example of the reversible, solid state dehydrogenation of a borohydride at temperatures below 350°C (200°C, 100 atm).

Fiscal Year (FY) 2011 Objectives

The objective of this project is to develop a new class of reversible materials that have the potential to meet the DOE kinetic and system gravimetric storage capacity targets. Current investigations include:

- The study of novel, high hydrogen capacity, borohydrides that can be reversibly dehydrogenated at low temperatures.
- The development of a method for the hydrogenation LiH/Al to LiAlH_4 at moderate pressures in non-conventional solvents.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (E) Charging/Discharging Rates
- (J) Thermal Management
- (P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

Introduction

The development of high capacity, hydrogen storage materials that can be recharged under moderate conditions is a key barrier to the utilization of hydrogen as an onboard energy carrier. Towards this end we have examined anionic borohydride complexes as hydrogen storage materials. Our initial focus was on anionic transition metal complexes. The anionic character of these compounds was found to result in an increased stability and a reduced volatility when compared to neutral transition metal borohydride complexes. Our efforts are currently focused on determining whether the thermodynamic parameters of these complexes will allow them to undergo reversible dehydrogenation. In the course of these investigations we have found that that ball-milled mixtures of MgB_2 and catalytic additives undergo full hydrogenation to $\text{Mg}(\text{BH}_4)_2$ at high pressures. In consideration of the >14 wt% hydrogen that is potentially cyclable with this system, it has become the focus of our efforts in the area of borohydride complexes.

In collaboration with the University of New Brunswick (UNB), we are also developing new approaches utilizing supercritical fluids and non-conventional solvents for the direct synthesis of AlH_3 and LiAlH_4 . LiAlH_4 releases hydrogen according to the two reactions seen in equations 1 and 2. Although the second reaction is endothermic ($\Delta H = +25 \text{ kJ/mol H}_2$), the first reaction is exothermic

($\Delta H = -10$ kJ/mol H_2). Since entropic change is strongly positive for hydrogen release, the first reaction is thermodynamically irreversible under all practical conditions and it has been widely accepted that LiAlH_4 cannot be recharged and there have been no reports of its use for reversible hydrogen storage. However, the unfavorable thermodynamics may be altered by carrying out the reaction in solution, with the solvation of LiAlH_4 contributing to an (ideally) endothermic ΔH value. As early as 1963, [1] reported that a mixture of LiH and activated Al in tetrahydrofuran (THF) or diglyme solvent reacted with 350 bar H_2 at 120°C to produce LiAlH_4 . Improved syntheses of the THF adduct has recently been reported by [2] and researchers at Brookhaven National Laboratory by using Ti additives to significantly lower the required pressure and temperature. While the methods of both Ashby and Ritter result in the ultimate formation of LiAlH_4 from LiH , Al and H_2 , they are impractical because of the requirements of high temperature, high pressure, and/or mechanical energy during the synthesis as well as subsequent heating removal the THF solvent (vacuum drying at 60°C for several hours). As Ashby noted, it is very difficult to remove the final vestiges of THF and the prolonged baking in vacuo required to remove THF results in the dehydrogenation of the majority of a Ti -activated product. We have discovered that by the this difficulty can be circumvented by utilizing liquefied dimethyl ether as the reaction solvent as it is sufficiently coordinating to support the nascent LiAlH_4 in the reaction environment, yet which is also volatile enough to be removed easily once it has served this purpose. Our highly efficient, room temperature direct synthesis of LiAlH_4 in liquefied Me_2O shows great promise as a practical method for the re-hydrogenation of LiH/Al to LiAlH_4 .

Approach

Having demonstrated the reversible elimination of over 11 wt% hydrogen from $\text{Mg}(\text{BH}_4)_2$, we wish to develop methods for hydrogen cycling in this system under less forcing conditions. In order to accomplish this, we required a more detailed understanding of the dehydrogenation reaction pathway. Thus we have monitored both the dehydrogenation and re-hydrogenation reactions by X-ray diffraction and magic angle spinning boron-11 nuclear magnetic resonance spectroscopy (MAS ^{11}B NMR) and conducted quantitative thermal volumetric pressure-composition-temperature measurements.

We have found that nearly the entire 7.9 wt% theoretical cycling capacity can be restored in the first cycle of re-hydrogenation of Ti -doped LiH/Al in liquefied dimethyl ether at room temperature under 100 bar of $\text{Me}_2\text{O}/\text{H}_2$. Calculations show that this recharging process approaches 60% well-to-tank efficiency. Dimethyl ether performs well as the solvent for this reaction since it is more polar and

volatile than diethyl ether, it forms a strong complex with Li^+ , and it evaporates quickly at room temperature (boiling point = -24°C). However, the cycling capacity dramatically drops off over the first five cycles of dehydrogenation/re-hydrogenation. In order to overcome this limitation, we have explored the extension of the maximum cycling capacity of Ti -doped LiAlH_4 through variation of the dopant concentration, recharging conditions, and variation dopants.

Results

Task 1. Characterization of the Active Titanium Species in Ti Doped NaAlH_4

This task has been completed.

Task 2. Spectroscopic Studies of Complex Hydrides

This task has been completed.

Task 3. Thermodynamic Properties of Complex Hydrides

This task has been completed.

Task 4. Kinetic Enhancement of “Thermodynamically Tuned” Binary Hydrides

This task has been completed.

Task 5. Synthesis and Evaluation of Novel Borohydrides

Our earlier studies found that it was possible to fully hydrogenate MgB_2 to $\text{Mg}(\text{BH}_4)_2$ under high hydrogen pressures. It was not clear from the results of these study whether $\text{Mg}[\text{B}_{12}\text{H}_{12}]$ is an intermediate in the reaction pathway that operates under these conditions. To answer this question, we have studied the early stages of the solid state dehydrogenation $\text{Mg}(\text{BH}_4)_2$ in the solid state by ^{11}B NMR spectroscopy. The dehydrogenation of $\text{Mg}(\text{BH}_4)_2$, was followed by temperature programmed desorption/thermal gravimetric analysis over a set of isothermal temperatures (300, 350, 400°C) at various reaction times. The study was conducted with the concomitant analysis of the volatile gas species by temperature-programmed desorption/thermogravimetric analysis/mass spectroscopy (TPD/TGA/MS). Over this temperature range, a decrease of 6-10 mass% from the $\text{Mg}(\text{BH}_4)_2$ sample was observed with H_2 as the only volatile species detected by MS. At the end of each TPD experiment, the residual decomposition products were dissolved in aqueous media for analysis by solution phase NMR spectroscopy. Figure 1 shows representative $^{11}\text{B}[\text{H}]$ NMR spectra from samples heated to 300, 350 and 400°C . Four major resonances are observed in each spectra; boric acid at 5 ppm, $[\text{B}_{12}\text{H}_{12}]^{2-}$ at -15.6 ppm, $[\text{B}_{10}\text{H}_{10}]^{2-}$ at -29.2 ppm and $[\text{B}_3\text{H}_8]^-$ at -31 ppm. The results of these studies are summarized in Table 1. The major species observed in the ^{11}B NMR after hydrolysis of the thermal decomposition products is boric acid resulting from the hydrolysis of the unstable polyborane species

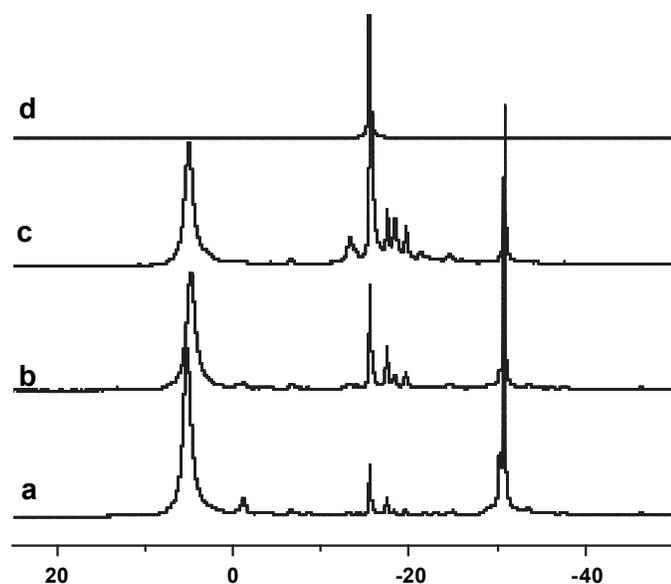

FIGURE 1. Solution $^{11}\text{B}\{^1\text{H}\}$ NMR of products resulting from dehydrogenated $\text{Mg}(\text{BH}_4)_2$ dissolved in aqueous solutions. a) $\text{Mg}(\text{BH}_4)_2$ heated to 300°C for 12 h, b) $\text{Mg}(\text{BH}_4)_2$ heated to 350°C for 6 h, c) $\text{Mg}(\text{BH}_4)_2$ heated to 400°C for 2 h, and d) $\text{MgB}_{12}\text{H}_{12}$.

TABLE 1. ^{11}B NMR analysis of the major products (mol%) formed in decomposition of $\text{Mg}(\text{BH}_4)_2$ followed by partial hydrolysis. Chemical shifts are reported relative to $\text{BF}_3\cdot\text{OEt}_2$ at 0 ppm.

(δ ppm)	Species	300°C	350°C	400°C
5	$\text{B}(\text{OH})_4^-$	86	87	83
-15.2	$(\text{B}_{12}\text{H}_{12})^{2-}$	0.4	1.5	4.5
-29.2	$(\text{B}_{10}\text{H}_{10})^{2-}$	0.8	0.2	0.0
-30.3	$(\text{B}_3\text{H}_8)^-$	12.6	9.0	6.5

formed during the decomposition of $\text{Mg}(\text{BH}_4)_2$. In addition to the unstable polyborane species a small amount of the stable dodecaborane $[\text{B}_{12}\text{H}_{12}]^{2-}$ is observed. However, the yield, ranging from 0.4 to 4.5 mol% is significantly less than the theoretical yield assuming complete conversion of $\text{Mg}(\text{BH}_4)_2$ to magnesium dodecaborane, ca. 16.6 mol% $(\text{B}_{12}\text{H}_{12})^{2-}$ (8.0 wt% H_2). It is also notable that a significant concentration of the triborane is present, especially at lower temperatures. The results of these studies indicated that the first step in the decomposition of $\text{Mg}(\text{BH}_4)_2$ involves the formation of a meta-stable triborane species, $\text{Mg}(\text{B}_3\text{H}_8)_2$. In order to verify this conclusion, we investigated the slow dehydrogenation of $\text{Mg}(\text{BH}_4)_2$ en vacuo at 200°C over a five-week period. Solid state and solution ^{11}B NMR spectra (solution NMR seen in Figure 2a) of the dehydrogenated product showed that there is much higher selectivity for the production of $\text{Mg}(\text{B}_3\text{H}_8)_2$ at this lower temperature.

We next probed the reversibility of the dehydrogenation of the $\text{Mg}(\text{BH}_4)_2$ to $\text{Mg}(\text{B}_3\text{H}_8)_2$. Experiments were carried

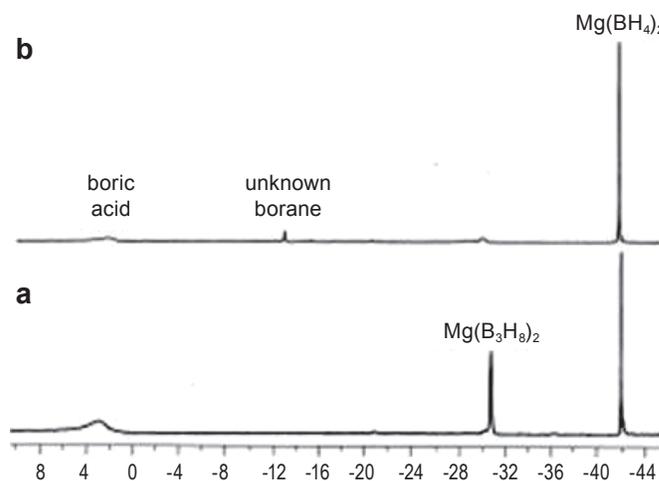

FIGURE 2. $^{11}\text{B}\{^1\text{H}\}$ spectra of: (a) $\text{Mg}(\text{BH}_4)_2$ following solid state dehydrogenation at 200°C for five weeks and (b) re-hydrogenation of under 120 atm of H_2 at 250°C for 48 h.

at 250°C under 120 atm of H_2 . As seen in Figure 2b, ^{11}B NMR analysis consistently indicated that $\text{Mg}(\text{B}_3\text{H}_8)_2$ undergoes nearly complete conversion of the triborane back to $\text{Mg}(\text{BH}_4)_2$ after 48 h. This is the first example of the **reversible**, solid-state dehydrogenation of a borohydride occurring at temperatures below 350°C . However, it is also noted that the hydrogen cycling capacity associated with the reaction seen in equation 3 is only 2.5 wt%.

Our results suggests that the higher borane clusters form from the smaller clusters through a sequential borohydride insertions into growing polyboranes, in concert with the formation of hydrogen and the corresponding metal hydride. The stability of the corresponding metal hydride formed in the decomposition of borohydride may explain in part the observed reversibility for some borohydrides and the irreversibility of other borohydrides. The thermodynamics of the reaction, hydrogen desorption or hydrogen absorption, depends on the stability of the MH in addition to the stability of the polyborane intermediate. As such, formation of a more stable metal hydride, e.g., LiH compared to MgH_2 , will make the thermodynamics for the reverse reaction less favorable. This mechanism provides an alternate explanation for incomplete reversibility in borohydrides as once $\text{MgB}_{12}\text{H}_{12}$ is formed, it is difficult to regenerate borohydride. Clearly hydrogen addition to arachnopolyborane species (observed as boric acid after hydrolysis of the decomposed borohydride) is kinetically accessible whereas hydrogen addition to the thermodynamically stable closoborane species is kinetically inaccessible.

As part of effort of this project, we have synthesized and fully characterized the novel anionic transition metal borohydride complexes, $\text{LiSc}(\text{BH}_4)_4$, $\text{NaSc}(\text{BH}_4)_4$, $\text{KSc}(\text{BH}_4)_4$ and $\text{Na}_2\text{Mn}(\text{BH}_4)_4$. As seen in Table 2, we have

found that these complexes all release a significant wt% of hydrogen upon heating to moderate temperatures, <200°C. Thus it was of interest to probe whether, like $\text{Mg}(\text{BH}_4)_4$, re-hydrogenation could be achieved following dehydrogenation to lower boranes at moderate temperatures. Promising initial results were obtained with $\text{KSc}(\text{BH}_4)_4$ as the ^{11}B NMR spectrum of samples following dehydrogenation for 24 h at 200°C are predominated by a peak at -32 ppm, which clearly indicates that triborane, $[\text{B}_3\text{H}_8]^{2-}$ is the only major product of the dehydrogenation. Attempts were made to re-hydrogenate the material back to the starting borohydride by placing the dehydrogenation samples under 120 atm of H_2 at 250°C for five days. The MAS ^{11}B NMR spectrum showed that a hydrogenated product did arise. However, the -10 ppm chemical of the observed product peak clearly does not match the -38 ppm shift of $\text{KSc}(\text{BH}_4)_4$ but rather that of KBH_4 . In a previous DOE collaborative project with UOP, we screened the hydrogen storage potential lithium salts of transition metal borohydride complexes of the first transition metal series using a high throughput apparatus. This study also indicated that several of these complexes were stable at room temperature and released hydrogen at temperatures relevant to on-board hydrogen storage applications. However, lithium copper borohydride was the only compound to show reversibility under moderate conditions. This finding stands unique as no other transition metal borohydride complex has been found to regenerate the parent borohydride complex upon direct hydrogenation or show a stable, non-diminishing hydrogen cycling capacity. We have attempted to confirm that $\text{Li}_2\text{Cu}(\text{BH}_4)_4$ will undergo reversible dehydrogenation. A sample of the complex hydride was prepared by ball milling a 4:1 molar mixture of CuCl_2 and LiBH_4 . Similar to the findings of the earlier preliminary study, we found that heating our sample of $\text{Li}_2\text{Cu}(\text{BH}_4)_4$ to 230°C for five h resulted in the release of 2.9 wt% hydrogen. However, the results of attempted re-hydrogenation under 120 atm of H_2 at 100°C for 24 h have been variable and no firm conclusions have been reached to date.

Task 6. Recharging of Light Metal Hydrides in Supercritical and Non-Conventional Fluids

In an attempt to stabilize the cycling hydrogen capacity, we investigated the effect of the substitution of TiCl_3 with other dopants (e.g. ScCl_3 and CeCl_3). Doping of LiH/Al with 0.05 mol% ScCl_3 resulted in only partial hydrogenation

TABLE 2. Temperatures and hydrogen wt% evolved during the first step in the dehydrogenation of novel anionic transition metal borohydride complexes.

Complex	T (°C)	wt% H (theoretical)
$\text{LiSc}(\text{BH}_4)_4$	175	3.5 (14.6)
$\text{NaSc}(\text{BH}_4)_4$	170	1.0 (12.8)
$\text{KSc}(\text{BH}_4)_4$	190	1.0 (11.3)
$\text{Na}_2\text{Mn}(\text{BH}_4)_4$	120	2.9 (6.9)

of the material (ca. 2 wt% H) while mixtures doped with same amount of CeCl_3 did not hydrogenate to any significant extent. When the level of dopant was increased to 1 mol%, the hydrogenated material was found to release approximately 6 wt% H upon dehydrogenation while the Ce-doped material did not show any signs of hydrogenation. These results indicate that for the LiAlH_4 system the catalytic performance of ScCl_3 supersedes that of CeCl_3 , but does not reach that of TiCl_3 .

Conclusions

We have established that the initial borane species produced in the dehydrogenation of $\text{Mg}(\text{BH}_4)_2$ is $\text{Mg}(\text{B}_3\text{H}_8)_2$. This conversion has been shown to be reversible at moderate temperature and pressure thus provides the first example of direct hydrogen cycling of a borohydride under moderate conditions. Although the 2.5 wt% cycling capacity does not meet current on-board storage targets, our results provide key experimental evidence that practical hydrogen storage based on a boron hydride is plausible. Heating to higher temperatures results in a series of BH condensation reactions leading to a complex mixture of polyboranes. Given the nature of the reaction pathways discussed in this work it is recommended that the stability of the corresponding metal hydride (as well as the polyborane) be considered in the design and development of borohydrides for reversible hydrogen storage.

Future Directions

Adjustment of conditions to maximize trade off between cycling capacity and temperature/pressures required for reversible dehydrogenation of $\text{Mg}(\text{BH}_4)_2$ and perhaps other borohydrides under moderate conditions.

Contract Number: DE-FC3605GO15062

Project Start Date: January 1, 2005

Project End Date: August 31, 2011

Insights gained from these studies will be applied toward the design and synthesis of hydrogen storage materials that meet the following DOE 2010 hydrogen storage targets:

- Cost: \$3-7/gasoline gallon equivalent at the pump
- Specific energy: 1.5 kWh/kg (4.5 wt% H)
- Energy density: 0.9 kWh/L (0.028 kg/L)

FY 2011 Accomplishments

- We modified the synthetic method of AlB_4H_{11} . Several grams of AlB_4H_{11} were synthesized using the modified method at OSU.
- Both infrared (IR) and pressure-composition-temperature (PCT) tests showed that AlB_4H_{11} is partially reversible at relatively mild condition such as 220°C and 100 bar of hydrogen. Differential scanning calorimetry (DSC) measurements also showed that AlB_4H_{11} dehydrogenates around 125°C with a broad endothermic peak.
- In collaboration with both Northwestern University and the National Institute of Standards and Testing (NIST), the structure units, a triangle of B_3 and a BH_4 group, were completely identified.
- We modified the synthetic method of AlB_6H_{13} (a sister compound to AlB_4H_{11}) and characterized its properties for potential hydrogen storage applications together with the Oak Ridge National Laboratory (ORNL).
- We recently developed simple and efficient methods for the preparation of both NaB_3H_8 and $NH_4B_3H_8$. They release more hydrogen during hydrolysis under mild condition than the most studied hydrogen storage materials such as $NaBH_4$ and NH_3BH_3 .
- We developed a new method to prepare $[H_2B(NH_3)_2][B_3H_8]$ which has high hydrogen capacity of 18.4 wt%.

Fiscal Year (FY) 2011 Objectives

- Develop a high-capacity lightweight hydride for reversible vehicular hydrogen storage, capable of meeting or exceeding the 2010 DOE/FreedomCAR targets.
- Synthesize and study aluminoborane compounds and other lightweight, high-capacity boron hydrides for hydrogen storage.
- Perform detailed characterization of the decomposition mechanisms, desorbed gaseous species and structures of the synthesized compounds.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Multi-Year Research, Development and Demonstration Plan (MYPP):

- (D) Durability/Operability
- (P) Lack of Understanding of Hydrogen Physisorption and Chemisorption
- (E) Charging/Discharging Rates
- (J) Thermal Management

Technical Targets

This project is conducting synthesis and studies of the decomposition mechanism of aluminoborane compounds.

Introduction

The DOE defines on-board hydrogen storage for mobile vehicles as a “Grand Challenge”. It is one of the biggest hurdles to the implementation of hydrogen-powered vehicles. Metal hydrides have the advantages of the highest volumetric density, relatively low working pressure, and reasonable working temperature range. The disadvantage of current reversible hydrides is a significant weight penalty. Metal borohydrides have among the highest gravimetric hydrogen storage capacities with the potential to meet the DOE gravimetric density targets and to offset the system weight penalties. However, desorption temperature, reversibility and formation of gaseous borane compounds during desorption are challenging issues for these materials.

This project attempts to develop a high-capacity lightweight hydride for reversible vehicular hydrogen storage, capable of meeting or exceeding the 2010 DOE/FreedomCAR targets.

Approach

- Explore aluminoborane compounds such as $\text{AlB}_4\text{H}_{11}$ and other high-capacity, lightweight boron hydrides.
- Study the structure and the decomposition mechanisms using multiple techniques such as interrupted PCT tests, nuclear magnetic resonance (NMR), IR, DSC, and residual gas analysis.
- Develop reversibility strategy from detailed mechanistic understanding of the complex desorption processes (such understanding is crucial for reversibility of all borohydrides).
- Synthesize new hydrides and complexes in collaboration with ORNL, Sandia National Laboratories, and NIST.

Results

A modified method for synthesizing aluminoborane, $\text{AlB}_4\text{H}_{11}$, was developed and applied to the preparation of $\text{AlB}_4\text{H}_{11}$ in gram quantities at OSU. Careful measurements were performed on $\text{AlB}_4\text{H}_{11}$ to investigate its properties as a potential hydrogen storage material. Both IR and PCT tests indicate that this compound is partially reversible at relatively mild conditions such as 220°C and 100 bar of hydrogen, which further supports our conclusion of reversibility based on previous NMR observations. Furthermore, DSC measurements show that $\text{AlB}_4\text{H}_{11}$ dehydrogenates around 125°C with a broad endothermic peak, thus it is thermodynamically reversible. Encouraged by these results which suggest that $\text{AlB}_4\text{H}_{11}$ might be a good candidate for reversible vehicular hydrogen storage, we devoted considerable amount of effort to figure out the molecular structure of $\text{AlB}_4\text{H}_{11}$. Structural identification is crucial for understanding the desorption mechanisms and the partial reversibility.

The identification of the molecular structure of $\text{AlB}_4\text{H}_{11}$ has been difficult because of its polymeric/amorphous nature and its insolubility in major solvents [1]. The former prevents us from determining the structure through X-ray diffraction or neutron diffraction. The latter prevents us from performing solution NMR and mass spectroscopy tests to obtain structural information. The available structural information from solid NMR and IR spectra is insufficient for structural identification. In collaboration with Northwestern University and NIST, we employ both experimental measurements (IR, NMR, and neutron vibration analysis) and theoretical calculations (prototype electrostatic ground state [PEGS] + density functional theory [DFT]) to define the structure of $\text{AlB}_4\text{H}_{11}$.

Even though $\text{AlB}_4\text{H}_{11}$ was synthesized from a benzene solution, it is not soluble in benzene once it is formed. In order to gain more structural information from experiments,

we examine the mother/residual solution by ^{11}B and $^{11}\text{B}\{^1\text{H}\}$ NMR after the precipitation of $\text{AlB}_4\text{H}_{11}$ to determine if trace amount of the polymeric product is retained in the solution. Two boron signals at $\delta -36.7$ and -53.3 ppm observed in solution NMR may be associated with the two signals at $\delta -37.4$ and $\delta -50$ ppm of product in its solid ^{11}B NMR [2]. The process of the reaction between $\text{Al}(\text{BH}_3)_4$ and B_2H_6 is also monitored by ^{11}B and $^{11}\text{B}\{^1\text{H}\}$ NMR with an attempt to find the transformation from starting materials to the product. Several small signals appeared at $\delta -33.5$, -38.2 , -44.7 -52.8 and -53.7 ppm as the reaction proceeds. The peaks at $\delta -38.2$ and -44.7 ppm may be related to dimer or polymer of $\text{HAl}(\text{BH}_4)_n$ ($\delta -38.3$ and $\delta -43.3$ ppm) and the peaks at $\delta -53.7$ ppm may be associated to product ($\delta -50$ ppm in its solid ^{11}B NMR) [3]. So the reaction probably starts with dimerization or polymerization of $\text{Al}(\text{BH}_4)_3$ and then transfers to the product. Though $\text{AlB}_4\text{H}_{11}$ did not dissolve in major solvents, we found that it is soluble in (or reacted with) liquid ammonia without any bubble formation. The ^{11}B NMR spectra of $\text{AlB}_4\text{H}_{11}$ in liquid ammonia clearly show a quintet and a nonet which are assigned to BH_4^- and B_3H_8^- groups (Figure 1). This observation suggests that a B_1 unit and a B_3 unit groups exist in the structure of $\text{AlB}_4\text{H}_{11}$. The neutron vibration spectrum of $\text{AlB}_4\text{H}_{11}$ is recorded in NIST (by Terry Udovic and his co-workers) for comparing with theoretical results.

Based on the available information, six possible structures were predicted through (PEGS + DFT) calculation by Northwestern University (Chris Wolverton, Yongli Wang, and Yongsheng Zhang). Three of these structures (#3, #5, and #6) are more stable than others based on the calculated ground-state energies. It is interesting that all these stable structures contain a B_1

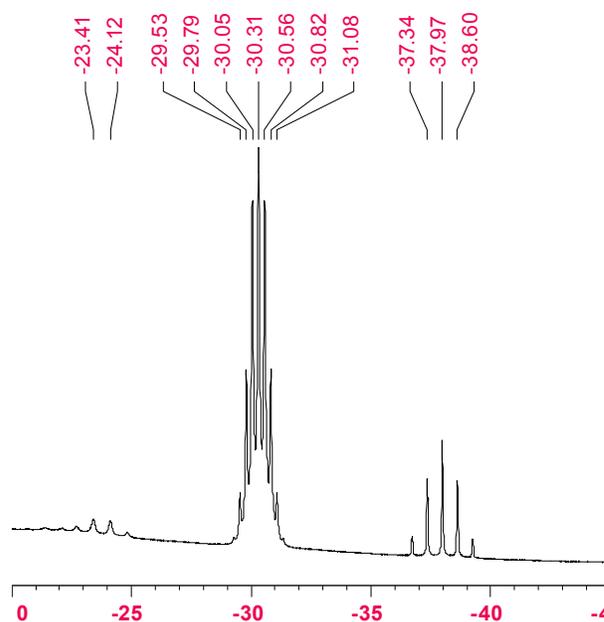

FIGURE 1. ^{11}B NMR Spectrum of $\text{AlB}_4\text{H}_{11}$ in Liquid Ammonia

unit and a B_3 unit which either connected directly (as in structure #3) or separated by Al atom (as in structures #5 and #6). The presence of the B_1 unit and the B_3 unit in these structures is consistent with the experimental observations.

Simulation of the neutron vibration spectra for structures #5 and #6 has been performed by NIST for comparing with the experimental vibration spectra of AlB_4H_{11} . Figure 2 shows that even though some agreements are observable, the overall agreement is less than ideal, indicating that both structures #5 and #6 need further refinement to reflect the correct structure of AlB_4H_{11} . It is worthwhile mentioning that even for well-defined structures from single crystal data, the simulated and experimental neutron vibration spectra do not match perfectly for many compounds.

The ^{27}Al NMR of AlB_4H_{11} in liquid ammonia shows two Al signals which are inconsistent with structures #5 or #6 because that Al has an identical chemical environment in structure #5 or structure #6. With this new observation, the structure of AlB_4H_{11} is simulated again using PEGS+DFT by inputting only B_3H_7 and BH_4 units and Al atoms. It is surprising that the energy of the modified structure is at least 40 KJ/mol lower than that of structures #5 and #6.

After spending tremendous efforts by OSU, Northwestern University, and NIST on this collaborative research, the structure units are completely identified. The

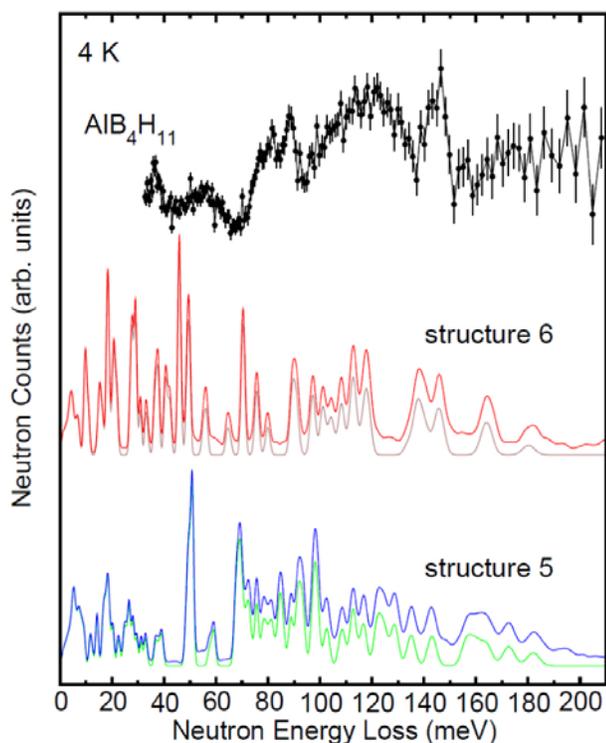

FIGURE 2. The Neutron Vibration Spectrum of AlB_4H_{11} and Simulated Vibration Spectra of Structures #5 and #6 predicted by the Northwestern University

structure of AlB_4H_{11} consists of B_3H_7 units and BH_4 unit that are separated by Al atoms (Figure 3). Only a slight uncertainty still exists in terms of the exact arrangement of these structure units. The structural information will help us to understand the desorption mechanisms and partial reversibility of AlB_4H_{11} .

With the experience of preparing AlB_4H_{11} , we have successfully synthesized AlB_6H_{13} , another aluminoborane compound, through the reaction between $Al(BH_4)_3$ and B_4H_{10} . Since the starting materials are not commercially available, considerable efforts are devoted to the preparation of the precursors [4]. Overall, the process includes five reactions (reactions 1 to 5):

However, preliminary characterization of its properties as a potential storage material, in collaboration with ORNL, shows a very discouraging result: a large amount of borane complexes were observed during desorption, which discourages further study of this compound for hydrogen storage.

To investigate more boron-containing lightweight hydrides for hydrogen storage, we focus on a type of boron compounds with a formula of $M_xB_3H_8$, which may be less stable than M_xBH_4 and thus may be easier for dehydrogenation and rehydrogenation. We first developed a simple and efficient route to unsolvated NaB_3H_8 [5], and investigated its hydrogen release properties. Pyrolysis test results are discouraging since large amount of gaseous species were observed, indicating that this compound is not suitable for on-board reversible hydrogen storage. It is

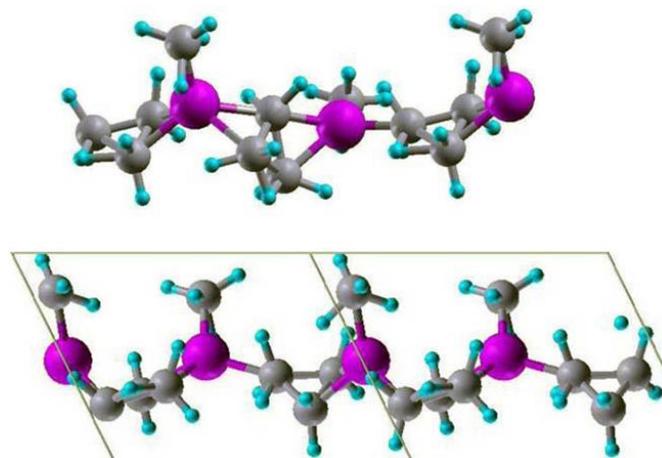

FIGURE 3. Two different lowest energy structures for AlB_4H_{11} . They have the same B_3H_7 and BH_4 structure units but slightly different arrangements.

found that NaB_3H_8 is highly soluble in water. Quantitative measurements of hydrogen released using a Toepler pump and gas buret showed that upon adding 14 mmol water to 1 mmol NaB_3H_8 with Pt/C (1 mol % Pt), a near theoretical value of 8.85 mol hydrogen is released in 20 mins via hydrolysis. Therefore, this system has a high theoretical hydrogen weight percent [$\text{wt}\% = \text{H}_2/(\text{NaB}_3\text{H}_8 + \text{H}_2\text{O})$] of 10.5 wt%. It is also observed that NaB_3H_8 is significantly more stable in water (distilled water is used in the study) than NaBH_4 . The fairly stable aqueous NaB_3H_8 solution without additives can be a good candidate for certain applications where hydrogen is consumed continuously. In this regard, NaB_3H_8 has advantages over the most studied hydrogen storage materials such as NaBH_4 and NH_3BH_3 via hydrolysis [6].

We have also successfully developed a simple and high-yield synthesis of $\text{NH}_4\text{B}_3\text{H}_8$ through a metathesis reaction between unsolvated NaB_3H_8 and NH_4Cl [7]. The crystal structure shows weak $\text{N}-\text{H}^{\delta+} \cdots \text{H}^{\delta-}-\text{B}$ interaction in $\text{NH}_4\text{B}_3\text{H}_8$, which is different from the close $\text{N}-\text{H}^{\delta+} \cdots \text{H}^{\delta-}-\text{B}$ contacts observed in $\text{NH}_3\text{B}_3\text{H}_7$ and NH_3BH_3 . $\text{NH}_4\text{B}_3\text{H}_8$ has a high hydrogen content of 20.5 wt%. Thermal decomposition analysis shows that 10 wt% hydrogen is released below 160°C , but with appreciable amounts of borane complexes. Therefore, $\text{NH}_4\text{B}_3\text{H}_8$ is unlikely a candidate for hydrogen storage through thermal decomposition.

Hydrolytic studies have shown that upon adding catalysts, $\text{NH}_4\text{B}_3\text{H}_8$ rapidly releases pure H_2 [7]. For an aqueous solution with a 1:18 molar ratio of $\text{NH}_4\text{B}_3\text{H}_8$ to H_2O , which represents a system density of 4.6 wt% H (water weight included), the commercially available 10 wt% Pt/C catalyst (1 mol% Pt) shows the best catalytic activity, with complete hydrolysis in less than 30 min (Figure 4). Lower-cost transition metal catalysts were also explored in our study and fairly good catalytic activity was observed for CoCl_2 . With 4 mol% loading of CoCl_2 , full hydrolysis was complete in about 100 min. A black powder appeared instantly when CoCl_2 was brought into contact with an aqueous $\text{NH}_4\text{B}_3\text{H}_8$ solution, suggesting the formation of cobalt boride as found during the hydrolysis of NaBH_4 . The ^{11}B NMR spectrum of the catalyzed hydrolysis solution of $\text{NH}_4\text{B}_3\text{H}_8$ and H_2O (1: 18 ratio) reveals one broad peak centered at 16 ppm which is likely associated with $\text{B}_3\text{O}_3(\text{OH})_4^-$ and $\text{B}_5\text{O}_6(\text{OH})_4^-$, along with another sharp peak situated at around 0 ppm that is also due to $\text{B}_5\text{O}_6(\text{OH})_4^-$. Similar products were also formed during the hydrolysis of $\text{NH}_3\text{B}_3\text{H}_7$.

Another amine borane compound, $(\text{NH}_3)_2\text{BH}_2\text{B}_3\text{H}_8$, with high hydrogen capacity of 18.4 wt%, has attracted little attention as a potential hydrogen storage material, probably because of its unavailability. The procedure reported before is through the reaction between ammonia and tetraborane, which is highly volatile and flammable [8,9]. Inspired by recent success in developing safe and efficient methods for synthesizing unsolvated NaB_3H_8 and $\text{NH}_4\text{B}_3\text{H}_8$, we developed a new method for synthesizing $(\text{NH}_3)_2\text{BH}_2\text{B}_3\text{H}_8$

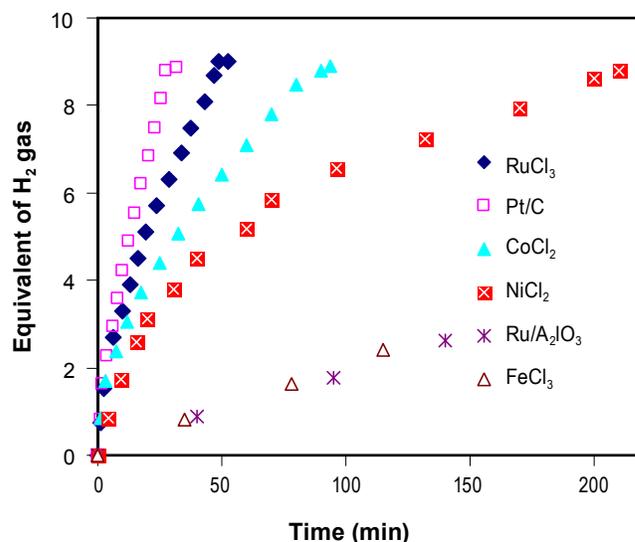

FIGURE 4. Hydrogen evolution at room temperature from an aqueous $\text{NH}_4\text{B}_3\text{H}_8$ solution (molar ratio of $\text{NH}_4\text{B}_3\text{H}_8:\text{H}_2\text{O}$ being 1:18) containing 10 wt% Pt/C (1 mol% Pt); 5 wt% $\text{Ru}/\text{Al}_2\text{O}_3$ (1 mol% Ru), RuCl_3 (1 mol% Ru), CoCl_2 (4 mol% Co), NiCl_2 (4 mol% Ni) and FeCl_3 (4 mol% Fe). Molar ratios are referenced to $\text{NH}_4\text{B}_3\text{H}_8$.

via a metathesis reaction. The method includes three steps (reactions 6, 7, and 8):

All three reactions are carried out in liquid ammonia. After the second step (reaction 7), $(\text{NH}_3)_2\text{BH}_2\text{Cl}$ is isolated from the tetrahydrofuran (THF) solution after removal of liquid ammonia. The desired $(\text{NH}_3)_2\text{BH}_2\text{B}_3\text{H}_8$ is extracted using THF. Overall, the new method is more efficient. The ^{11}B NMR spectrum of $(\text{NH}_3)_2\text{BH}_2\text{B}_3\text{H}_8$ in THF shows a triplet and a nonet corresponding to BH_2^+ and B_3H_8^- group. Crystal structure of an adduct with crown ether, $(\text{NH}_3)_2\text{BH}_2\text{B}_3\text{H}_8 \cdot 18\text{-crown-6}$ has been determined in which one ammonia molecule orients toward the crown ether to form three $\text{N}-\text{H} \cdots \text{O}$ hydrogen bonds between the hydrogen atoms of the ammonia and the oxygen atoms of the ether. Further characterization of its desorption products and mechanism is in progress.

Conclusions and Future Directions

- In collaboration with Northwestern University and NIST, we have now identified the structure units in polymeric/amorphous $\text{AlB}_4\text{H}_{11}$. The structure consists of B_3H_7 and BH_4 groups linked to a polymer chain via Al atoms.
- $\text{AlB}_6\text{H}_{13}$ (a sister compound to $\text{AlB}_4\text{H}_{11}$) was synthesized and characterized for potential hydrogen storage, and was found not a viable hydrogen storage material.

- Simple and efficient methods for the preparation of both NaB_3H_8 and $\text{NH}_4\text{B}_3\text{H}_8$ were developed. These compounds were found unsuitable for reversible hydrogen storage, but showed good properties via hydrolysis.
- We developed a new method to prepare $[\text{H}_2\text{B}(\text{NH}_3)_2][\text{B}_3\text{H}_8]$ which has high hydrogen capacity of 18.4 wt%.
- As the program/project is drawn to completion, we will do our best in completing the analysis and reporting.

- Cost: \$4/kWh net
- Specific energy: 1.5 kWh/kg
- Energy density: 0.9 kWh/L

Introduction

The effort at the University of Illinois at Urbana-Champaign focuses on resolving issues within current hydrogen storage materials using a combination of electronic structure calculations and state-of-the-art compositional and structural characterization methods. We tie together theoretical understanding of electronic, enthalpic, thermodynamic, and surface effects affecting performance of storage materials with microcompositional and microstructural experimental analysis, coordinated with collaborative partnerships with other institutions; current partnerships are with Savannah River National Laboratory, Dr. Ragaiy Zidan, and University of Missouri, Professor Eric Majzoub. These efforts enable a more efficient approach to designing a new system with the required properties.

Objectives

The main focus of this research project is to:

- Advance the understanding of the microstructural and modeling characteristics of complex hydrides.
- Provide more reliable theoretical methods to assess hydrogen-storage materials, including key issues affecting materials under study.

Technical Barriers

This project addresses the following technical barriers from the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (E) Charging/Discharging Rates
- (D) Durability/Operability

Technical Targets

This project is conducting fundamental experimental and theoretical studies of candidate light-weight systems for on-board regeneration. Insights gained from these studies will be applied toward the design and synthesis of hydrogen storage materials that meet the following DOE 2010 hydrogen storage targets:

Approach

We employ state-of-the-art characterization tools to investigate the microstructural and microchemical changes that occur in candidate material systems during the uptake and release of hydrogen. The characterization is coupled with first-principles, electronic-structure and thermodynamic theoretical techniques to predict and assess meta-stable and stable phases, as well as surface effects that can poison or limit kinetics. Electronic-structure and thermodynamic calculations are used to enhance the understanding of experimental characterization results on candidate systems. This combined theoretical/characterization effort provides fundamental insight to the processes governing hydrogen uptake and release. In the following, a selection of the highlights from the work performed in Fiscal Year 2011 is described.

Experimental Project

Our experimental effort utilizes the advanced characterization capabilities of a state-of-the-art transmission electron microscope (TEM). An environmental transfer TEM stage enables air-sensitive materials to be loaded into the stage in the environment of a glove box and transferred to the microscope without exposure to the environment. In addition, electron tomography is being applied to gain three-dimensional information as to the particle shape, the distribution of catalyst particles dispersed by ball-milling

and the infiltration of the storage medium in nano-confined scaffolds. These approaches are being used to characterize air-sensitive nano-confined hydrogen storage materials to gain a better understanding of the effect of processing conditions on the resulting specimen structure and the effect of the number of cycles. Finally, scanning tunneling microscopy (STM) experiments are being conducted to identify the roadblock to hydrogen uptake and release in Al. The progress made this fiscal year is described in the following sections.

Nano-Porous Frameworks for Supporting Hydrogen Storage Materials

In collaboration with Professor Eric Majzoub and coworkers from the University of Missouri, we are investigating LiBH_4 -infiltrated nano-porous carbon scaffolds. Existing work suggests that reducing the particle size of complex metal hydride materials (to 10 nm or smaller) enhances the kinetics and thermodynamics of hydrogen uptake and release. Infiltrating these materials into nano-porous scaffolds holds potential as a means for constraining particle size to the scaffold pore size as well as preventing the storage medium from sintering or its constituents from diffusing too far away.

The scaffolds we are examining were reported to be nano-porous carbon composed of long cylindrical columns packed into a hexagonal arrangement that run the entire length of the powder grains. The bright-field electron micrographs presented as Figures 1a and 1d are of the carbon scaffold and were reported to be representative of a side view and a pore-down view of the columns, respectively [1]. In these images, the columns (light) appear to be 2.1-2.5 nm wide with wall thicknesses (dark) of 9.1-9.8 nm and a column spacing of 13 nm. Similarly, pore diameters are 3-4.25 nm and the pore spacing is 14 nm. In contrast, we have shown that in both bright-field and high-angle annular dark-field scanning transmission electron images, Figures 1b-c and 1e-f, the column widths and wall thicknesses are identical (4-5 nm with a spacing between 8-9.5 nm) irrespective of the viewing direction and imaging mode. A second size of column, roughly half the width and half the spacing, is also seen though is less common. Still, the column diameters and wall thicknesses match each other. These new findings conform to the expected values based off other measurement techniques.

Our investigation has also revealed a number of interesting features about the scaffold structure, which are providing insight into the connection between processing conditions and how the scaffold grows. The columns form a layered structure, the sheets of columns of which are not always oriented in the same direction. Figure 1f shows one such particle in which the column layers are offset at hexagonal angles, giving incorrectly the appearance of pores. Other particles possess not only different orientations of columns but different sizes and curvatures of columns all within the same powder grain. Many particles are also

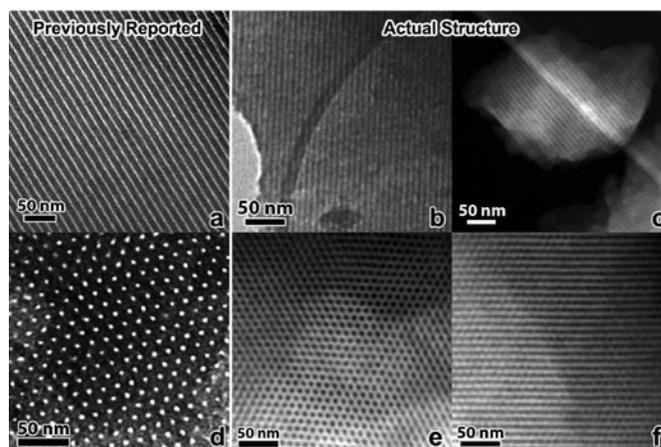

FIGURE 1. (a) Bright-field (BF) TEM micrograph from Majzoub showing a large disparity between column width (light) and wall thickness (dark). (b) BF TEM micrograph taken at UIUC exhibiting no such disparity. (c) High-angle annular dark-field (HAADF) scanning transmission electron microscopy (STEM) micrograph taken at UIUC showing the same as (b). (d) BF TEM of pores again showing inaccurate structure. (e) HAADF STEM image from UIUC of pores and (f) layers of columns offset at hexagonal angles to give the appearance of pores.

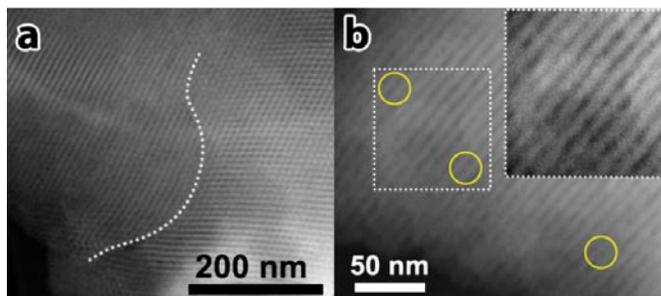

FIGURE 2. HAADF STEM micrographs showing (a) multiple domains of columns with different orientations within a scaffold particle (domain boundary shown by dotted line), and (b) column blockages (circled). The inset is a close-up of the boxed region, with the contrast adjusted for ease of viewing.

made of multiple domains of different column orientations, Figure 2a, the size and quantity of which may be a consequence of growth parameters. This domain structure might explain why the observed maximum practical loading capacity of these scaffolds is lower than would be expected according to scaffold volume. Any domains without pores directly open to the surface would be difficult or impossible to infiltrate fully. Similarly, column blockage has been observed, Figure 2b, and could also reduce the loading capacity. The extent of column blockage may be related to the concentration of oxygen flowed during synthesis. Further study of scaffold structures produced under a variety of processing conditions will elucidate their effect on the resulting microstructure, allowing optimal growth conditions to be determined.

In order to help understand and explain the gradual loss of total storage capacity observed with hydrogen cycling of

these systems [1], specimens that were desorbed at 500°C in a differential scanning calorimeter (DSC) were examined via electron microscopy. In these specimens, protruding material, in the form of bristles and nodules, were seen on the surfaces of the specimens. As shown in the images presented in Figure 3, the bristles were typically 16-24 nm wide with aspect ratios ranging from above 3:1 to over 6:1, though bristles down to around 13 nm and over 30 nm wide were observed. The nodules were usually many tens of nanometers in width and came in a variety of shapes. These bristles and nodules are not products of electron beam damage, as can sometimes be seen in bulk versions of these materials. Unlike the latter, these protrusions are present in their full form from the very beginning of observation and do not grow larger under continued exposure to the beam.

A possible explanation for these formations is that they are one or more components of the storage medium (Li and/or B) that migrates out from the carbon scaffold pores during hydrogen desorption, segregating to the scaffold particle surface where it grows into nodules and bristles. This reduces the amount of nano-scale infiltrated material available to participate in hydrogen uptake, lowering the total storage capacity of the system. Additionally, if the protrusions are composed of only either Li or B, this segregation of reaction components would also lead to a reduction in storage capacity, as would if the protrusions were a new stable, lower-reactivity compound. The low atomic mass of the storage medium (Li, B) makes chemical identification of the bristles and nodules quite difficult. In addition, the small size of the protrusions, as well as their composition, makes focused-probe methods impossible, as the bristles and nodules are immediately destroyed under such an intense electron beam. This behavior, though, strongly suggests that they are purely B and/or Li. We are currently investigating other techniques to find one that possesses the necessary resolution and chemical sensitivity, but will not destroy the protrusions.

The spatial density of surface bristles and nodules can vary dramatically across a single host scaffold particle. Some regions had densely packed patches of bristles while others were bare. It is possible that their distribution is related to where the column domains contact the surface.

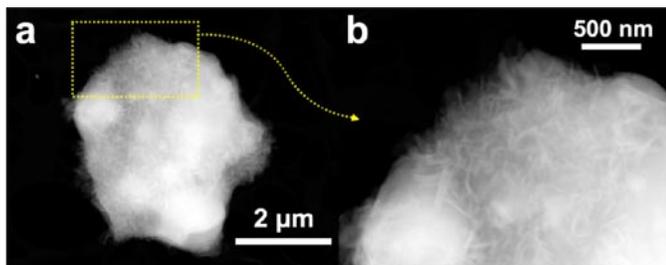

FIGURE 3. HAADF STEM images of a host scaffold particle covered in bristles and nodules. The area outlined in yellow in (a) is shown closer up in (b) to make the dense covering of bristles easier to see.

If the domain was oriented such that the column pores face the surface, it would be easier for the infiltrated storage material to migrate out of the pores and onto the surface to grow these protrusions.

The desorption temperature of these specimens (500°C) was higher than is used during standard cycling (300-350°C), so this behavior may be lessened or absent entirely under normal conditions. We are currently examining specimens of a variety of different filling ratios as they are heated from room temperature up to 500°C to determine the role of temperature in the formation of the bristles and nodules.

Preliminary studies, using a variable temperature scanning tunneling microscope, of clean Al surfaces and Al surfaces with sub-monolayer coverage of Ti, showed interesting results on the association of alane formation with the Ti atoms and with surface vacancies. Despite numerous attempts these results were difficult to reproduce. However, our recent first principle calculations, which are described in the following section, have provided insight as to the important role of surface defects. This insight suggests an alternate surface preparation strategy to the one used previously and another set of experiments has been initiated. New materials have been acquired, which we will use in our attempt to confirm our previous observations of Ti-catalyst activity on Al surfaces and the formation of alane with H₂ exposure.

Our latest experiments, using an STM with more sensitive spectroscopic capabilities to probe electronic structure, confirm that titanium catalyst deposited on an aluminum surface retains its metallic character; no energy gap is observed. Subsequent experiments will measure whether this changes with hydrogen exposure.

Theory

Transition-metal catalysts are used extensively in hydrogen storage materials to increase H absorption and desorption kinetics. Using density functional theory (DFT) calculations, we elucidated the catalytic effect of Ti substitution on H₂ desorption from a MgH₂(110) surface. Kinetic energy barriers of different reaction pathways of H desorption are calculated via the nudged-elastic-band (NEB) method. We found that a single Ti dopant is effective in reducing the kinetic barrier by 0.41 eV due to a concerted motion of H₂ surface desorption and H bulk diffusion. We also find that magnetic degrees of freedom must be carefully included to describe the crossover of magnetic states during catalyzed H₂ surface desorption. As shown in Figure 4, there are two concerted activation steps. In the early stage of reaction, the diffusion of in-plane hydrogen from first and second tri-layers to the surface brings a high hydrogen coordination number (HCN) of 8 to Ti, and the system prefers to have a magnetic moment of 0 μ_B. The activation barrier is small. In the second activation step to desorb H₂, the barrier is large. And importantly, because of the decrease in HCN to 6, the system prefers to have a magnetic

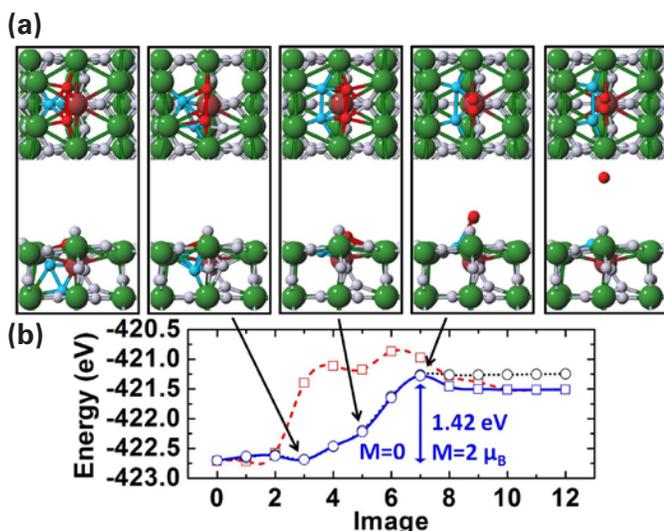

FIGURE 4. Minimum energy pathway (MEP) for H_2 desorption from Ti-doped $\text{MgH}_2(110)$ surface, with large green spheres for Mg, large red for Ti and small gray for H. a) The leftmost (rightmost) sub-figure is the initial (final) state with a magnetic moment of $0 (2) \mu_B$. Three other intermediate states (Nudged elastic band images 3, 5 and 7 indicated by arrows) are also shown. Two bridge Hs that desorb from surface are highlighted in red. Two in-plane hydrogen atoms (one in the first tri-layer and the other in the second tri-layer) that diffuse to top of the surface are highlighted in blue. b) Total energy along reaction coordinates. MEP for the same initial state with moment of $0 \mu_B$ and MEP for a degenerated initial state with a magnetic moment of $2 \mu_B$ are included as red dashed line and black dotted lines for comparison. The activation barrier is 1.84 and 1.46 eV, respectively. The square (circle) stands for the state with a magnetic moment of $2 (0) \mu_B$.

moment of $2 \mu_B$. The overall kinetic barrier is 1.42 eV. In contrast, without such crossover of magnetic moment, the barrier is 1.46 eV for the same initial state with a magnetic moment of $2 \mu_B$ and 1.84 eV for a degenerated state with a magnetic moment of $2 \mu_B$.

Our earlier report and also previous studies have shown that the overall desorption energy of H (or formation energy) from MgH_2 nanoparticles only decreases significantly when the size of the particle falls below 5 formula units. We have shown via DFT simulation that there is no size effect on the initial desorption of H from a MgH_2 surface and a MgH_2 amorphous nanoparticles. We have considered both singly- and doubly-bonded H. Figure 5(a) shows that a singly-bonded H is removed from an amorphous MgH_2 NP of 31 formula units. The desorption energy is 148 kJ/(mol- H_2) in reference to free H_2 . Because a singly-bonded H cannot be found on $\text{MgH}_2(110)$, where only doubly-bonded H exist, we constructed a stepped surface, see Figure 5(b). The desorption energy of singly-bonded H from this step surface is 140 kJ/(mol- H_2) and within 6% of that from a finite nanoparticle. For a doubly-bonded H, we found a similar result. All the data are shown in Figure 5(c). The lack of size effect in the initial H desorption can be understood by the fact that the Mg-H bond is ionic and local in nature.

Motivated by our earlier STM observations, we used DFT to study the atomic processes of alane formation on Ti-doped Al(111) surfaces and elucidate the role of Ti and vacancies. Figure 6 shows the reaction pathways of alane formation on Al(111) with and without Ti doping. Without Ti (see Figure 6(a)), the pristine Al(111) surface is known to react weakly with hydrogen. The dissociative adsorption

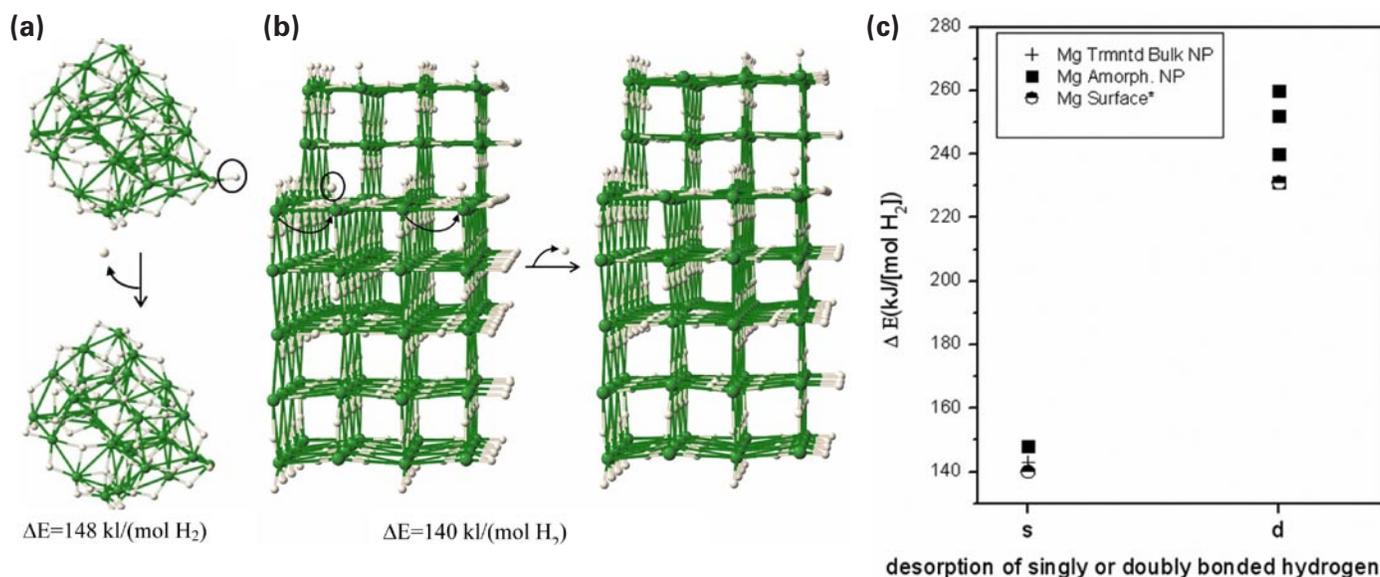

FIGURE 5. Desorption of H from MgH_2 nanoparticle and bulk surface. Singly-bonded H is desorbed from a) an amorphous MgH_2 nanoparticle and b) a stepped surface of MgH_2 . c) Desorption energies for both singly- and doubly-bonded H in different structures. In the amorphous MgH_2 nanoparticle, several doubly-bonded H sites that are non-equivalent are shown together.

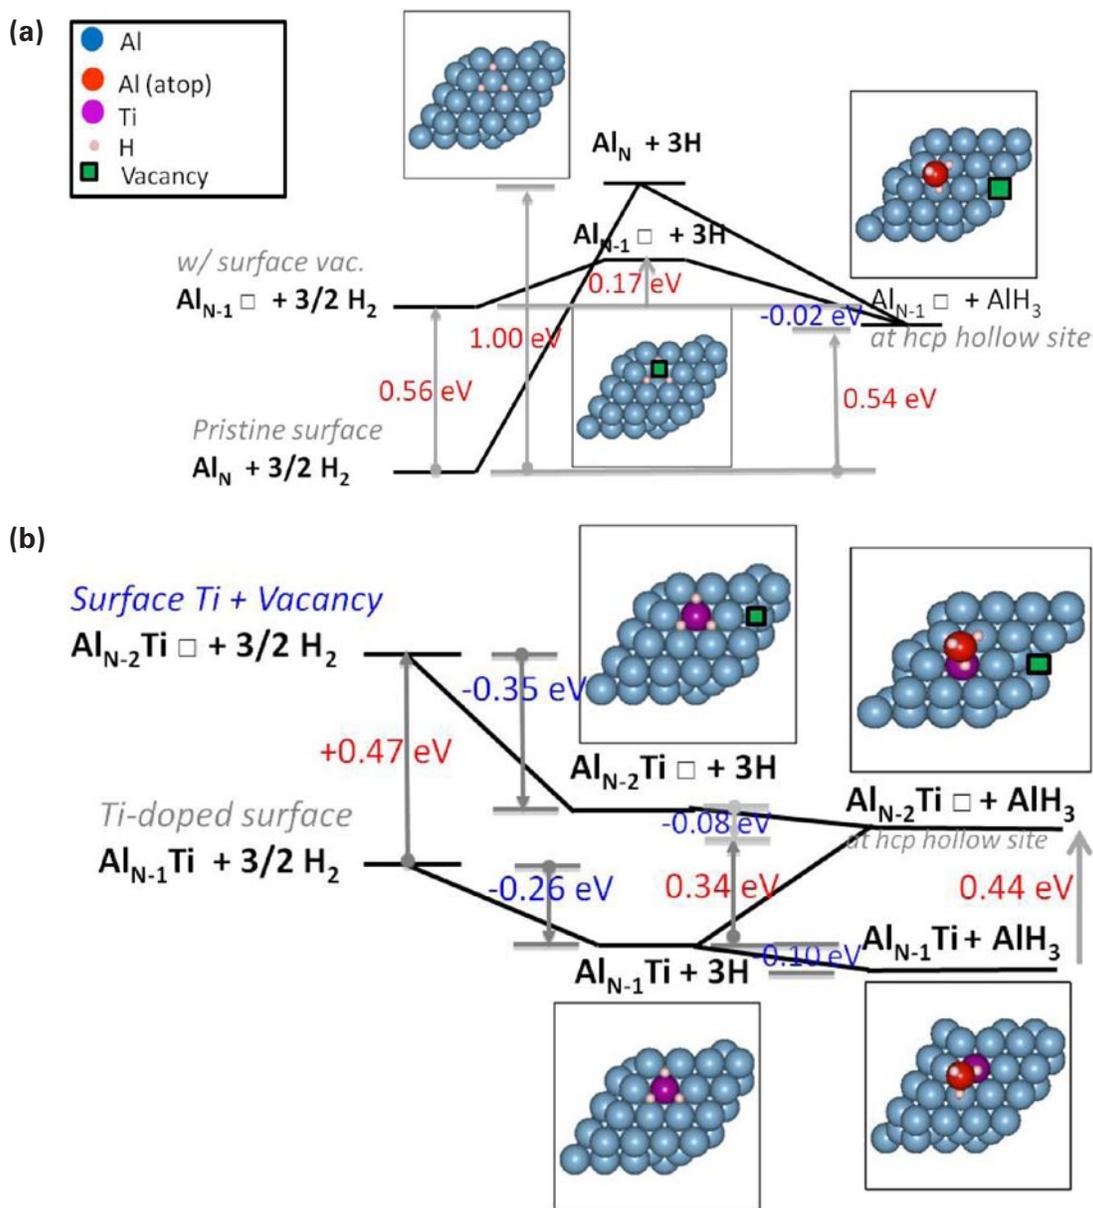

FIGURE 6. Reaction pathways for alane formation on Al(111) (a) without (b) with Ti dopant. In each case, both the absence and presence of Al vacancy are considered.

of H_2 on Al(111) surface costs energy. Using one and a half H_2 molecules and pristine Al(111) surface as the energy reference, the formation of three atomically adsorbed H on Al(111) is 1.00 eV higher. The system can lower energy by 0.46 eV with the formation of an alane molecule, which prefers to adsorb on a neighboring 3-fold hollow site, leaving behind a surface Al vacancy. Overall, the reaction to form alane on pristine Al(111) is endothermic with a reaction energy of 0.54 eV. In contrast, if Al(111) already has an Al vacancy, it only costs 0.17 eV to dissociate $(3/2)\text{H}_2$, which prefers to adsorb at the vacancy site. Then it gains 0.19 eV to form an alane molecule, such that the overall alane formation is slightly exothermic with a reaction energy of

-0.02 eV. This is due to the fact that the initial reactant Al phase is destabilized by creating one Al vacancy and moving the displaced Al atom to a bulk environment, which shifts the initial state to be 0.56 eV higher. More importantly, the presence of Al vacancy helps to lower the energy cost to dissociate H_2 .

By introducing Ti on Al(111) (see Figure 6b), the Al vacancy formation energy is reduced to 0.47 eV, reflecting the tendency for Ti and Al to form an alloy. With Ti, the dissociation of H_2 becomes favored in both cases, with an energy drop of 0.26 and 0.35 eV without and with an Al vacancy, respectively. Atomic H prefers to stay with Ti and adsorbs on the 3-fold hollow site around Ti. Then

the formation of alane is favored by a small energy drop of 0.08 eV in the vacancy case. Without a vacancy, the formation of alane can also proceed with an energy drop of 0.10 eV provided an activated Al atom is available from the creation of a vacancy at another site. Otherwise, a direct conversion to alane by creating a local Al vacancy costs 0.34 eV. But the overall formation of alane in this case with Ti is slightly endothermic with a reaction energy of only 0.08 eV. With the availability of an activated Al atom diffusing on the surface, the formation of alane molecule in both cases is endothermic. Further study of the kinetic energy barrier of each step is in progress.

Overall, however, these results explain and agree well with our STM studies performed on Al(111) dosed with Ti dopants and H₂; moreover, these results explain the observed formation of alane in ball-milling experiments, where vacancies occur as a inherent consequence of the processing, e.g., those at Ames Laboratory by V. Pacharsky.

Project Start Date: October 1, 2005

Project End Date: Project continuation and
direction determined annually by DOE

Fiscal Year (FY) 2011 Objectives

Develop onboard vehicle storage systems using aluminum hydride that meets all of DOE's targets for the proton exchange membrane (PEM) fuel cell vehicle:

- Produce aluminum hydride material with a hydrogen storage capacity greater than 9.7% gravimetric ($\text{kg-H}_2/\text{kg}$) and 0.13 $\text{kg-H}_2/\text{L}$ volumetric.
- Develop practical and economical processes for regenerating aluminum hydride.
- Assist in developing aluminum hydride slurry storage systems for better than 6% hydrogen gravimetric material density, 0.07 $\text{kg-H}_2/\text{L}$ volumetric hydrogen storage capacity, and well-to-wheels efficiencies greater than 60%.

Technical Barriers

This project addresses the following technical barriers from the storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (B) System Cost
- (E) Charging/Discharging Rates

Technical Targets

Listed in Table 1 are the 2015 Hydrogen Storage targets along with BNL's current 2011 aluminum hydride project status. The well-to-wheels efficiency listed in the table under the column for 2011 Status was taken from an independent analysis of an aluminum hydride storage system by Argonne

National Laboratory. The Argonne analysis assumes 70-wt% aluminum hydride slurry, uses trimethylamine as the stabilizing agent for regenerating aluminum hydride and assumes the availability of low grade heat in determining the 55% efficiency. The tank's operating temperature of 80°C was the lowest temperature measured by BNL for AlH_3 slurries that meets the DOE fuel flow target of 0.02 (g/s)/kW. The criteria for meeting this flow target is 96% hydrogen release in 60 minutes or less from a 10 liter tank. The 0.0582 gravimetric storage parameter listed in Table 1 is a measured value from a 60-wt% slurry consisting of 9.7-wt% aluminum hydride particles and does not take into account the balance of plant weight.

TABLE 1. Progress in Meeting Technical Hydrogen Storage Targets

Aluminum Hydride Regeneration			
Storage Parameter	Units	2015 Target	2011 Status
Gravimetric	wt% H_2	0.055	0.0582
Volumetric	$\text{kg H}_2/\text{L}$	0.040	0.070
Full Flow Rate (temperature)	(g/s)/kW °C	0.02 80	0.02 80
Well-to-Wheels Efficiency	$\text{kW-H}_2/\text{kW}$	60%	55%
Refueling Time	min	3.3	To be determined

FY 2011 Accomplishments

- Demonstrated 6 wt% H_2 slurries using mineral oil and glycols as the liquid carrier.
- In the aluminum hydride synthesis process identified diphenyl methane as a safe solvent substitute for toluene.
- Demonstrated that aluminum hydride slurries can meet DOE's fuel flow targets at temperatures less than the fuel cell operating temperature of 100°C.

Introduction

The FY 2011 objective was to achieve DOE's 2015 system fill target of 5 kg of H_2 in 3.3 minutes. Since aluminum hydride exists only as a solid, this objective was redirected towards formulating a 'pumpable' 6% by H_2 wt AlH_3 slurry. In order to meet this 1.5 kg H_2 per minute target, the slurry had to be stable against phase separation and sedimentation with a viscosity less than 1,000 centipoise. This type of slurry could be made, however the condition of remaining "pumpable" after the

release of hydrogen at temperatures of 120°C was not met by using either mineral oil or glycol as the liquid carriers.

Approach

AlH_3 is classified as a kinetically stabilized material. In the past we have used a nucleation and growth chemistry model to describe the stability of AlH_3 . This chemical model was useful in defining an induction period (nucleation) along with a kinetic decomposition period (growth). However recently, we found that a statistical approach (hyperbolic secant probability distribution function, Eqn. [1]) is very useful in describing the AlH_3 decomposition rate under isothermal conditions:

$$f(t) = (1/2t_k) \text{sech}[(\pi/2)(t-t_m)/t_k] \quad [1]$$

In Eqn. [1], t_m is the time when the decomposition rate reaches its peak value and $(1/2t_k)$ is the peak kinetic decomposition rate. The integration of the probability distribution function $f(t)$ over time yields the cumulative distribution function $F(t)$. This function is more convenient to work with than the probability density function, since it is the percent loss of hydrogen as a function of time. Integrating over time Eqn. [1] yields the following expression for the cumulative distribution function $F(t)$:

$$F(t) = (2/\pi) \tan^{-1}(\exp[(\pi/2)(t-t_m)/t_k]). \quad [2]$$

The induction period (IP) is now defined as the time when $F(t) = 0.02$. In other words, the time it takes for 2% decomposition. Setting $F(t) = 0.02$, replacing (t) with IP and solving for IP gives the following:

$$\text{IP} = t_m + (2t_k/\pi) \ln\{\tan(0.01\pi)\} = t_m - (2t_k/\pi)3.4601. \quad [3]$$

The time required for 96% release of hydrogen after the induction period is:

$$\Delta t(96\%) = (2t_k/\pi) \ln\{\tan(0.49\pi)\} - (2t_k/\pi) \ln\{\tan(0.01\pi)\} = (4t_k/\pi)3.4601. \quad [4]$$

Note that $\ln\{\tan(0.49\pi)\} = 3.4601$ and $\ln\{\tan(0.01\pi)\} = -3.4601$.

This model implies that surface coatings can increase the induction period by increasing t_m (see Eqn. [3]). Eqn. [4] shows that the time release of hydrogen $\Delta t(96\%)$ depends only on t_k and not t_m . Recall that $(1/2t_k)$ is the peak decomposition rate. Thus, the increase in IP, that results from increasing t_m , will essentially have no effect on the time it takes to release the remainder (96%) of the hydrogen. The results of this study support this model, since it shows that surface coatings can improve the stability of AlH_3 against decomposition; but once decomposition has started, the rate is then controlled by catalysts and the sample temperature.

Results

A 6% (or larger) by weight slurry is best achieved by using micron-sized particles. The preferred method

for making micron-sized AlH_3 particles is by nucleating and growing these particles from an alane-etherate in an inert solvent solution. The inert solvent can be benzene or toluene; and just recently, we found that diphenyl methane is also a suitable medium. In simple terms, AlH_3 solubility decreases with increasing temperatures so by raising the temperature one would expect aluminum hydride to precipitate out of solution. The complication is that aluminum hydride decomposes at temperatures above 100°C. Thus far, only the alane etherate compounds have yielded aluminum hydride by this method. Attempts to recover aluminum hydride from alane-amine complexes have not yet been successful by this approach. We are, however, able to control particle size by controlling the rate at which the diethyl ether is removed from the reactor. Controlling the particle morphology is more challenging. Figure 1 shows individual particles and clusters of particles with aspect ratios close to 1, yet Figure 2 shows that under very similar conditions rod-shaped particles can also be produced. These particles are formed in batch and semi-continuous reactors. The batch reactor is 1 liter in size and makes 1.25 gram of product per batch. The recovered AlH_3 is then washed in either diethyl ether or hydrochloric acid. The semi-continuous method has a port connection for introducing the alane-etherate to a 1.5 liter reactor and we have used this method to produce up to 5 grams of AlH_3 . After the wash, a milliliter of diethylene dibutyl ether glycol (density 0.80 g/ml) is mixed with the 1.25 grams of AlH_3 to make a nominally 60% aluminum hydride-glycol slurry. A similar procedure was used to prepare a mineral oil slurry where 4 milliliters of mineral oil and 0.15 grams of dispersant (Triton x-100) was used along with the AlH_3 .

A series of isothermal kinetic decomposition experiments were performed on these aluminum hydride glycol and mineral oil slurries. Figure 3 shows plots of

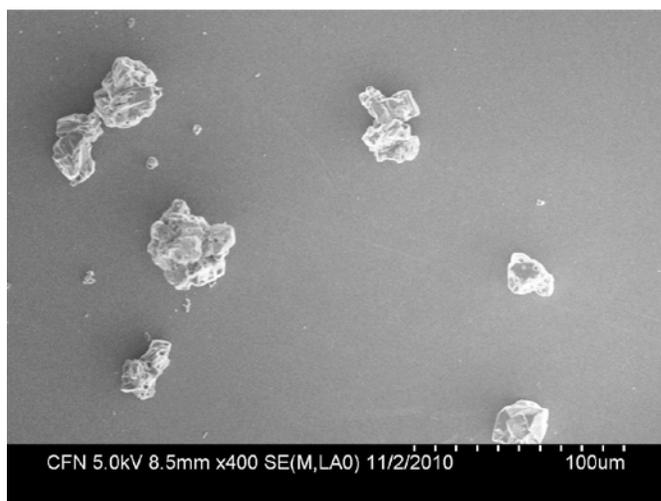

FIGURE 1. Electron micrograph of 97% pure alpha aluminum hydride particles in cluster shapes precipitated from an alane-etherate/toluene solution (sample AH-3390).

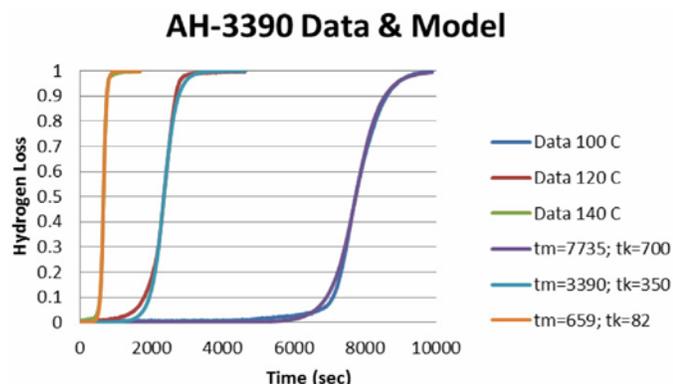

FIGURE 3. Fractional decomposition of AlH_3 at the three temperatures of 100, 120 and 140°C showing experimental data and fit using the statistical model.

the hydrogen loss as a function of time for the aluminum hydride-glycol slurry at three temperatures: 100, 120 and 140°C. Also plotted on this figure are the results from the statistic model with the corresponding two parameter fit (t_m , t_k). The good fit between the experimental data and model allows us to discuss the data in terms of t_m and t_k . For the catalyzed glycol slurries $t_k \sim 250$ ($T = 120^\circ\text{C}$), while this parameter is much greater for the mineral oil slurries $t_k \sim 700$ ($T = 120^\circ\text{C}$). At this point we can only speculate why the catalyzed glycol slurries have better decomposition kinetics than the mineral oil slurries. Figure 4 shows how the acid wash affects the IP. Incorporating a wash at the end of the synthesis increases the IP by applying an oxide/hydroxide coating on the surface of the AlH_3 particle. In this experiment one half the particles were acid washed and the other half were only washed in diethyl ether. Note that even though the IP increased after the acid wash, the peak

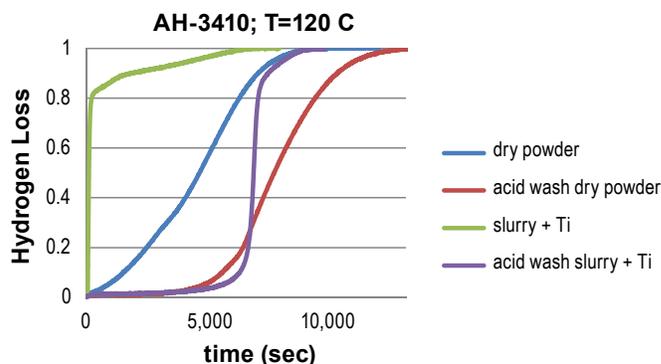

FIGURE 4. AlH_3 decomposition data for particles with and without acid wash as a function of time.

decomposition rate t_k remained essentially constant ($t_k = 100$ & 300 for the two Ti-catalyzed samples; $t_k = 2,100$ and $2,400$ for the two samples without catalysts). The non-symmetric result (green line) for the catalyzed slurry in Figure 4 has been attributed to non-uniform mixing of the catalyst in the slurry.

Conclusions and Future Directions

- 6 wt% H_2 AlH_3 slurries were prepared and performed satisfactory at temperatures less than 100°C .
- Determined that surface coatings can stabilize AlH_3 against the start of decomposition. We also found that using a hydrochloric acid wash is an effective means of applying surface coatings on one micron or larger AlH_3 particles.
- The AlH_3 decomposition rates after the induction period are controlled mainly by temperature and catalyst loading. Morphology, particle size and the type of liquid carrier also affect decomposition kinetics, but to a lesser extent.
- The future direction is to develop the procedure and hardware to increase AlH_3 production from 5 grams/week to 50 grams/week.

TABLE 1. Alane Compared With 2015 Target

Storage Parameter	2015 Target	AlH ₃
Gravimetric Capacity	0.055 kg H ₂ /kg System	0.1 kg H ₂ /kg AlH ₃
Volumetric Capacity	0.04 kg H ₂ /L System	0.149 kg H ₂ /L AlH ₃

FY 2011 Accomplishments

- Developed a pressurized dimethyl ether (DME)-based synthesis for alane that eliminates need for vacuum drying of alane and yield α -alane crystallites.
- Demonstrated electrochemically active compounds and used electrochemical impedance spectroscopy (EIS) to show that kinetic improvements were due to more than increased ionic conductivity.
- Continued production of gram quantities of alane with improving energy efficiency.

Introduction

The DOE is supporting research to demonstrate viable materials for on-board hydrogen storage. Aluminum hydride (alane – AlH₃), having a gravimetric capacity of 10 wt% and volumetric capacity of 149 g H₂/L and a desorption temperature of ~60°C to 175°C (depending on particle size and the addition of catalysts) has the potential to meet the 2010 and 2015 DOE targets [1,2].

The main draw back for using alane as a hydrogen storage material is unfavorable thermodynamics towards hydrogenation. Past attempts to regenerate alane under mild conditions were reported, including attempts based on electrochemical methods [3, 4]. However, recent results on the regeneration of alane reported by Zidan et al. [5] were the first to show a reversible cycle utilizing electrochemistry and direct hydrogenation, where gram quantities of alane were produced, isolated and characterized. This regeneration method is based on a complete cycle that uses electrolysis and catalytic hydrogenation of spent Al(s). This cycle avoids the impractical high pressure needed to form AlH₃ and the chemical reaction route of AlH₃ that leads to the formation of alkali halide salts, such as LiCl or NaCl, which become a thermodynamic sink because of their stability. During FY 2011, the electrochemical synthesis of alane described in Zidan et al. [5] has been improved allowing higher cell efficiency while increasing the alane production rate. Improvements are achieved by the use of LiAlH₄ and the introduction of LiCl [6] which acts as an electro-catalytic additive (ECA) and greatly enhanced the electrochemical process. A pressurized solvent electrochemical method for alane production has also been developed and demonstrated that reduces the need for parasitic vacuum processing of the alane to remove solvents.

Fiscal Year (FY) 2011 Objectives

- Identify energy efficiency improvements for the alane production process of over 50%.
- Characterize new electrochemical additives for alane production.
- Improve production process and properties of alane adducts.

Technical Barriers

This project addresses the following technical barriers from the Technical Plan - Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (B) System Cost
- (C) Efficiency
- (R) Regeneration Processes

Technical Targets

In this project studies are being conducted to lower cost and improve efficiency of the electrochemical method to form AlH₃. This material has the potential to meet the 2015 technical target for on-board hydrogen storage as shown in Table 1.

Approach

Experimentally, the electrolysis was carried out as described in the electronic supplementary information of Zidan et al [3]. However, LiAlH_4 was used instead of NaAlH_4 . Both, tetrahydrofuran (THF) and diethyl ether (Et_2O) were used as aprotic solvents for the alane regeneration. Research on the electrochemical properties of MAlH_4 ($\text{M} = \text{Na}, \text{Li}$) in THF and Et_2O has been reported [7, 8] but these studies were not directed at the regeneration and characterization of alane. Also, the work of Senoh et al [7, 8] was performed with Ni electrodes different to this work in which Al is used as working electrode. The use of Al is essential to the alane regenerative process and the reaction with the ECA as discussed later.

Results

To test the effect of the LiCl two cells were prepared using LiAlH_4 and triethylenediamine (TEDA) in THF and LiCl was added to one of the cells. TEDA was incorporated in the solution to easily detect and visualize the formation of alane as $\text{AlH}_3\text{-TEDA}$ (white precipitate [3]) during the experimental test. Figure 1 shows 10 min of the bulk electrolysis at 2.1 V for the alane production using the two cells described above. The high potential used during the electrolysis was applied to produce enough alane in those 10 min for visualization purpose and comparison. Alane-TEDA is not expected to decompose during the conditions of these tests. Figure 2 shows an increase of 80% in the current when LiCl was used. The total charge for cell 2 was two times the total charge obtained with cell 1. Since the charge is proportional to the moles of product produced, the amount of $\text{AlH}_3\text{-TEDA}$ was doubled when the ECA was used in cell 2. The precipitated alane-TEDA was separated from solution and weighted. Consistently, Cell 2 was found to produce twice as much $\text{AlH}_3\text{-TEDA}$.

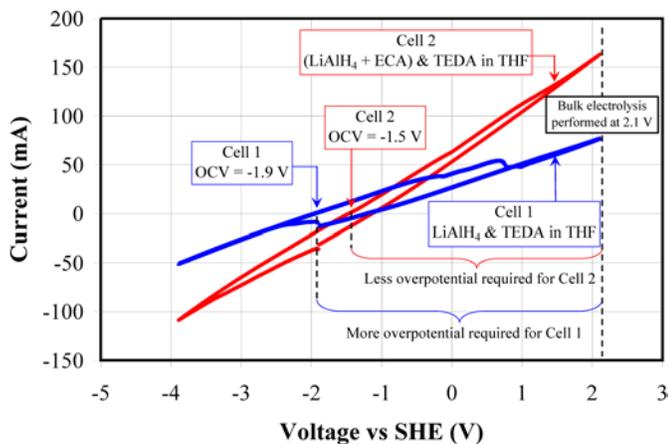

FIGURE 1. Cyclic voltammograms at 50 mV/s for the formation of $\text{AlH}_3\text{-TEDA}$ using identical electrochemical cells with 1 M of LiAlH_4 and TEDA in THF without LiCl (Cell 1) and with LiCl (Cell 2).

EIS was performed on the cells with and without the LiCl. Figure 3 shows that the high frequency value, which represents the resistance of the cells, is about 113 and 114 $\Omega\text{-cm}^2$ for the cells without and with LiCl, respectively. This shows that LiCl does not have a significant effect in the resistance (or conductivity) of the solution. That is, the LiCl is not acting as an electrolyte. Consequently, the increase in current and efficiency discussed above are an electro-catalytic effect of the added species.

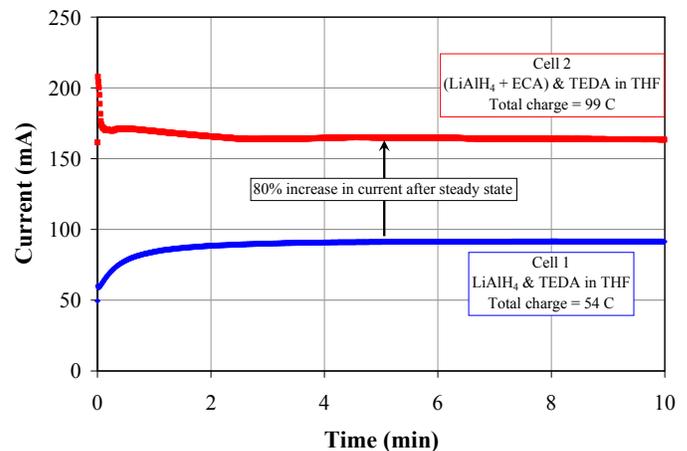

FIGURE 2. Bulk Electrolysis for the Production of $\text{AlH}_3\text{-TEDA}$ using two Identical Electrochemical Cells with 1 M of LiAlH_4 in and THF without LiCl (Cell 1) and with LiCl (Cell 2)

Minimizing the use vacuum pump

Anode:

Cathode:

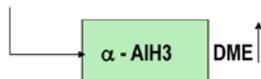

FIGURE 4. Pressurized Solvent System to Improve Overall Energy Efficiency of Alane Production

Therefore, the electrochemical synthesis of alane has been improved by adding LiCl to a solution of $\text{LiAlH}_4\text{-THF}$. We have shown that LiCl function as an electro-catalytic additive in a cyclic process that increases the current. This process lead to a higher cell efficiency and higher amount of alane produced.

Analysis from the DOE Hydrogen Storage Team and has shown that the main energy losses in the production of alane will be the energy required to run the vacuum pump during product separation. Therefore, a pressurized solvent system (similar to work reported earlier by Shane et al. on LiAlH_4 [9]) was developed to increase the energy efficiency of alane production and purification. Figure 4 outlines the concept for alane synthesis using a system with pressurized DME. The DME solvent is polar, aprotic and has good safety characteristics. Using this method, alane can be purified and crystallized just through the release of the DME solvent from the system. X-ray diffraction data from alane produce in DME shows a relatively pure crystalline alpha phase.

Conclusions and Future Directions

- Work with industrial partners to lower the cost of alane production for use as high energy density storage materials in near term portable power systems.
- Perform electrochemical production of alane and alane adducts in a pressurized solvent environment and demonstrate production of α -alane using these methods.

Start Date: September 30, 2008

Projected End Date: September 30, 2011

Technical Targets

The objective of this project is to achieve tunable thermodynamics and/or kinetics by confining metal hydrides within the chemically and geometrically well-defined pores of templates such as metal-organic frameworks (MOFs) and porous carbons, thus allowing faster H₂ desorption at a lower temperature than bulk. The project addresses the following DOE technical target (Table 1), as outlined in the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

TABLE 1. DOE Targets for Hydrogen Storage

Parameter	DOE 2010 Target	Project Status
Maximum Delivery Temperature	85°C	Tunable kinetics demonstrated for nano-confined NaAlH ₄ and LiBH ₄ . Size-dependent desorption enthalpy observed for NaAlH ₄ .

Fiscal Year (FY) 2011 Objectives

- Achieve tunable thermodynamics for high-gravimetric-capacity metal hydrides by creating and stabilizing nanoparticles with controlled size, composition, and properties.
- Develop synthetic routes for reactive metal nanoparticles within crystalline nanoporous materials and block copolymer templates.
- Systematically probe the effects of size and composition to determine the onset and extent of nanoscale effects on the thermodynamics and kinetics of hydrogen sorption.
- Benchmark theoretical approaches to modeling the thermodynamics of metal hydride nanoparticles, and develop computational tools to guide synthesis.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (C) Efficiency
- (P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

FY 2011 Accomplishments

- Demonstrated size-dependent thermodynamics for LiBH₄ infiltrated into porous carbon templates: the bulk orthorhombic-to-hexagonal phase change is not observed, no melting transition occurs, and the material is amorphous.
- Showed that nano-confined NaAlH₄ thermodynamics are tunable: reaction to form the stable intermediate Na₃AlH₆ is not observed. The enthalpy of H₂ desorption for the one-step decomposition to form NaH, Al, and H₂ is size dependent, consistent with theoretical results.
- Nano-confined NaAlH₄ decomposes more than an order of magnitude faster than bulk hydride.
- Predicted that (MgAlH₅)_n clusters are destabilized relative to MgH₂ and that compositional tuning of ΔH° is feasible.

Introduction

Some of the most attractive hydrogen storage materials, such as MgH₂, AlH₃, and LiBH₄, have unfavorable desorption thermodynamics and are either too stable (e.g. MgH₂ and LiBH₄) or too unstable (e.g. AlH₃) in bulk form to be of use for vehicular transport applications. However, recent theoretical and experimental results indicate that decreasing particle size can substantially reduce the stability of metal hydrides, leading to lower desorption temperatures. The key challenges that must be addressed

are to: 1) develop synthetic routes that provide controlled size and composition; 2) stabilize particles over time; and 3) develop computational tools to guide synthesis that can accurately address particle sizes spanning the micro-to-meso length scales. This project addresses all three challenges and, if successful, will create for the first time nanoscale hydrogen storage materials with tailorable composition and size compatible with fuel-cell materials over a wide range of operating temperatures.

Approach

We are using highly ordered, chemically tailorable nanoporous templates to create particles ranging in size from <1 nm to 20 nm, the critical size range at which nanoscale effects are anticipated. These templates are infiltrated with hydride precursors or hydrides themselves, using mild synthetic routes that eliminate template degradation. The resulting template-stabilized nanoparticles are characterized to determine particle size, composition, and desorption thermodynamics and kinetics. Validated computational modeling tools guide synthesis. This approach allows nanoparticle dimensions and hydride composition to be systematically varied, enabling the effects of nanoscale dimensions on hydride thermodynamics to be determined.

Results

Tunable Thermodynamics and Kinetics for Nano-Confined NaAlH_4

NaAlH_4 is perhaps the most thoroughly characterized hydride in terms of its thermodynamics and kinetics of H_2 desorption. As such, it is an excellent test case for determining the influence of size and confinement environment on hydride thermodynamics and kinetics. This year, we performed detailed measurements to determine both ΔH° and E_a , using an infiltrated MOF with 1.3-nm pores and a melt-infiltrated porous carbon with uniform 4-nm diameter pores. The results show that both thermodynamics and kinetics are modified and suggest that these properties can be tuned by adjusting pore size.

Our experiments show that confining NaAlH_4 to ≤ 4 nm pores has several effects on the reaction. The H_2 desorption data for particles in the 1.3-nm MOF template (Figure 1) display evidence of at least two distinct reaction zones: a thermodynamic vapor-solid equilibrium at low reaction extent (<110°C) and a kinetically limited regime at temperatures up to 170°C. We characterized the reactant-product mixture obtained from vapor-solid equilibrium regime, using the 1.3-nm templated hydride, and see no evidence of Na_3AlH_6 . This shows that under these conditions the reaction proceeds by a one-step process, which is different from the bulk behavior.

We also measured the temperature dependence of the H_2 vapor pressure to determine the heat of desorption (ΔH°).

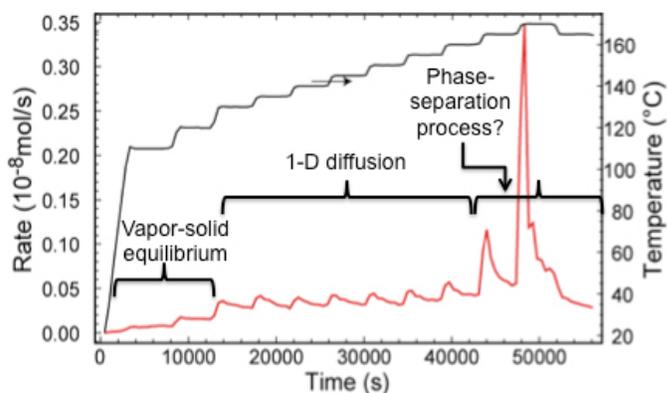

FIGURE 1. Hydrogen desorption from NaAlH_4 infiltrated into the 1.3-nm pores of the MOF Cu-BTC. Light-gray line indicates the temperature profile of the experiment, in which H_2 was detected using a molecular-beam mass spectrometer.

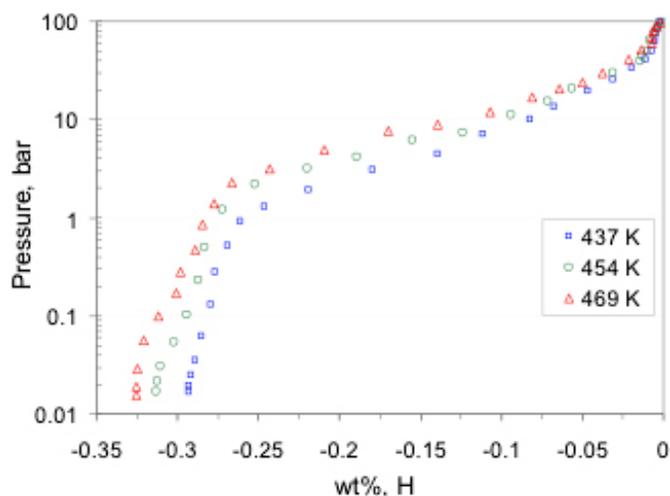

FIGURE 2. Pressure-Concentration-Temperature (PCT) Curves of NaAlH_4 Confined in 4-nm Nanoporous Carbon

The pressure-composition isotherms of NaAlH_4 confined in 4-nm nanoporous carbon (Figure 2) are not completely flat and exhibit only one plateau, whereas bulk Ti-catalyzed NaAlH_4 exhibits two flat plateaus corresponding to a two-step mechanism that forms first Na_3AlH_6 followed by NaH formation. Hydride confined to 4-nm pores has a lower ΔH° than bulk (Table 2), while hydride confined to the 1.3-nm pores of the MOF actually has a higher ΔH° . The increased ΔH° for small particles agrees with the results of both our nano-prototype electrostatic ground state/density functional theory (DFT) calculations and with a report in the literature for NaAlH_4 within a porous (0.5–4 nm) carbon template [1]. This is the first quantitative evidence that hydrogen desorption thermodynamics can be tuned by controlling particle size. However, our results below concerning LiBH_4 show that this behavior is very specific to the particular hydride.

TABLE 2. Comparison of Measured ΔH° and E_a

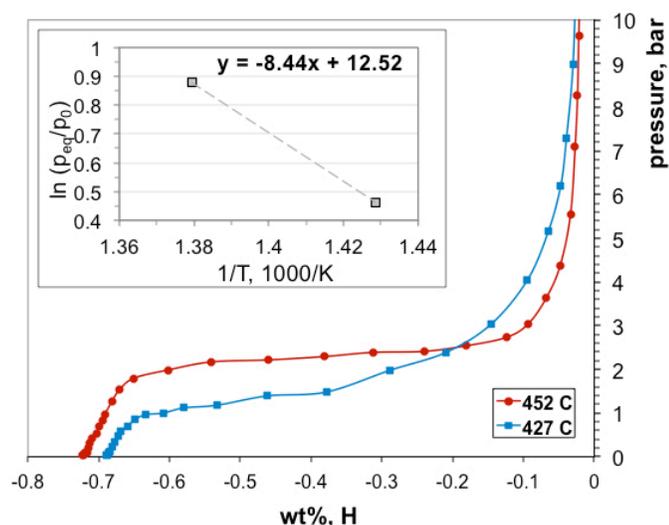

Reaction	1.3 nm ^a		4 nm ^b		Bulk ^c	
	ΔH°	E_a	ΔH°	E_a	ΔH°	E_a
$\text{NaAlH}_4 \rightarrow \text{NaH} + 0.33\text{Al} + 1.5\text{H}_2$	47	47–53	35 ± 10	--	40	121
$\text{NaAlH}_4 \rightarrow 0.33\text{Na}_3\text{AlH}_6 + 0.67\text{Al} + 1.0\text{H}_2$	N/A	N/A	N/A	N/A	37	118

^aCu-BTC (MOF) template, solution infiltrated; ^bPorous carbon, melt-infiltrated; ^cUncatalyzed; N/A – not applicable.

The behavior of the 1.3-nm NaAlH_4 (Figure 1) nanoparticles in the kinetic regime is consistent with a one-dimensional diffusion model. The measured activation energy (Table 2) is considerably smaller than the uncatalyzed bulk value and somewhat smaller than the value previously reported for 2–10 nm NaAlH_4 particles on carbon nanofiber [2]. This trend indicates that size has a stronger effect on the desorption kinetics than the chemical environment of the template. The activation energies obtained using the MOF template and the carbon nanofibers are rather similar, although the chemical environments are different; in fact, it is not clear that NaAlH_4 is actually “confined,” but rather is “supported” on the surface of the carbon nanofibers, differentiating this template even further from the enclosed pores of the MOF.

Controlling the Decomposition Pathway of LiBH_4 via Confinement in Highly Ordered Nanoporous Carbon

We find that nanoscale LiBH_4 melt-infiltrating into 4-nm nanoporous carbon (NPC; 4-nm hexagonally packed cylindrical pores) is kinetically destabilized relative to bulk, but the thermodynamics are unchanged relative to bulk. The PCT for LiBH_4 @NPC were measured at three different temperatures (Figure 3). The PCT has a clearly identified plateau region, from which we obtain ΔH° and entropy ΔS°

**FIGURE 3.** PCT Curves of LiBH_4 @NPC Measured at Three Different Temperatures

of $70 \text{ kJ mol}^{-1} \text{H}_2$ and $104 \text{ J K}^{-1} \text{mol-H}_2^{-1}$, respectively. This strongly suggests that in contrast to NaAlH_4 , confinement, or particle size alone, has no effect on the thermodynamics of LiBH_4 decomposition. This result may be somewhat surprising in light of the many theoretical studies on nanoscale materials such as MgH_2 and other simple saline hydrides. It suggests, therefore, that decomposition of this hydride is thermodynamically limited by the strength of the B-H bonds in the BH_4 anion, which Fourier transform infrared data (not shown) indicate are similar to those of the bulk.

The benefits of incorporating LiBH_4 into ordered 4-nm pore frameworks are twofold. First, the desorption behavior up to six cycles is clearly reversible [3]. Second, the release of diborane per gram of infiltrated LiBH_4 can be dramatically reduced compared with both bulk hydride and hydride confined in 15 nm or 9 nm NPC. These observations clearly show that confining hydrides within a nanoporous material can change a material that is unusable in bulk form to one that could have practical utility in some applications. Importantly, the differences between the behavior of NaAlH_4 described above and LiBH_4 in these hard-carbon frameworks indicate that the interactions with the framework are hydride dependent, suggesting that a proper choice of hydride and framework chemistry can lead to a storage material having the desired properties.

Computational Modeling of Hydride Nanoparticles

The narrow range that ΔH° can assume for a successful vehicular hydrogen storage material ($20\text{--}50 \text{ kJ mol}^{-1}$) lies roughly between two physical bounds: chemical bonds that are usually too strong, and hydrogen bonds that are usually too weak. One strategy for modulating ΔH° is to use compositional tuning in conjunction with nanoscale confinement. Our prior work demonstrated that MgH_2 nanoclusters are destabilized, but only at extremely small sizes (<5 formula units). Here, we describe high-accuracy fixed-node diffusion quantum Monte Carlo (DMC) calculations to evaluate the change in energy for the removal of H_2 from mixed Mg-Al clusters, which we hypothesized would have stability intermediate between MgH_2 and AlH_3 . Our results show that this is indeed the case and show that ΔH° values between $20\text{--}50 \text{ kJ mol}^{-1}$ can be obtained.

The DMC calculations confirm our hypothesis. First, they indicate that mixed Mg-Al nanoclusters are stable, i.e., ΔE is greater than zero (Figure 4). Second, the desorption

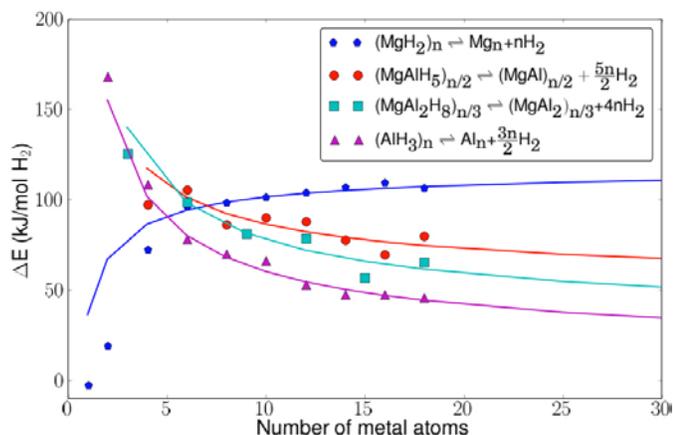

FIGURE 4. Alloying Mg and Al at the nanoscale results in particles with intermediate hydrogen desorption energy and enhanced stability over bulk. The hydrogen desorption energy is a function of size. All data are from DMC calculations.

energy of these clusters is intermediate between the pure materials. For example, the $\text{MgAl}_2/\text{MgAl}_2\text{H}_8$ stoichiometry in addition to the $\text{MgAl}/\text{MgAlH}_5$ stoichiometry, as is evident in Figure 4. This can be understood from the fact that the hydrides are ionic and the pure metallic clusters have metallic bonding. As a result, there are no bond networks to create nonlinear effects as a function of size. There are only magic numbers in the binding energy of the metals for small sizes, but this effect diminishes with increasing size and does not change the overall trend.

The size range at which ΔE is predicted to reach a value between 20 kJ mol^{-1} and 50 kJ mol^{-1} range is given in Table 3. From the DMC results, the estimated size range for the MgAl alloy is from ~ 74 metal atoms up to the bulk, whereas Al alone has only a very small range between 10 and 40 atoms. This confirms that alloying can significantly alter the size range in which nanoparticles have the desired desorption energies. However, the effects of errors in DFT predictions are very evident here. The estimated size ranges are dramatically different for the various functionals. It is thus clear that the accuracy of the method used to obtain ΔE is critical.

TABLE 3. Estimated Size Range with ΔE in the Range $20\text{--}50 \text{ kJ mol}^{-1}$

	DMC	B3LYP	LDA	M06	PBE
MgAl	74 – ∞	Never	44 – ∞	Never	16 – ∞
Al	10 – 40	17 – 2,000	13 – 100	15 – 80	7 – 20

Conclusions and Future Directions

- We demonstrated that size-dependent effects on both the thermodynamics and kinetics of hydrogen desorption from metal hydrides are possible as a result of nanoconfinement.

- Our results show that 1–4 nm NaAlH_4 nanoclusters undergo single-step decomposition with fast kinetics, effectively increasing the storage capacity by 50% under fuel cell conditions.
- We predict that MgH_2 H_2 desorption thermodynamics can be shifted to a more favorable thermodynamic regime by creating Mg-Al-H nanoclusters.
- During the remainder of the project, we will develop a synthetic method to make mixed Mg-Al-H nanoclusters, and will complete H_2 desorption measurements for NaAlH_4 , MgH_2 , LiBH_4 , LiNH_2 , and $\text{Ca}(\text{BH}_4)_2$ in MOFs and nanoporous carbons.

E-mail: Ned.Stetson@ee.doe.gov

Project Start Date: June 2010
Project End Date: Project continuation and
direction determined annually by DOE.

- Specific energy: 1.5 kWh/kg
- Energy density: 0.9 kWh/L
- Cost: \$4/kWh net

FY 2011 Accomplishments

- Uptake, neutron powder diffraction (NPD), and neutron vibrational spectroscopy (NVS) measurements of H₂ in Fe-MOF-74 indicate even closer contacts between H₂ molecules compared to other MOF-74 variants.
- Robust yet low uptakes of H₂ in model zeolite compounds were characterized by NPD and NVS, marking the first time that H₂ adsorption sites were identified in a zeolite.
- Surfaces areas of synthesized amorphous metal-organic gels were found to be comparable to those of crystalline parent materials.
- NVS measurements of spillover hydrogen on activated carbons indicate excess-hydrogen modes at room temperature.
- The structure of the newly synthesized mixed-metal amidoborane Na₂Mg(NH₂BH₃)₄ was solved by X-ray diffraction (XRD), characterized by NVS, and found able to release 8.4 wt% hydrogen with significantly less toxic gases.
- NVS measurements of novel complex borohydrides NaB₃H₈, NH₄B₃H₈, and NH₃B₃H₇ indicated only limited agreement with density functional theory (DFT) phonon calculations, suggesting that the DFT descriptions of the bonding interactions need to be improved.
- Quasielastic neutron scattering (QENS) measurements of Cs₂B₁₂H₁₂ allowed us to characterize, in detail, the rotational dynamics of the B₁₂H₁₂²⁻ anions, a by-product of borohydride dehydrogenation.
- QENS and NVS measurements of LiBH₄ sequestered in 2-nm-pore carbon scaffolds indicated that the LiBH₄ is disordered and exhibits significant non-bulk-like behavior with respect to BH₄⁻ rotational dynamics.

Fiscal Year (FY) 2011 Objectives

- Support the DOE-funded hydrogen storage projects by providing timely, comprehensive characterization of materials and storage systems using state-of-the-art neutron methods.
- Direct partner synthesis efforts based on the understanding gained through the use of these methods.
- Demonstrate the fundamental characteristics of useful hydrogen storage materials.

Technical Barriers

This project addresses the following technical barriers from the Storage section (3.3) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

Technical Targets

NIST provides important materials metrologies for Center partners using neutron-scattering measurements to understand and characterize hydrogen-substrate interactions of interest in a variety of materials ranging from H₂ adsorbed in nanoporous materials to H chemically bonded in complex-hydride materials. Insights gained from these studies will be applied toward the design and synthesis of hydrogen storage materials that meet the following DOE 2011 storage targets:

Introduction

To obtain the DOE levels of hydrogen storage in a timely manner, it is imperative that trial-and-error testing of materials be avoided. Thus, the focus must be upon the rational design of new systems. From a thorough understanding of the physics and chemistry that governs the hydrogen-substrate interactions, we will be able to make a more concerted effort to push the frontiers of new materials.

The key to improving materials is a detailed understanding of the atomic-scale locations of the hydrogen and determining how it gets there and how it gets out. Neutron scattering is perhaps the premier technique for studying hydrogen and the NIST Center for Neutron Research is currently the leading facility in the U.S. for studying these materials.

Approach

NIST provides important materials characterization for DOE-funded, hydrogen storage sub-program partners using neutron-scattering measurements to probe the amount, location, bonding states, dynamics, and morphological aspects of (i) molecular hydrogen in carbon-based materials such as polymers, metal organic frameworks (MOFs), and carbonaceous materials such as carbon nanohorns, and (ii) atomic hydrogen in a variety of complex hydride materials including those containing boron and nitrogen, as well as their intermediates and by-products. NIST works directly with DOE and other partners that produce novel hydrogen storage materials to analyze the most promising samples and to help determine and resolve the fundamental issues that need to be addressed.

Results

MOFs have recently come under intense investigation for gas storage and separation applications, owing to their high internal surface areas, convenient modular synthesis, and chemical tenability. Previously, we have reported a number of MOFs in which removal of a solvent molecule from the coordination sphere of the framework metal cations yielded strong adsorption sites for H_2 . One possibility for improving the isosteric heat of adsorption within this structure type would be through constructing the structure with M^{2+} cations having a smaller radius. The greater charge density of the exposed metal cations on the framework surface should then be more effective at inducing a dipole in H_2 , leading to stronger binding. In collaboration with University of California, Berkeley, the M^{2+} -MOF-74 (M^{2+} =Mg, Co, Ni, Zn) series of MOFs was extended to include Fe-MOF-74. With a high surface area measured at $1,300 \text{ m}^2/\text{g}$, and five-fold coordinated metal ions decorating the inside of the one-dimensional hexagonal pores, we have expanded the family as well as allowed ourselves to probe the extent of hydrogen interactions with the system incorporating magnetic ions. Neutron diffraction reveals three different adsorption sites as a function of increased loading (see Figure 1). The D_2 - Fe^{2+} interaction is characterized by a relatively close 2.46 \AA distance, with the higher loading sites interacting at a short van der Waals distance of 3.22 \AA to 3.24 \AA . This results in even closer contacts between hydrogen molecules, providing a very dense monolayer packing in the pore with inter-molecular distances from 2.86 \AA to 3.07 \AA . Further studies are ongoing.

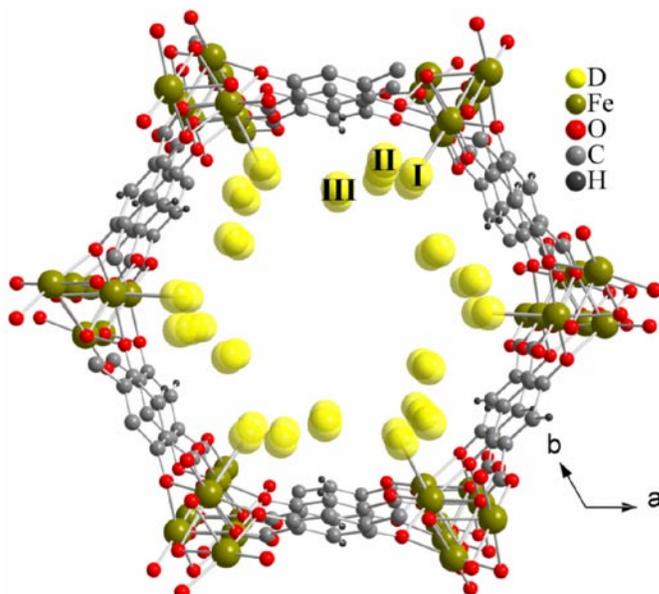

FIGURE 1. Neutron Diffraction Allows the Identification of Three Different D_2 Adsorption Sites in Fe-MOF-74

In collaboration with University of Maryland and University of Delaware, NPD and NVS measurements of hydrogen adsorption in Cu-SSZ-13 zeolite located two binding sites, one at the 8-member ring window and another near the Cu^{2+} cation. The Cu^{2+} site is not occupied at low hydrogen loadings but fully occupied at moderate pressures. The H_2 adsorption for the Cu^{2+} -exchanged zeolite is enhanced (by $\approx 4\%$ at 1 bar) over H-SSZ-13 due to the extra Cu^{2+} binding sites. At 77 K and 1 bar, the mass ratios of adsorbed H_2 /zeolite for H-SSZ-13 and Cu-SSZ-13 are relatively low, 1.38 g/kg and 1.48 g/kg , respectively.

In collaboration with Lawrence Livermore National Laboratory, we additionally attempted to synthesis amorphous MOF gels in an effort to further increase MOF surface areas and micropore volumes. Reaction of iron nitrate and benzenetricarboxylic acid in ethanol produced the desired short-range-ordered material, but with a low surface area of $280 \text{ m}^2/\text{g}$. The surface area increased to $510 \text{ m}^2/\text{g}$ after annealing to 120°C , and was further improved to $1,300 \text{ m}^2/\text{g}$ upon drying in supercritical CO_2 . This is still a relative low surface area and would need to be improved upon. For this material, the increasing surface area is not reflected in the hydrogen uptake increases expected and speculate that the access for hydrogen is unhindered relative to nitrogen.

In collaboration with University of Maryland and General Motors, the first example of a mixed-metal amidoborane $Na_2Mg(NH_2BH_3)_4$ was successfully synthesized, and its structure (Figure 2) and bonding were characterized by XRD and NVS [1]. It forms an ordered arrangement in cation coordinations, i.e., Mg^{2+} bonds solely to N⁻ and Na^+ coordinates only with BH_3^- . Compared

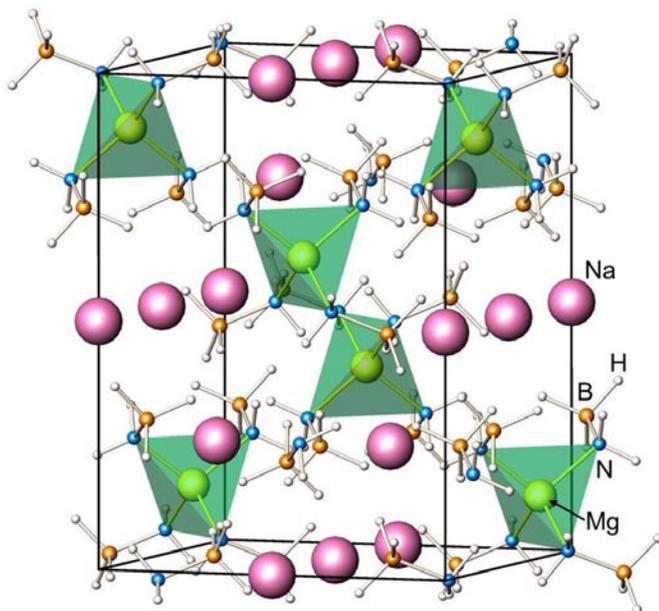

FIGURE 2. The Structure of $\text{Na}_2\text{Mg}(\text{NH}_2\text{BH}_3)_4$

to ammonia borane and monometallic amidoboranes, $\text{Na}_2\text{Mg}(\text{NH}_2\text{BH}_3)_4$ can release 8.4 wt% hydrogen with significantly less toxic gases, such as ammonia and borazine, and no detectable diborane. This study suggests that hydrogen-release properties of amidoboranes can be rationally and significantly improved by tuning the atomic interactions and thus producing more desired structures through the formation of mixed-metal amidoboranes.

In collaboration with Ohio State University, we used NVS to characterize the bonding associated with the novel lightweight borohydride materials NaB_5H_8 , $\text{NH}_4\text{B}_3\text{H}_8$, and $\text{NH}_3\text{B}_3\text{H}_7$. The limited agreement between the vibrational spectra and DFT phonon calculations suggested that the DFT descriptions of some weak bonding interactions present may be somewhat lacking. This reinforces the reality that there is a need to develop more accurate DFT descriptions of weak bonding potentials, such as associated with hydrogen-bonding interactions.

In collaboration with University Missouri-St. Louis, a comparison was made between LiBH_4 sequestered inside 2 nm ordered pores of a carbon scaffold [2] and bulk LiBH_4 . Using QENS, the relative mean square displacement of H atoms determined from a neutron fixed-window scan shows that the onset of BH_4^- rotational motion occurs ~ 100 K lower for the nanoconfined material than for bulk LiBH_4 . From NVS measurements (Figure 3), it is clear that the nanoconfined LiBH_4 exhibits a much broader BH_4^- torsion peak (at 52 meV or 419 cm^{-1}) compared with bulk LiBH_4 . In contrast, the BH_4^- bending modes are little perturbed by nanoconfinement. Hence, although the bending modes are fairly insensitive to near-neighbor interactions, NVS indicates a large inhomogeneity in the rotational potentials experienced by the nanoconfined LiBH_4 . Overall, compared

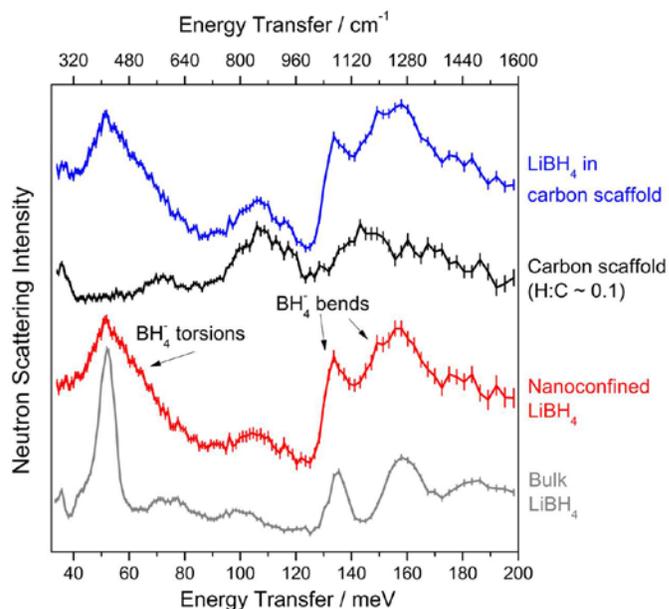

FIGURE 3. NV spectra of nanosequestered LiBH_4 + carbon scaffold (with 2 nm pores), the corresponding bare carbon scaffold, and bulk LiBH_4 . The spectrum of the nanosequestered LiBH_4 with the carbon scaffold spectrum subtracted is also shown.

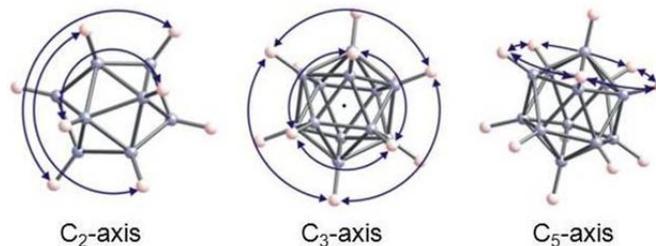

FIGURE 4. Possible Rotational Jumps of the $\text{B}_{12}\text{H}_{12}^{2-}$ Anion with Respect to its Local Axes of Symmetry

to prior results using carbon scaffolds with pores larger than 4 nm, nanoconfinement in the smaller 2 nm pores appears to more dramatically perturb the bulk thermodynamic properties of LiBH_4 .

In collaboration with Sandia National Laboratories and University of Maryland, we used QENS to investigate the rotational dynamics of $\text{B}_{12}\text{H}_{12}^{2-}$ anions (Figure 4), which are by-products of borohydride dehydrogenation. Elastic incoherent structure factor data for the prototypical $\text{Cs}_2(^{11}\text{B})_{12}\text{H}_{12}$ were measured from 430 K to 530 K [3], suggesting that the $\text{B}_{12}\text{H}_{12}^{2-}$ anion (encaged in a cube defined by eight Cs^+ cations) changes from uniaxial (C_3 -axis or C_5 -axis) rotational jumps near 430 K to a combined mechanism involving, on average, independent two-axis (C_3 -axis and/or C_5 -axis) rotational jumps between 480 K and 530 K. Alternatively, if one assumes that the anions are undergoing temperature-dependent rotational trapping, then

the elastic incoherent structure factor is also consistent with a jump model involving a temperature-dependent mobile fraction of anions statistically tumbling between discrete crystallographic sites.

Conclusions and Future Directions

- Neutron methods have provided crucial, non-destructive characterization tools for the DOE Hydrogen Storage sub-program.
- Fe-MOF-74 behaved similarly to other MOF-74 variants with respect to H₂ adsorption sites, with a relatively closer H₂-M²⁺ distance compared to other larger-cation variants.
- The observed H₂-Cu²⁺ interactions in Cu-SSZ-13 zeolite illustrate the need to better understand the relationship between accessible ions and hydrogen-storage characteristics in porous storage materials.
- The specific surface areas of synthesized amorphous metal-organic gels could not be enhanced relative to their crystalline parent materials.
- We synthesized the first mixed-metal amidoborane, one of a class of tailored compounds that may potentially have more favorable cycling behavior for hydrogen storage.
- The limited agreement between DFT phonon calculations and NV spectra for novel borohydride compounds reflects the need for better DFT descriptions of weak bonding interactions.
- We continued to characterize various aspects of nanoconfinement in an attempt to understand its effect on the hydrogen cycling of LiBH₄ and indeed observed more pronounced non-bulk-like effects as the pore size was decreased to 2 nm.
- We characterized the rotational dynamics of B₁₂H₁₂²⁻ anions in the prototypical Cs₂B₁₂H₁₂ compound. Ongoing work will investigate the dynamics of this anion in the lighter alkali-metal variants, Li₂B₁₂H₁₂ and Na₂B₁₂H₁₂.
- We will continue to support the DOE Hydrogen Storage sub-program where needed.

Contract Number: DE-FG36-08GO18143

Project Start Date: September 1, 2008

Project End Date: March 31, 2012

Technical Targets

This project is developing new liquid phase materials for hydrogen storage that can be readily regenerated. Insights gained from these studies will be applied toward the design and synthesis of hydrogen storage materials that meet the following DOE 2015 hydrogen storage targets:

- Specific energy: 1.8 kWh/kg (5.5 wt%)
- Energy density: 1.3 kWh/L (4.0 vol%)

FY 2011 Accomplishments

- Synthesized the parent six-membered fully charged fuel of Material System (1) and partially charged parent BN-indole Material System (7).
- Formulated N-H (1), N-tBu (1'), and N-Me (1'') materials as liquids.
- Experimentally determined the energetic landscape of Material System (1) and provided a direct comparison with the computationally predicted values.
- Developed catalysts and conditions to optimize release of H₂ from Materials System (1).

Fiscal Year (FY) 2011 Objectives

The objective of this project is to develop novel boron-nitrogen heterocycles as liquid-phase hydrogen storage materials with storage capacities and thermodynamic properties that have the potential to lead to rechargeable systems capable of meeting DOE targets. We seek to:

- Develop new materials that:
 - are structurally well-defined along the desorption/absorption processes
 - exhibit appropriate enthalpy of H₂ desorption
 - are liquids at operating temperatures
 - possess high H₂ storage capacities
- Identify catalysts that will release hydrogen from these materials at temperatures <200°C.
- Develop conditions that will readily recharge the spent fuel.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

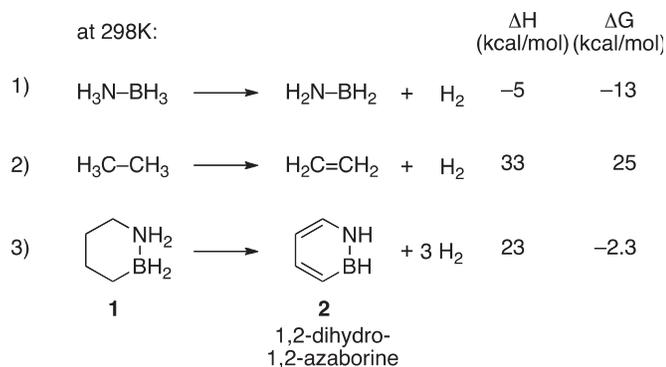

- (A) System Weight and Volume
- (C) Efficiency
- (E) Charging/Discharging Rates
- (R) Regeneration Process

Introduction

Hydrogen storage is a vital component in the development of a hydrogen-based energy infrastructure. Boron nitrogen containing compounds, e.g., ammonia borane (H₃N-BH₃ or AB), have attracted much attention as chemical H₂ storage materials because of their high gravimetric hydrogen densities and fast kinetics of H₂ release. This project is developing structurally well-defined liquid carbon-boron-nitrogen (CBN) hydrogen storage materials (i.e., heterocycles containing carbon, boron, and nitrogen) that have the potential to be reversibly regenerated using molecular hydrogen. A liquid phase, hydrogen storage system that can be regenerated using molecular hydrogen is highly desired for many reasons, including versatility, lower cost and improved efficiency, and durability. Such a storage material will allow on-board hydrogen storage. It can also be applied as an off-board energy carrier for vehicle and stationary applications that takes advantage of the existing liquid fuels infrastructure.

Approach

In order to accomplish reversibility, neutrality in free energy of the hydrogen release process (i.e., $\Delta G \sim 0$ kcal/mol) at the operating temperature is pivotal. The dehydrogenation of AB is exergonic by -13 kcal/mol at 298 K (eq 1). In contrast to AB, the dehydrogenation of

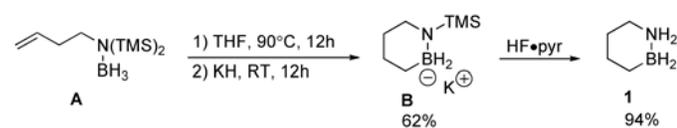

its isoelectronic organic counterpart, ethane (CH_3-CH_3), is endergonic by +25 kcal/mol (eq 2). The coupling of endothermic dehydrogenation from CC with exothermic dehydrogenation from BN in a cyclic six-membered framework could lead to a reversible H_2 storage system. Indeed, high-level computational analysis indicates that the release of H_2 from CBN heterocycles such as **1** has favorable overall thermodynamics conducive to reversibility, (e.g., see eq 3). The potential for reversible hydrogen release/uptake and the relatively high gravimetric hydrogen density of CBN heterocycle materials (e.g. 7.1 wt% for **1**) render their preparation and development an important goal. This project is investigating several CBN heterocycle materials for H_2 storage applications using a synergistic theoretical and experimental approach. Synthesis will be a crucial component of this project given the relatively unexplored nature of these CBN heterocycles. The structurally well-defined nature of these CBN heterocycle materials will facilitate their characterization and mechanistic investigation of the proposed desorption/absorption processes.

Results

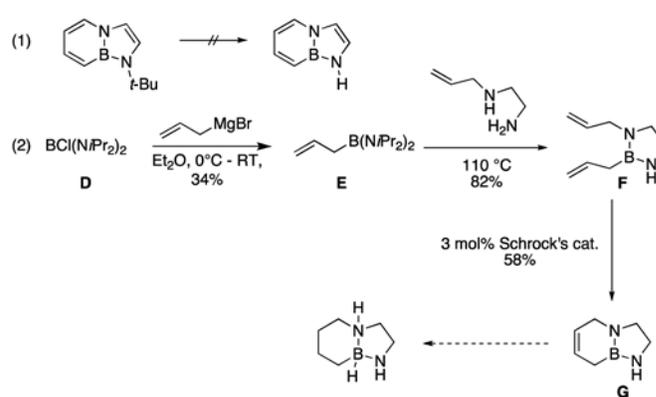

Synthesis of Parent CBN Heterocycle Materials

We have successfully synthesized the parent charged fuel, **1**, illustrated in Scheme 1. From the *N*-bis-protected homoallylic amine BH_3 adduct **A**, refluxing in tetrahydrofuran (THF) followed by treatment of the crude product with KH furnished the potassium salt **B** in 62% yield. Subsequent treatment with 2 equivalents of HF-pyridine afforded **1** in 94% yield.

In Phase I of this project we developed a synthesis of the *N*-*t*-Bu derivative of the spent fuel of Material (7). However, we found that it was challenging to remove

SCHEME 1. Synthesis of Parent Fuel Material System (1)

SCHEME 2. Progress toward the Synthesis of the Parent CBN Material System (7)

the *t*-Bu group from nitrogen to generate the parent unsubstituted fuel system (Scheme 2, eq 1). In Phase II, we developed a new synthetic route to (7) without the use of protecting group strategies (Scheme 2, eq 2). Treatment of chloroborane **D** with allyl magnesium bromide produced allylborane **E**. Condensation of **E** with *N*-allylethylene diamine furnished intermediate **F**, which upon ring closing metathesis produced the bicyclic material **G** without a protecting group on nitrogen. Intermediate **G** is a partially spent fuel intermediate of System (7), and we envision that it will serve as a very useful compound for the preparation of the fully charged fuel and other partially spent fuel of this system. Based on preliminary thermodynamic analysis, we believe that the challenges associated with System (7) are similar to those of System (1). Thus, we conclude that it would be most prudent to focus on System (1).

Formulation of CBN Heterocycles as Liquids

We formulated the parent fully charged fuel **1** and the *N*-substituted fuels **1'** and **1''** as liquids. Melting points and liquid densities were also determined for **1**, **1'** and **1''** (Table 1). Compounds **1** and **1''** are liquids at an

TABLE 1. Formulation of CBN Heterocycles as Liquids

entry	neat material	THF solution	Et ₂ O solution
	mp: 63-63 °C d (kg/L): 0.99 ± 0.05 vol (g H ₂ /L): 70 wt (%): 7.1	sol (g/L): 434 ± 20 d (kg/L): 0.8992 vol (g H ₂ /L): 30.7 wt (%): 3.4	sol (g/L): 346 ± 30 d (kg/L): 0.781 ± 0.02 vol (g H ₂ /L): 24.5 wt (%): 2.2
	mp: 96-98 °C d (kg/L): 0.61 ± 0.07 vol (g H ₂ /L): 25 wt (%): 4.3	sol (g/L): 284 ± 28 d (kg/L): 0.8892 vol (g H ₂ /L): 11.7 wt (%): 1.3	sol (g/L): 84.4 ± 4 d (kg/L): 0.7134 vol (g H ₂ /L): 3.47 wt (%): 0.4
	mp: 72-73 °C d (kg/L): 0.87 ± 0.08 vol (g H ₂ /L): 53 wt (%): 6.1	sol (g/L): 292 ± 5 d (kg/L): 0.8992 vol (g H ₂ /L): 17.8 wt (%): 2.0	sol (g/L): 106 ± 18 d (kg/L): 0.7134 vol (g H ₂ /L): 6.5 wt (%): 0.73

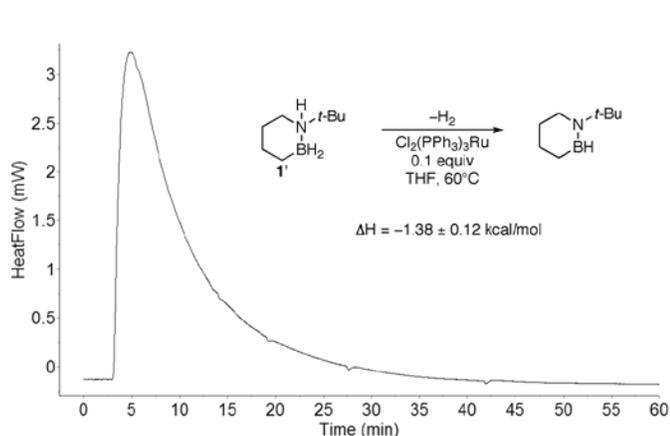

operating temperature of 80°C. Assuming the release of 3 equivalents of H₂, **1** and **1'** exhibit reasonable volumetric and gravimetric capacities (**1**: 7.1 wt%, 70 g H₂/L; **1'**: 6.1 wt%, 53 g H₂/L). At ambient temperatures **1** and **1'** are solids. When solubilizing additives are added to these materials at ambient temperature, the storage capacities are significantly reduced (e.g., see THF solution column). A slurry formulation will result in storage capacities that are between the limiting scenarios (i.e., values between the “neat material” and “THF solution” columns) at ambient temperatures.

Thermodynamics of Hydrogen Uptake and Release

We determined the enthalpy of hydrogenation uptake of the spent fuel material **2'** and the partially spent materials **3'**, **4'**, and **6'** *experimentally* via reaction calorimetry. As part of this process, we determined a lower resonance stabilization energy (RSE = 16.6 ± 1.3 kcal/mol) of our CBN heterocyclic system vs. the corresponding non-BN-containing carbocyclic system (~32 kcal/mol). This is consistent with the observed improved H₂ adsorption ability of CBN materials compared to the carbocyclic system. We were also able to determine the enthalpy of the dehydrogenation from the *N*-*t*Bu model fuel **1'**, catalyzed by 10 mol% Cl₂(PPh₃)₃Ru. A representative heat flow trace is illustrated in Scheme 3 (left). Thus, we have completed the experimental thermodynamic analysis (values in parenthesis) of this material system shown in Scheme 3 (right), which agree reasonably with computationally predicted values (values in brackets).

Development of Catalysts and Conditions to Optimize H₂ Release from **1**

During the course of our investigations of heterocycle **1**, we determined that it readily released two equivalents of H₂ to form trimer **T** in quantitative yield with virtually no formation of potential fuel cell poisons encountered in AB decomposition (e.g., no formation of ammonia or borazine).

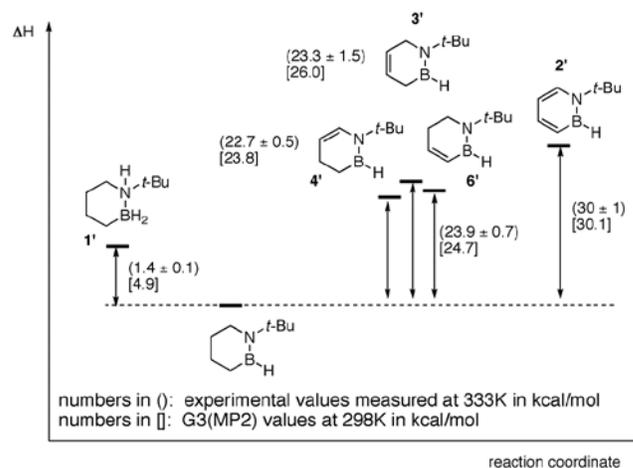

SCHEME 3. Thermodynamics of Hydrogen Release from CBN Material System (**1**)

We screened a variety of hetero- and homogeneous catalysts and conditions to release up to two equivalents of H₂ from **1**. We focused on three main factors: 1) cost of catalyst; 2) catalyst loading; 3) reaction time. In a general procedure, we added a solution of **1** and the catalyst to a J-Young tube, which we sealed and immersed in an 80°C oil bath; reaction progress was monitored by ¹¹B nuclear magnetic resonance. Selected results are listed in Table 2. At 80°C in toluene, many catalysts enabled complete release of two equivalents of H₂ within 60 minutes. The most active catalysts were the rhodium dimers [Cl(cod)Rh]₂ and [(nbd)ClRh]₂ (entries 7 and 8, respectively) which achieved complete trimer formation in 15 minutes at 5 mol% catalyst loading. The low cost, heterogeneous catalyst CoCl₂ (entry 5) enabled the complete release of two equivalents H₂ in 30 minutes at 10 mol% catalyst loading. As a control, we heated a sample of **1** at 80°C in toluene with no catalyst; only starting material was observed after 3 hours.

We measured the amount and rate of H₂ release from **1** with 5 mol% CoCl₂ in toluene using an automated gas burette system. As can be seen from Figure 1, release of

TABLE 2. Optimization Survey of Catalysts and Conditions to Release Two Equivalents of H₂ from the Parent of Material System (**1**)

Entry	Catalyst	Loading (mol%)	Time(min)	% Yield T
1	(dppe)NiCl ₂	10	60	100
2	[Cl(cod)Ir] ₂	10	60	100
3	[(C ₂ H ₂) ₂ ClRh] ₂	10	60	100
4	(PPh ₃) ₂ NiCl ₂	5	60	100
5	CoCl ₂	10	30	100
6	Cp*RuCl ₂	5	30	100
7	[Cl(cod)Rh] ₂	5	15	100
8	[(nbd)ClRh] ₂	5	15	100

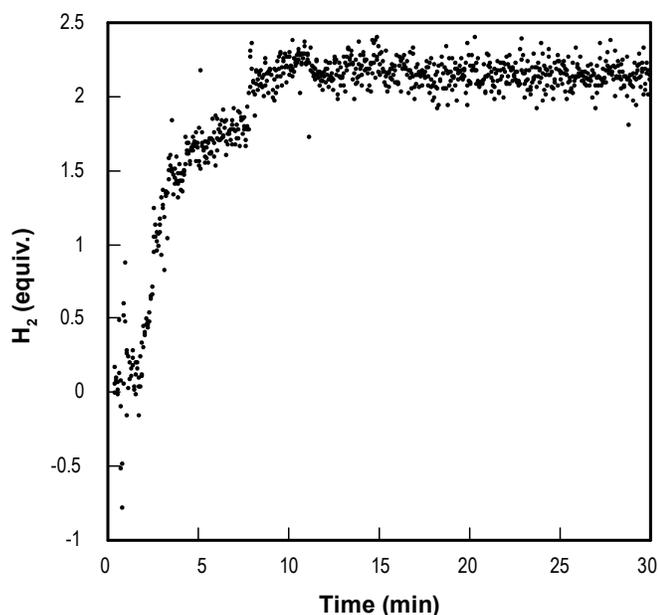

FIGURE 1. Automated Burette Measurement of H₂ Release from **1**

the first equivalent of H₂ from **1** takes place in less than 5 minutes from the instant the reaction flask is submerged in an 90°C oil bath. Trimer formation (coinciding with the release of an additional equivalent of H₂) is complete within 15 minutes of start of the reaction.

Conclusions and Future Directions

In summary, we expanded our synthetic toolbox for the preparation of CBN heterocycles to achieve the synthesis of the parent charged fuel **1**, and N-substituted derivatives **1'** and **1''**. The synthetic availability of CBN heterocycle materials enabled us to experimentally determine thermodynamic data for hydrogen uptake and release from these materials, and optimize conditions for release of H₂ from **1**. We determined that the parent charged fuel **1** readily releases two equivalents of H₂ in a clean and quantitative process to form a well-defined trimer product under mild conditions using a relatively cheap CoCl₂ catalyst. We also demonstrated that compound **1** is thermally stable up to its melting point, and that decomposition with concomitant H₂ release requires a catalyst.

In FY 2012, we will:

- Optimize our current synthesis with regard to scale up of Material System (1).
- Develop/optimize conditions/catalysts for H₂ desorption for Material System (1).
- Improve energy efficiency for recharging the spent fuel of Material System (1).

direction determined annually by DOE

other compositions of AB/ionic liquid (IL) systems; the original concept was developed by the Center's partner, Professor Larry Sneddon of the University of Pennsylvania. This work showed great promise with gravimetric and volumetric capacities as well as charging/discharging rates. Subsequent work at LANL has shown that these IL-based fuels could also be regenerated off board without separating the spent fuel from the IL. Successful development of fluid systems should meet the following DOE 2015 targets:

- Gravimetric Capacity (3 kWh/kg)
- Volumetric Capacity (2.7 kWh/L)
- H₂ Discharge Rate (minimum full flow rate 0.02 H₂ g/s kW)
- H₂ Purity (99.99 % H₂)
- Start-Up Time to Full Flow (5 s @ 20°C, 15 s @ -20°C)
- Shelf life: Loss of Usable H₂ (0.05 g/hr-kg H₂ stored)

FY 2011 Accomplishments

- Thermal stability of the ILs is dominated by choice of the cations/anions that comprise the IL.
- Pt and Rh on alumina were screened for their ability to improve H₂ release and minimize impurities over the base AB/IL systems. No improvement was observed.
- Hydrazine regeneration method was determined compatible with a spent fuel/IL composition
- H₂ release in the presence of dipentylamine or trimethylborazine did not prevent a phase change in the spent fuel.

Fiscal Year (FY) 2011 Objectives

- Develop liquid, pumpable ammonia-borane (AB) fuels with high H₂ content.
- Catalyst development for fluid phase storage materials that increases rate and extent of H₂ release while minimizing impurities.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (B) System Cost
- (C) Efficiency
- (E) Charging/Discharging Rates
- (R) Regeneration Processes

Technical Targets

A significant barrier to the application of off-board regenerable hydrogen storage materials is on- and off-boarding of the fuel and spent fuel, respectively. A fluid, pumpable liquid fuel that remains liquid through dehydrogenation to the spent fuel form is desired for more readily engineered fueling concepts. This project is exploring

Introduction

Chemical hydrogen storage (CHS) involves storing hydrogen in molecular chemical bonds where an on-board chemical reaction is used to release hydrogen. Currently, the resulting spent fuel may be regenerated off-board using chemical processing. CHS provides a diversity of options to enable hydrogen for transportation as well as other niche and stationary applications. Especially attractive, CHS offers the potential for no direct hydrogen handling by the consumer, as well as low pressure storage concepts.

Researchers at LANL and the University of Pennsylvania are focused on the development of liquid AB fuels that integrate with the Hydrogen Storage Engineering Center of Excellence (HSECoE). We are currently studying the formation and stability of these liquid AB materials, as well as catalytic release of hydrogen. Candidate materials can be readily evaluated using resources developed by the HSECoE, including a validation test bed.

Approach

The large number of available ILs necessitates screening criteria. Using thermoanalytical methods (differential scanning calorimetry, thermogravimetric analysis [TGA]), properties of ILs were measured to gauge suitability for HSECoE's systems. To address the issue of H₂ release kinetics and impurity formation, commercially available heterogeneous catalysts were evaluated against the control (uncatalyzed) system. Research at the University of Pennsylvania addressed the phase change issue by dehydrocoupling AB in the presence of dipentylamine, a species known to make a form of spent AB fuel (polyborazylene) soluble in benzene.

Results

Thermal stability is an essential characteristic of any IL used to generate a liquid phase with AB. Using TGA, we have identified trends in cation/anionic choice which govern thermal stability (Figure 1). Further testing of ILs should yield greater confidence in compositional requirements.

To further reduce gaseous impurities and accelerate H₂ release, a selection of commercially available heterogeneous catalysts (Pt, Rh) were evaluated. As can be observed (Figure 2), no substantial change in the rate or extent of H₂ release was observed with these catalysts (only Pt data shown). There was a qualitative reduction in borazine as seen in a flow-through experiment (results not shown), thus achieving one of our two stated goals. We are confident that further catalyst evaluation will result in accelerated H₂ release.

Lastly we endeavored to maintain the liquid phase of AB/IL throughout the dehydrogenation process by using additives. Work at the University of Pennsylvania

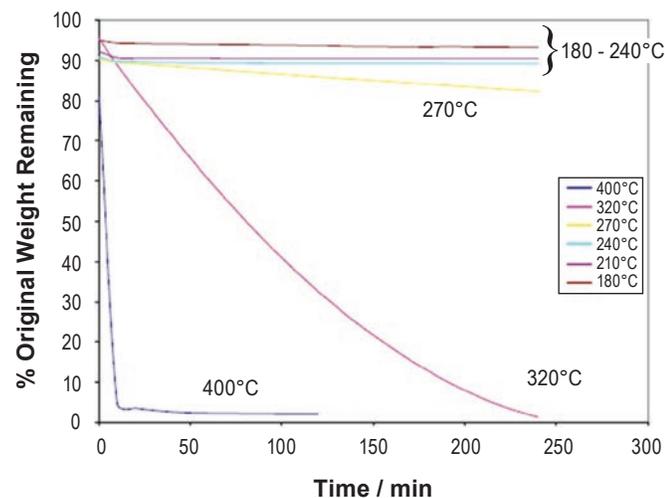

FIGURE 1. Decomposition of an IL assessed by isothermal TGA experiments. This IL shows a wide stability range (starts to decompose at 270°C) and will be used for the HSECoE validation test bed.

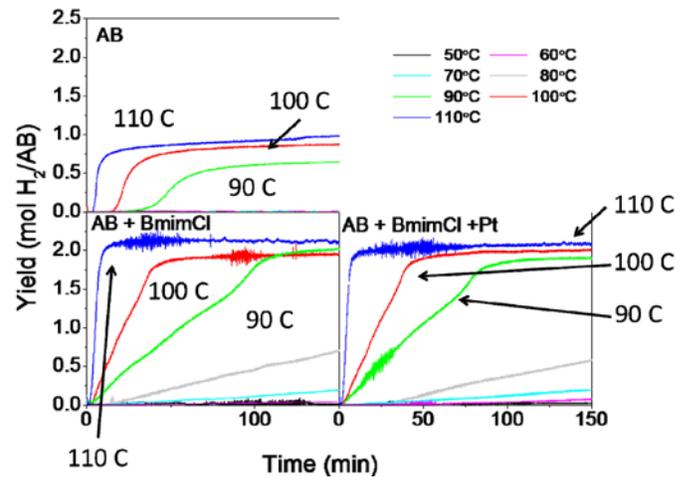

FIGURE 2. Dehydrogenation of AB, AB/IL (BmimCl), and AB/IL + Pt catalyst using an automated buret. The IL has a marked effect on H₂ release and extent relative to pure AB. The addition of the heterogeneous catalyst, however, does not dramatically alter H₂ performance.

had previously identified a reagent, dipentylamine, which could transform polyborazylene (a form of spent AB fuel) into a benzene soluble species [1]. With this knowledge, AB/IL dehydrocoupling was performed in the presence of dipentylamine and alkylated borazines with goal of making the spent fuel more soluble and preventing a phase change. As can be seen (Table 1), neither reagent prevented a phase change.

TABLE 1. Additives used with AB/IL Systems (Bmim – butyl, methylimidazolium, Bmmim – butyl, dimethylimidazolium, Pmim – propyl, methylimidazolium). Neither dipentylamine nor trimethylborazine at a 5% loading altered the state of the final spent fuel (solid in all cases).

IL	Temperature	Additives	Final Physical State
Bmim Cl	85°C	5% Dipentylamine	Solid
Bmmim Cl	85°C	5% Dipentylamine	Solid
Bmim Cl	85°C	5% trimethylborazine	Solid
Pmim I	85°C	5% trimethylborazine	Solid

Conclusions and Future Directions

- Cation/anion selection rules for IL performance (thermal degradation) have been partially identified. Further screening is required to be confident in these generalities. In the future, quantitative solubility of AB and spent fuel will be performed to further guide ionic liquid selection.
- A select group of commercially available noble metal catalysts were evaluated for their ability to accelerate H₂ release and reduce impurity formation. Qualitatively the impurity borazine was reduced in flow-through experiments using heterogeneous platinum catalysts.

Continued catalyst evaluation is planned to meet the DOE targets.

- Regeneration of spent fuel/IL was performed and was generally a success. Characteristics of the IL to yield a more robust process were identified.
- A preliminary survey of additives that were postulated to maintain the liquid phase of AB/IL throughout H₂ release was completed. At the AB loading of 50 wt%, a solid product was obtained after >2 equivalent of H₂ was released indicating that more work is necessary on the spent fuel composition to maintain a fluid, pumpable state for off-boarding of spent fuel. Future work will focus on different alkylborazines and fuel blends which should impart additional solubility on the spent fuel.

FY 2011 Accomplishments

- A highly porous and robust 3,3,4-connected MOF (PCN-80) has been synthesized with a unique octa-topic ligand featuring 90°-angle-dicarboxylate moiety. PCN-80 has Brunauer-Emmett-Teller (BET) and Langmuir surface areas of 3,850 m² g⁻¹ and 4,150 m² g⁻¹, respectively. It exhibits high gas-uptake capacity for H₂ of 4.8 wt% (29 g L⁻¹) at 44 bar and 77 K.
- Porous polymer networks (PPNs) grafted with sulfonic acid (PPN-6-SO₃H) and its lithium salt (PPN-6-SO₃Li) exhibit dramatic increase in isosteric heats of hydrogen-adsorption.
- Highly stable PPNs are synthesized through Yamamoto homo-coupling reaction between tetrahedral monomers. Among those polymers, PPN-4 shows exceptionally high Langmuir surface area of 10,063 m² g⁻¹ (SA_{BET}: 6,461 m² g⁻¹). It also exhibits ultra-high hydrogen storage capacity (8.3 wt% at 55 bar and 77 K).

Introduction

In the past decade, there has been an escalation of interest in the study of MOFs due to their fascinating structures and intriguing application potential. Their exceptionally high surface areas, uniform yet tunable pore sizes, and well-defined adsorbate-MOF interaction sites make them suitable for hydrogen storage. Various strategies to increase the hydrogen capacity of MOFs, such as using pore size comparable to hydrogen molecules, increasing surface area and pore volume, utilizing catenation, and introducing coordinatively unsaturated metal centers (UMCs) have been widely explored to increase the hydrogen uptake of the MOFs. Recently, inelastic neutron scattering and neutron powder diffraction as well as computational studies suggest that the choice of both metal centers and ligands can play an important role in tailoring the gas-framework interactions.

Fiscal Year (FY) 2011 Objectives

- Design, synthesize, and characterize metal-organic frameworks (MOFs) with active metal centers aligned in porous channels and accessible by H₂ molecules.
- Through optimized, cooperative binding, the MOFs are expected to have enhanced affinity to H₂.
- These MOFs can help to reach the DOE 2010 and ultimately 2015 hydrogen storage goal.

Technical Barriers

This project addresses the following technical barriers from the Storage section (3.3.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (P) Lack of Understanding of Hydrogen Physisorption and Chemisorption
- (Q) Reproducibility of Performance

Technical Targets

- The focus of the proposed research is the use of concepts evident in metalloproteins to guide the synthesis of MOFs with gas-adsorption affinity around 15 to 20 kJ/mol for hydrogen.
- The overall objective is to achieve the DOE 2010 and 2015 system goals, primarily the gravimetric and volumetric storage goals, at or near ambient temperatures and moderate pressure for on-board vehicular hydrogen storage (Table 1).

Additionally, those ligands containing phenyl rings have been proved favorable for hydrogen adsorption. MOFs with hydrogen uptake approaching the DOE 2010 gravimetric storage goal under reasonable pressure but cryo-temperature (typically 77 K) were reported. However, the weak interaction between hydrogen molecules and MOFs has been the major hurdle limiting the hydrogen uptake of MOFs at ambient temperature.

Approach

Our strategy to enhance H₂ uptake was as follows: (1) prepared the catenation isomer pair to evaluate the contribution from catenation to the hydrogen uptake of a MOF material. Catenation can be utilized to reduce pore sizes in porous MOFs and has also been explored as an efficient method to improve the hydrogen uptake of MOFs. (2) Synthesized porous MOFs with high hydrogen adsorption capacities based on different coordinatively UMCs. The implementation of coordinatively UMCs into porous MOFs has been considered one of the most attractive ways to improve their affinities to hydrogen. (3) Hydrogen storage studies in MOFs containing nanoscopic cages based on double-bond-coupled di-isophthalate linkers. Those ligands containing phenyl rings in MOFs have been proved favorable for hydrogen adsorption. (4) Design and synthesize porous MOFs based on an anthracene derivative which can provide additional hydrogen binding sites to increase the hydrogen uptake. (5) Obtained stable MOFs with high surface areas by the incorporation of mesocavities and microwindows. (6) Constructed MOFs with “close-packing” alignment of open metal sites, which can increase the number of nearest neighboring open metal sites of each H₂-hosting void in a three-dimensional framework so that they can interact directly with the guests (H₂ molecules) inside the void. (7) Built up porous lanthanide MOFs and studied their potential application in gas adsorption. (8) Prepared an unprecedented linkage isomer pair of MOFs and studied the impact of pore size on H₂ storage capacity in MOFs. (9) Incorporated polyyne unit into MOFs, which has higher H₂ affinity. (10) Design and synthesize PPNs with high chemical stability suitable for further decoration. (11) Incorporated metal ions into PPNs, which can enhance the isosteric heats of hydrogen-adsorption.

Results

In the past year, we have prepared a series of MOFs and PPNs and explored their applications in hydrogen storage. Table 2 shows the comparison of hydrogen uptakes of selected MOFs and PPNs. Next we will discuss in detail the results of H₂ uptakes of these materials.

Functional MOFs Based on MOF-177

As we all know, MOF-177 is a porous material with high surface area (SA_{Langmuir} : 5,640 m² g⁻¹) and high

TABLE 2. Comparison of Hydrogen Uptakes of Selected MOFs and PPNs

Material	ΔH_{ads} (kJ/mol)	H ₂ Adsorption			
		Gravimetric H ₂ Uptake (wt%)	Volumetric H ₂ Uptake (g/L)	T (K)	P (bar)
PCN-26	6.81	2.86	24.7	77	32
PCN-69	8.14	5.20	19.5	77	50
PCN-103(N)	6.60	5.60	25.6	77	40
PCN-103(O)	-	5.40	24.6	77	45
PCN-103(Ch)	-	5.10	26.0	77	50
PCN-80	5.20	4.80	29.0	77	44
PCN-46	7.20	5.31	32.3	77	32
PPN-4	4.0	8.34	28.2	77	55

hydrogen storage (7.0 wt% at 60 bar and 77 K). Our tactics for preparing the functionalized MOF is to construct isostructural MOF-177 by designing a new functional organic ligand with the methyl, amino, hydroxyl and chiral group (Figure 1a). As expected, the four new ligands reacted with zinc salt to form four novel MOFs with isostructural MOF-177 (Figure 1b). Based on the N₂ sorption isotherm, PCN-103(N) has a BET surface area of 4,300 m² g⁻¹ (SA_{Langmuir} : 5,500 m² g⁻¹) and a total pore volume of 1.95 cm³ g⁻¹, which is similar to those results of MOF-177. PCN-103(O) has a BET surface area of 2,866 m² g⁻¹ (SA_{Langmuir} : 4,587 m² g⁻¹), while PCN-103(Ch) a BET surface area of 2,850 m² g⁻¹ (SA_{Langmuir} : 4,144 m² g⁻¹) (Figure 1c). The saturated excess gravimetric H₂ uptake of PCN-103(N) is 5.60 wt% at 40 bar, PCN-103(Ch) has a saturated excess gravimetric H₂ uptake of 5.10 wt% at 50 bar, while PCN-103(O) has a saturated excess gravimetric H₂ uptake of 5.40 wt% at 45 bar (Figure 1d).

A Robust MOF with Flexible Octatopic Ligand

A newly designed flexible octatopic carboxylic acid ligand, tetrakis[(3,5-dicarboxyphenyl)-oxamethyl]methane acid (H₈TDM) has been used to react with CuBr₂ affording an MOF, Cu₄(H₂O)₄(TDM)_xS (PCN-26, S presents non-coordinated solvent molecules). PCN-26 was constructed by two different types of cages, octahedral and cuboctahedral, to form a polyhedron-stacked three-dimensional framework with open channels in three directions. In PCN-26, both [Cu₂(O₂CR)₄] secondary building units (SBUs) and quaternary carbon atoms of TDM⁸⁻ act as four-connected nodes, while the CH₂O-isophthalate moieties act as three-connected nodes, the framework is a 3-nodal net and adopts a new network topology with the Schläfli symbol of {3¹¹.4¹⁰.5⁷}₄{3².6².7²}₂{3⁶}. Three-dimensional square channels are observed from the *a*, *b* and *c* axis with the sizes of 7.57 × 7.57 Å, 8.13 × 8.13 Å and 7.93 × 7.93 Å, respectively. N₂ sorption measurements were performed at 77 K, 1 bar, giving a Langmuir surface area of 2,545 m² g⁻¹, a BET surface area of 1,854 m² g⁻¹, and total pore volume of 0.84 cm³ g⁻¹.

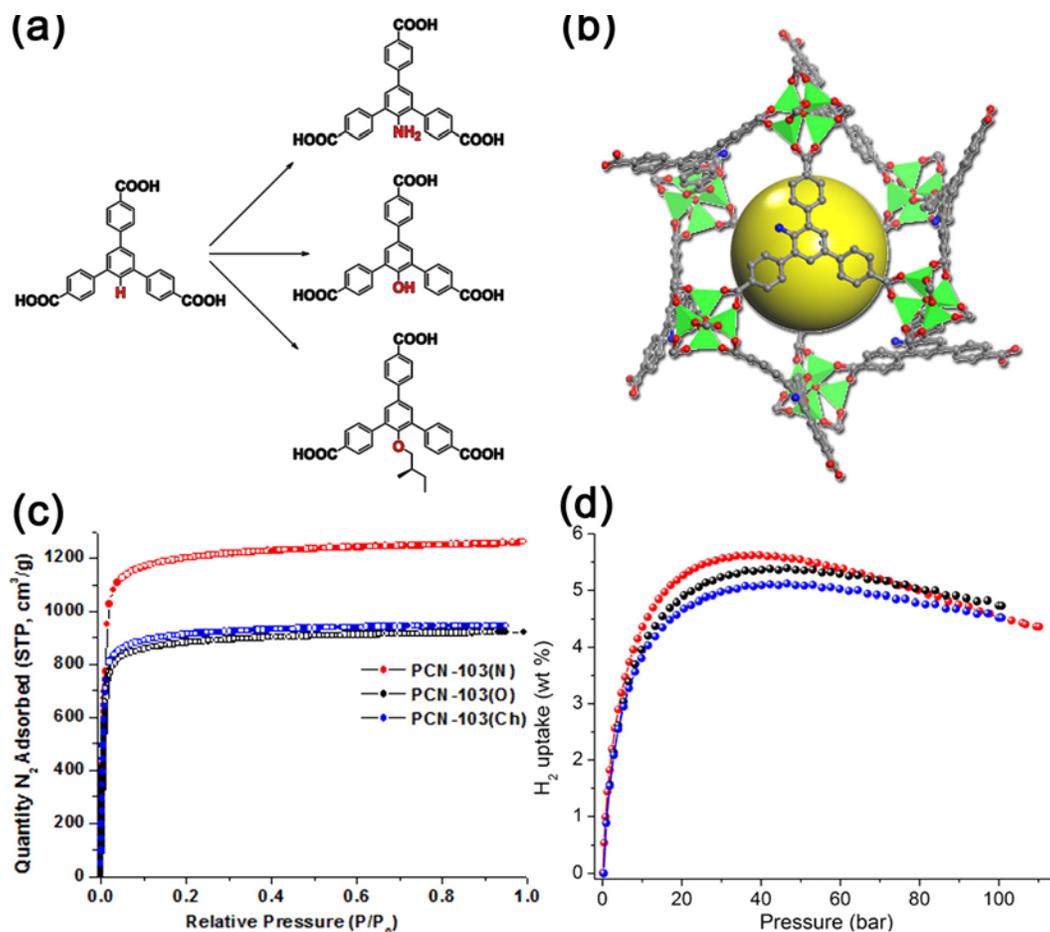

FIGURE 1. (a) The design of functional ligands; (b) the structure of PCN-103; (c) the N_2 isotherms of PCN-103(X) at 77 K; (d) the H_2 uptakes for PCN-103(X) at 77 K and high pressure range.

The PCN-26 has a saturated excess gravimetric hydrogen adsorption of 2.86 wt% at 77 K and 32 bar, with a hydrogen-adsorption enthalpy of 6.81 kJ mol^{-1} .

A Highly Porous and Robust 3,3,4-Connected MOF Assembled with a 90° -Angle-Embedded Octa-carboxylate Ligand

The octa-carboxylate ligand, BTTCd, with a 90° -angle-carbazole-3,6-dicarboxylate moiety as opposed to the widely used 120° -angle-isophthalate, was synthesized by a Cu(I)-catalyzed reaction between dimethyl 9H-carbazole-3,6-dicarboxylate and 3,3',5,5'-tetrabromo-1,1'-biphenyl followed by hydrolysis with potassium hydroxide in an overall yield of 30%. Solvothermal reaction of H_8 BTTCd and $Cu(NO_3)_2 \cdot 2.5H_2O$ in *N,N*-dimethylformamide (DMF) in the presence of HBF_4 afforded tetragonal-shaped green crystals of PCN-80 with molecular formula $[Cu_2(BTTCd)] \cdot 2DMF$. PCN-80 crystallizes in tetragonal $I4/mmm$ space group with $a = b = 23.057(2)$, $c = 30.762(3) \text{ \AA}$. In the structure of PCN-80, the novel BTTCd ligand contains four 90° -angle subunits (Figure 2a) where the carbazole ring is perpendicular to

the central benzene ring and the dihedral angle between adjacent carbazole rings is 47.4° . Every BTTCd ligand utilizes eight carboxylate groups to link eight 4-connected dicopper paddlewheel SBUs (Figure 2b) in a rectangular prismatic fashion to generate a porous (3,3,4)-connected network. There are three kinds of microporous cages with different sizes. L-cages (16.6 \AA in diameter) are formed by eight $[Cu_2(O_2CR)_4]$ SBUs, and twelve BTTCd linkers (Figure 2c); M-cages (13.4 \AA) from eight SBUs and four BTTCd linkers (Figure 2d); and S-cages (7.6 \AA) through four SBUs and two BTTCd ligands (Figure 2e). The overall structure consists of these three types of cages packed in a 1:1:1 ratio (Figure 2f). From the viewpoints of topology, the SBUs serve as 4-connected nodes, whereas BTTCd ligands as 3,3-connected nodes. As a result, PCN-80 adopts the very rare 3,3,4-c 3-nodal net (Figure 2g) with topological point symbol of $\{7^2 \cdot 8^2 \cdot 11^2\}\{7^2 \cdot 8\}\{7^3\}_2$, which is previously unreported.

The calculated free volume in fully desolvated PCN-80 is 72.1% by *PLATON* (1.8 \AA probe radius), and pore volume is $1.25 \text{ cm}^3 \text{ g}^{-1}$. To confirm the porosity of PCN-80, a fully desolvated sample was degassed under dynamic vacuum

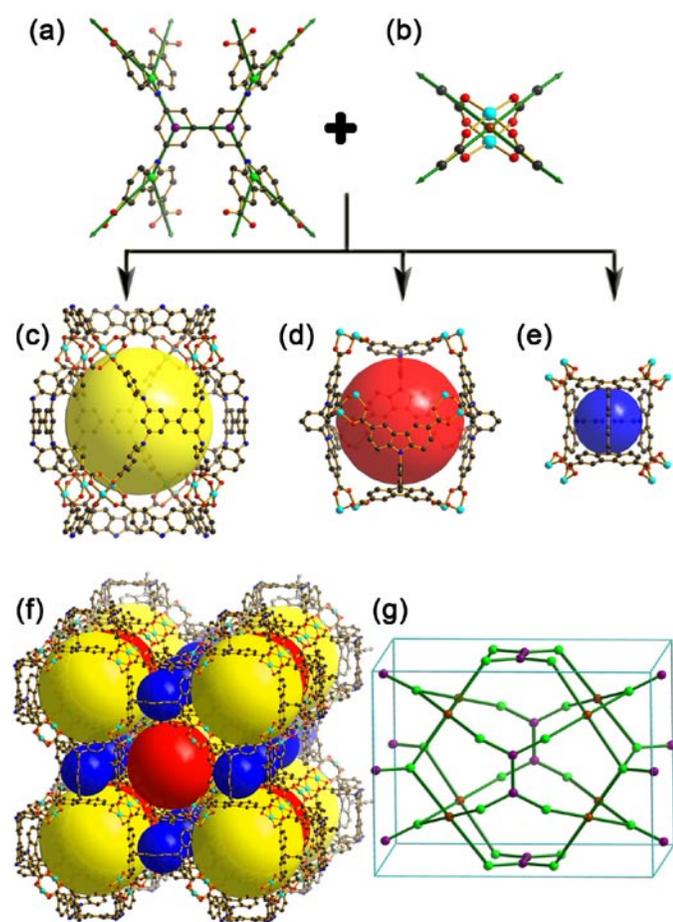

FIGURE 2. (a) 8-connected BTTC ligand; (b) 4-connected dicopper paddlewheel SBU; (c) large size cage (L-cage); (d) middle size cage (M-cage); (e) small size cage (S-cage); (f) cages and their three-dimensional packing in PCN-80; (g) topology of PCN-80.

at 80°C for 10 h after solvent exchange with methanol and then dichloromethane. A color change from green to deep-purple-blue was observed, typical for dicopper-paddlewheel frameworks in which open copper sites are generated. The N_2 sorption for PCN-80 at 77 K exhibited a reversible *Type-I* isotherm, a characteristic of microporous materials. The estimated apparent BET surface area was $\sim 3,850 \text{ m}^2 \text{ g}^{-1}$ (calculated $\sim 3,584 \text{ m}^2 \text{ g}^{-1}$) and Langmuir surface area $\sim 4,150 \text{ m}^2 \text{ g}^{-1}$, which is similar to PCN-66 (BET $\sim 4,000 \text{ m}^2 \text{ g}^{-1}$), among the highest reported to date for porous MOFs or covalent organic frameworks. Notably, the experimental surface area of PCN-80 perfectly agrees with that calculated using Material Studio 5.5. On the basis of the N_2 sorption isotherm, PCN-80 has a calculated total pore volume of $1.47 \text{ cm}^3 \text{ g}^{-1}$. Calculated with N_2 isotherm using DFT methods, the pore size distribution for PCN-80 indicates three different kinds of pores with diameters of 7.3, 11.8, and 14.5 Å, respectively, which is in good agreement with the crystal data.

In the low-pressure region, it is well known that the H_2 -uptake capacity is mainly controlled by the hydrogen

affinity towards the framework. PCN-80 exhibits H_2 -uptake capacity as high as 2.3 wt% at 77 K and 1 bar, which is among the highest at low pressure. The excellent performance of PCN-80 can be largely attributed to its microporous nature as well as high open-metal-site density upon activation. High-pressure gas sorption was performed on PCN-80 using volumetric measurement method. At 77 K, the excess H_2 -uptake capacity of PCN-80 reached its maximum value of 4.8 wt% (29 g L^{-1}) at 44 bar. Based on a variant of the Clausius-Clapeyron equation, the H_2 isosteric adsorption enthalpy of PCN-80 reaches 5.2 kJ mol^{-1} at low coverage.

Highly Stable Porous Polymer Networks with Exceptionally High H_2 -Uptake Capacities

Conventional Yamamoto homo-coupling reaction for polymerization was carried out at 80°C with DMF as the solvent. However, when the same reaction condition was applied to tetrakis(4-bromophenyl)silane or tetrakis(4-bromophenyl)adamantane, the surface areas of the synthesized materials were much lower than the calculated data. With the assumption that reduced temperature would slow down the reaction to yield polymers with higher molecular weight and avoid any unwanted side reactions, we adopted an optimized Yamamoto homo-coupling procedure, in which the reactions were carried out at room temperature in a DMF/tetrahydrofuran mixed solvent. Using this procedure, we were able to synthesize PPN-3 (X: adamantane), PPN-4 (X: silicon), and PPN-5 (X: germanium) with exceptionally high surface areas (Figure 3a and 3b). The surface area of PPN-3 synthesized through this procedure is much higher than the value previously reported, and the surface area of PPN-4 is close to the value predicted based on the molecular model, indicating the excellence of this optimized procedure. With the BET surface area of $6,461 \text{ m}^2 \text{ g}^{-1}$ and Langmuir surface area of $10,063 \text{ m}^2 \text{ g}^{-1}$, PPN-4 possesses, to the best of our knowledge, the highest surface area among all the reported porous materials so far. In addition, most of the pores in PPN-4 sit with the range of microporous or microporous/mesoporous range, which serves remarkably for gas storage purposes.

As the previously reported PPNs, PPN-3, PPN-4, and PPN-5 are off-white powders, not soluble in common organic solvents. There is no residual bromine from the elemental analysis result, indicating the completion of the reaction and the efficiency of Yamamoto homo-coupling. Surprisingly, a trace amount of nitrogen was detected in PPN-3 and PPN-5 (0.14 wt% and 0.11 wt%, respectively), which probably comes from the trapped 2,2'-bipyridine within the shrunken pores caused by network interpenetration. This network interpenetration may also account for the reduced experimental surface areas of PPN-3 and PPN-5 compared with the calculated data. Thermogravimetric analysis data show the three polymers possess good thermal stability and high decomposition temperatures of more than 450°C in a nitrogen atmosphere.

In addition, PPN-4 retains its structural integrity after being exposed to air for one month, as indicated by virtually no drop of N_2 uptake capacity at 77 K.

The exceptionally high surface area combined with excellent stability make PPN-4 a very attractive candidate for gas storage applications, particularly in H_2 for clean energy purposes. To evaluate its gas storage capacity, high-pressure excess adsorption of H_2 within PPN-4 were measured at 77 K (liquid nitrogen bath). As shown in Figure 3c, the excess H_2 uptake of PPN-4 at 77 K and 55 bar can reach 91 mg g^{-1} (8.34 wt%, total uptake: 158 mg g^{-1} , 13.6 wt%, 80 bar), which is by far the highest among all amorphous materials, and is also comparable to the best value reported in MOFs. The isosteric heat of adsorption for H_2 is around 4 kJ mol^{-1} (Figure 3d), which fits within the range of physisorption and indicates that the high surface area might be the sole factor in determining this high H_2 uptake capacity. Unlike MOFs, whose H_2 uptake capacity will decrease after several uptake-release cycles, the H_2 uptake capacity of PPN-4, even being exposed to air for several days, can be simply regenerated by heating under vacuum. The excellent physicochemical stability and impressively high delivery capacity (71 mg g^{-1} , 77 K, from

1.5 bar to 55 bar) make PPN-4 the currently unbeatable material for cryogenic H_2 storage application.

Post-Grafting Porous Polymer Networks for Hydrogen Storage

Theoretical studies on MOF and PPN materials have suggested that introduction of light, non-transition metal ions such as Li^+ , Na^+ or Mg^{2+} might afford non-dissociative hydrogen binding, thus enhancing overall adsorption of H_2 . In particular, Li-doped materials appear to be especially interesting in this regard. Here we report the post-grafting of PPN-6 with sulfonic acid and lithium sulfonate. PPN-6 (also known as porous aromatic framework [PAF]-1) was synthesized using an optimized Yamamoto homo-coupling reaction of tetrakis(4-bromophenyl)methane. The default diamondoid framework topology imposed by the tetrahedral monomers provides widely open and interconnected pores to efficiently prevent the formation of “dead space”, more importantly, the extremely robust all-carbon scaffold of the network can stand harsh reaction conditions and makes it perfect to build up polar organic groups on the biphenyl units; indeed, by reacting with chlorosulfonic acid in dichloromethane, PPN-6 was modified into PPN-6- SO_3H ,

(a) Synthetic route for PPN-3 (X: Adamantane), PPN-4 (X: Si), PPN-5 (X: Ge), and PAF-1 (X: C); (b) The default noninterpenetrated diamondoid network of PPN-4 (black, C; cyan, H; yellow, Si); (c) Excess and total H_2 adsorption isotherms of PPN-4 at 77 K; (d) Isosteric heat of adsorption for H_2 in PPN-4.

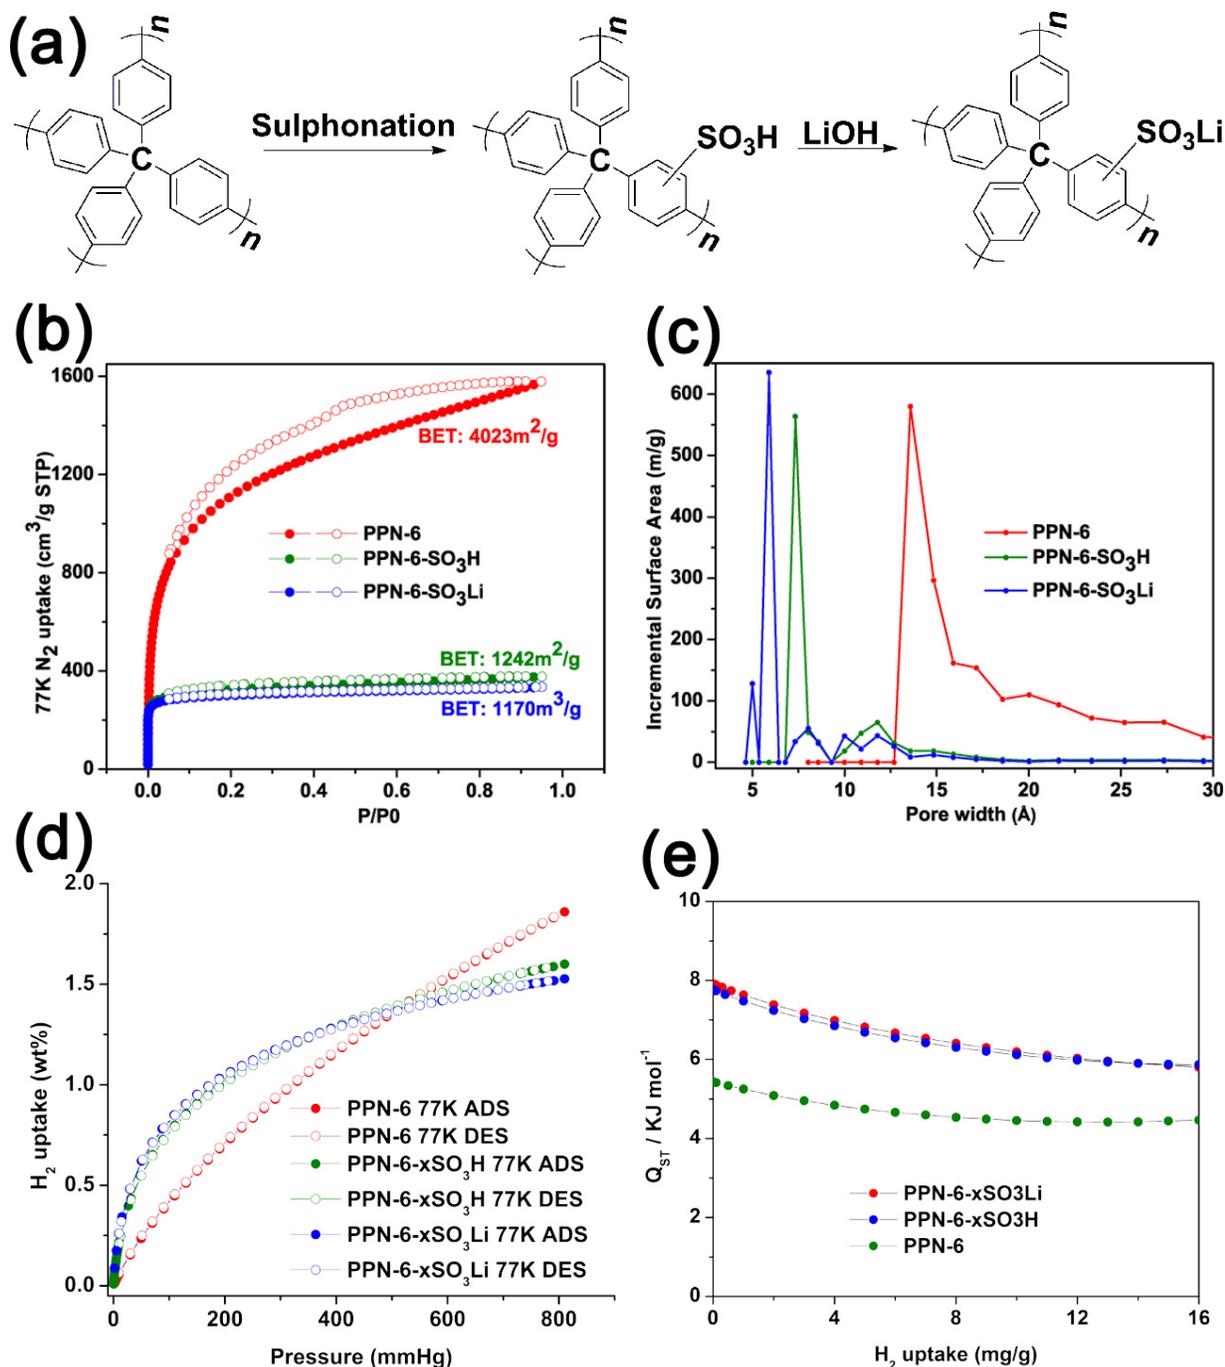

FIGURE 4. (a) Synthesis and post-synthetic grafting of PPN-6-X; (b) N₂ adsorption (closed)/desorption (open) isotherms of PPN-6-X at 77 K; (c) Pore size distribution curves of PPN-6-X; (d) Excess adsorption isotherms of PPN-6-X at 77 K; (e) Isothermic heat of adsorption for H₂ in PPN-6-X.

which was further neutralized to produce PPN-6-SO₃Li (Figure 4a). Nitrogen gas adsorption/desorption isotherms of the three networks were collected at 77 K (Figure 4b). Notably, the huge hysteresis in PPN-6 adsorption/desorption isotherm disappeared into nearly type-I isotherms in functionalized PPN-6. The BET surface areas were calculated from the adsorption branch of the nitrogen isotherms over a BET-theory-satisfied pressure range and were found to be 4,023, 1,242, and 1,170 m² g⁻¹ for PPN-6,

PPN-6-SO₃H and PPN-6-SO₃Li, respectively. The pore size distributions of the three networks have been calculated with their N₂ adsorption isotherms at 77 K (Figure 4c). Along with the decrease of surface area, the pore size becomes progressively reduced with aromatic sulfonation and lithiation. Recent studies have indicated several features that are desirable for enhancing storage capacity of small gas molecules. One such feature is the suitable pore size commensurate with the size of gas molecule. The relatively

small pore sizes of functionalized PPN-6 fall into the range of 5.0-10.0 Å. Though the experimental BET surface of PCN-6-SO₃Li area decreased, the H₂ isosteric heat increased 47% (Figure 4d and 4e), which is consistent with theoretical calculation. The introduction of other metal will also be studied, such as Mg, Ti, Ni, Co and so on.

Conclusions and Future Directions

Conclusions:

- Constructing new MOFs using 90°-angle-embedded octa-carboxylate ligand is proved as a general approach towards stable MOFs with high surface areas and high hydrogen uptake.
- PPNs with tunable pore size and surface area can be prepared with high chemical and thermal stability, which are good candidate for hydrogen storage.
- PPN postsynthetic modification and metal incorporation can remarkably enhance the heat of adsorption.

Future Directions:

- Further enhancement of H₂-MOF interaction by doping coordinatively unsaturated metal centers (heat of adsorption 15 kJ mol⁻¹). Based on theoretical calculations, main group metals such as Li, Mg and Ca will be tested.
- Working with partners, test H₂ uptake at temperatures higher than 77 K.
- Preparation of MOFs with high surface area and optimized cage size with newly designed ligands based on theoretical calculations.
- Incorporation of entatic-state metals based on theoretical guidance.
- Preparation of new PPNs containing active metals.

Contract Number: DE-FG36-08GO18141

Project Start Date: September 1, 2008 (funded from April 1, 2009)

Project End Date: January 31, 2013

Technical Targets

This project consists of several fundamental studies on COFs and ZIFs. Insights gained from these studies will be applied toward the design and synthesis of hydrogen storage materials that meet the following DOE 2015 hydrogen storage targets:

- Volumetric density: 40 g L⁻¹
- Gravimetric density: 5.5 wt%

FY 2011 Accomplishments

- Synthesized new COFs via hydrazone and imine condensation.
- Initiated metalation experiments of COFs.
- Began synthesis of mixed-metal ZIFs for improved adsorption enthalpy.
- Found linkers with optimal binding energy for H₂ storage (20 kJ/mol).
- Designed new architectures with these linkers and began simulation calculations of H₂ uptake.

Fiscal Year (FY) 2011 Objectives

- Design new covalent-organic frameworks (COFs) with strong H₂ binding sites.
- Predict H₂ uptake isotherm for designed frameworks employing a developed force field.
- Prepare stable frameworks with potential metal binding sites.
- Implement metalation experiments and evaluate their respective H₂ adsorption properties.
- Prepare a mixed-metal zeolitic imidazolate framework (ZIF).

Technical Barriers

This project addresses the following technical barriers from the Storage section (3.3.4.2) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (C) Efficiency
- (E) Charging/Discharging Rates
- (P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

Introduction

Storage of hydrogen in porous materials is a promising approach to achieve the DOE system requirements for use of H₂ as a transportation fuel. After the first report of successful H₂ storage in metal-organic frameworks (MOFs), the Yaghi group has succeeded in incrementally increasing the gravimetric and volumetric capacities in order to reach the highest H₂ uptake capacity, albeit at 77 K. However, for on-board vehicular H₂ storage it is necessary to improve the adsorption enthalpy of porous materials to achieve significant capacities at room temperature. Therefore, we are currently focusing our efforts on discovering highly porous materials with strong affinity for H₂.

Approach

To meet the DOE 2015 revised targets by physisorption, adsorbents must have high surface area (>3,500 m² g⁻¹) and relatively high density (>0.75 g cm⁻³). We have previously demonstrated how to design high surface area MOFs and COFs; however, in many cases, these materials do not show steep H₂ uptake in the low-pressure region indicative of the weak interaction with H₂. It is predicted that the impregnation of COFs with metals will enhance the

adsorption enthalpy, which has led us to explore methods for the preparation of metalated COFs. In this FY, we developed a new class of COFs for metal impregnation. Moreover, we developed the force field from *ab initio* calculations, which are used to estimate the isotherm of COFs containing the hydrazone and imine moieties as well as the H₂ uptake for a full and partial Pd(II)-metalated COFs. In addition, a new mixed-metal ZIF was designed and synthesized to incorporate strong H₂ binding sites in the framework.

Results

Metal impregnation is one of the most promising strategies to improve the adsorption enthalpy of COFs. However, before the metal impregnation experiments are carried out, it is necessary to prepare stable COFs that are capable of introducing metal binding sites in the framework through the condensation reaction. To this end, we designed and prepared new COFs having hydrazone and imine moieties.

Preparation of Hydrazone COF. Despite the significant interest in developing COFs for industrially relevant applications, only a small number of organic functionalities, such as boronates, borosilicate, and imine condensations have been employed in their preparation [1-3]. The relatively few examples of COF architectures, with respect to the vast library of possible organic reactions, can be attributed to the significant challenge of synthesizing crystalline solids constructed solely from strong covalent bonds. We have previously shown that this challenge is overcome by using dynamic covalent systems coupled with precisely controlled reaction conditions. Thus, we employed these same principles in the selection of hydrazide and aldehyde moieties as novel building blocks for COF

materials since the reversibility of hydrazone formation by modulating the pH is well documented.

COF-42 and COF-43 were synthesized by suspending 2,5-diethoxyterephthalohydrazide (1) and 1,3,5-triformylbenzene (2) or 1,3,5-tris(4-formylphenyl)benzene (3) in a flame-sealed Pyrex tube in a mixture of mesitylene, dioxane and acetic acid at 120°C (Figure 1). These materials were immersed in tetrahydrofuran to remove occluded guests for three days, and the solvent was subsequently removed by heating at 85°C under dynamic vacuum.

Powder X-ray diffraction (PXRD) measurements were performed on samples of COF-42 and COF-43 to determine their crystallinity. The experimental PXRD patterns of both COFs were indexed based on a primitive hexagonal lattice. Next, the raw data was compared to models of possible crystal structures that can be obtained from linking the trigonal and the linear building blocks. It is anticipated that two-dimensional trigonal layers will be formed given that the hydrazone moiety is approximately coplanar with respect to the aromatic rings due to resonance effects and internal hydrogen bonding. These layers can pack in eclipsed **bnn** (*P6/mmm*), or staggered modes, **gra** (*P6₃/mmc*). However, at this resolution, the framework topologies, for both COFs, as either **bnn** or **gra** could not be assigned.

Gas adsorption isotherms were measured on fully activated samples in order to ensure the architectural stability and porosity of each COF. The Ar isotherm of COF-42 measured at 87 K showed a sharp uptake below $P/P_0 = 0.05$ with a step at $P/P_0 = 0.05-0.20$. This profile is best described as Type IV isotherm, which is characteristic of mesoporous materials. The Brunauer-Emmett-Teller (BET) surface area of COF-42 was calculated to be 710 m² g⁻¹. The 87 K Ar adsorption isotherm of COF-43 also possesses a type IV shape indicating that it is a mesoporous material. The BET surface area of COF-43 was calculated

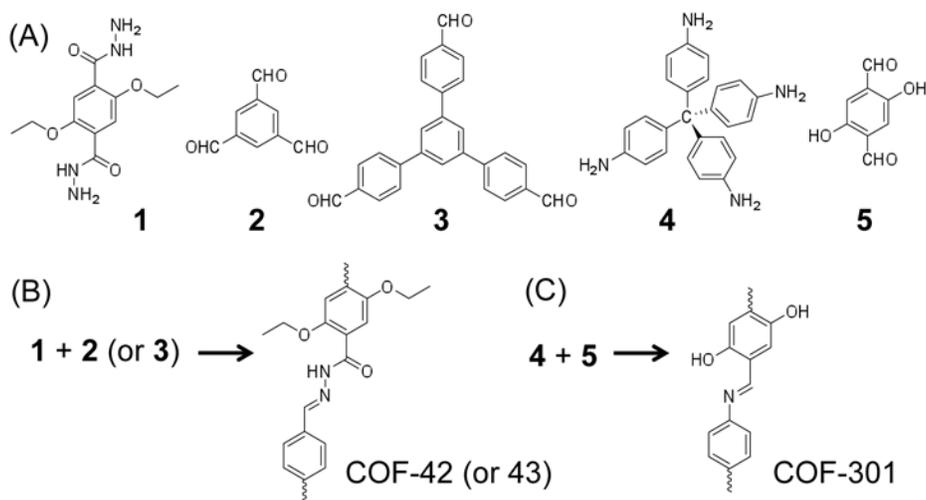

FIGURE 1. (A) Molecular structures of building units for COF synthesis. Reaction scheme of hydrazone (B) and imine COF (C) formation.

to be $620 \text{ m}^2 \text{ g}^{-1}$. Notably, the surface area and pore volume values obtained for COF-42 and COF-43 are comparable to those of other two-dimensional COFs with hexagonal pore systems [4]. A non-local density functional theory model was fitted to the isotherms of COF-42 and COF-43 yielding average pore sizes of 23 and 38 Å, respectively, these values are in good agreement with the expected pore size observed in the crystal simulations based on a **bnn** topology. More importantly, this is large enough to accommodate metal ions (and possibly their counter anions) in the pore.

The H_2 isotherms for these COFs are illustrated in Figure 2. The H_2 uptake for COF-42 and 43 at 1 bar and 77 K is 0.60 and 0.51 wt%, respectively. Although COF-42 has a smaller BET surface area, the H_2 uptake for COF-42 under the present experimental conditions was larger than that of COF-43. We attribute these results to the smaller pore diameter of COF-42. Furthermore, this theory is supported by the isosteric heats of adsorption (Q_{st}) data for these COFs (Figure 2, inset). The initial Q_{st} values for both COFs are almost the same (6.6 kJ/mol), because of the similarity in the surface environment of COFs. Once a majority of strong binding sites are occupied by H_2 , the adsorption potential in the pore should be more important (i.e. larger pore material has smaller adsorption potential). Consequently, it is likely that the values for COF-43 quickly dropped with an increase in the H_2 loading.

Preparation of Imine COF and its Metalation

Reaction. We have demonstrated the condensation of the tetrahedral building block tetra-(4-anilyl)methane with the linear linking unit terephthalaldehyde to produce a material with an extended three-dimensional framework structure (COF-300) [3]. COF-300 is an interpenetrated diamond net and has a one-dimensional channel with diameter of 7.8 Å. However, due to the lack of potential metal binding sites, it is not easy to metalate this material. To create

metal binding sites in the COF frameworks, we believe salicylidene-aminophenyl and iminopyridine moieties are good candidates. This year, we synthesized a new imine COF (termed COF-301).

The synthesis of COF-301 was carried out by solvothermal synthesis of a suspension of tetra-(4-anilyl)methane (**4**) and 2,5-dihydroxyterephthalaldehyde (**5**) in a mixture of 1,4-dioxane and aqueous acetic acid (Figure 1). The material is insoluble in water and common organic solvents such as hexanes, methanol, acetone, tetrahydrofuran, and *N,N*-dimethylformamide. Therefore, it seems the resultant crystalline material is an extended structure. The formation of imine linkages in COF-301 was confirmed by Fourier transform infrared spectra. The crystallinity of COF-301 was confirmed by PXRD analysis. Although its atomistic connectivity is not determined yet, it is presumed that the connectivity (topology) of COF-301 is a diamond net due to the similarity of PXRD pattern. However, no information is available with regard to the degree of interpenetration.

The permanent porosity of COF-301 was demonstrated by measuring N_2 adsorption at 77 K. The isotherm shows a sharp uptake below $P/P_0 < 0.10$. The application of the BET model results in a surface area of $1,040 \text{ m}^2/\text{g}$. The N_2 isotherm was fit with non-local density functional theory models from which the pore size distribution was calculated, resulting in a value of 10.5 Å, which is close to the values observed in the proposed structure (ca. 9.5 Å).

Prior to the metalation reaction, we predicted the total H_2 isotherms of pristine and COF-301-Pd (using PdCl_2 as the source) with different metal loadings. As shown in Figure 3, metalated material shows steep H_2 uptake below 10 bar even at room temperature, which is in sharp contrast to the pristine COF-301. The total H_2 uptakes at 100 bar are calculated to be 4.5, 3.7, 2.7 wt% for 100%, 50%, and 25%

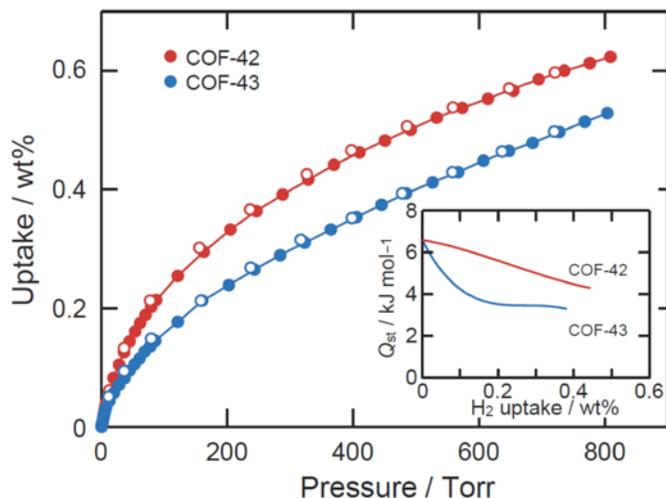

FIGURE 2. H_2 isotherms for COF-42 (red) and COF-43 (blue) at 77 K. Inset: coverage dependence of the isosteric heats of adsorption (Q_{st}) for H_2 in these COFs.

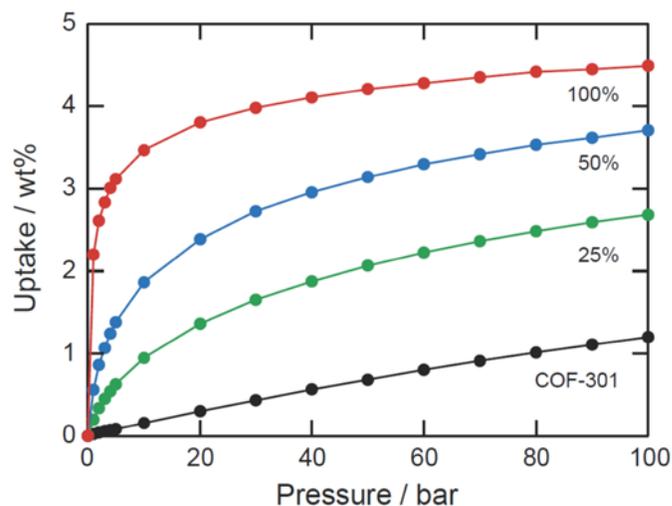

FIGURE 3. Predicted total gravimetric H_2 isotherms of pristine COF-301 and COF-301- PdCl_2 with different metal loadings (100%, 50%, and 25%).

Pd loading COF-301. These values are much greater than pristine COF-301 (1.2 wt%) under the same condition, so that it is presumed that the interaction between Pd and H₂ is strong enough to improve the H₂ uptake capacity. This is more obvious when we observe the average Q_{st} values which are 23.6, 17.8, 14.0 kJ/mol for 100%, 50%, and 25% Pd loading COF-301, while only 6.0 kJ/mol for pristine COF-301. Although the metalated compound would have a smaller pore volume and a larger bulk density, the simulated isotherms encourage us to implement the metalation. Therefore, we impregnated COF-301 with metal salts, and obtained materials are termed COF-301-M; M = Pd(II) and Pt(II).

The metalation of COF-301 was carried out by reflux reaction of a suspension of COF-301 and metal source (PdCl₂ or PtCl₂) in acetonitrile. The resulting yellow solid was filtered off, washed with ethanol, diethyl ether and dried under vacuum. After the metalation, the peak position of PXRD for metalated COF-301 is almost identical to that of COF-301. Therefore, we believe that the crystallinity of these metalated materials is retained, although the intensity of the pattern decreased. Currently, we do not have clear evidence to confirm whether the metal ion was bound to the framework. We plan to study the metal coordination environment using ¹⁵N enriched material.

Before the H₂ tests, we measured N₂ isotherms of a series of materials. After the metalation, the BET surface areas of the samples were much smaller than that of the pristine material (60 m²/g for COF-301-Pd, 20 m²/g for COF-301-Pt). Although the metalated samples have a larger density than the original COF-301, this should not be the only reason for the significant surface area drop. Possible explanation of this drop is (i) the presence of leaving groups (perhaps two Cl⁻) bound to the metal ion and/or unreacted metal salts (i.e. MCl₂), (ii) pore openings of the metalated samples could be partly blocked, which would reduce the accessible pore space, and/or (iii) crystallinity of the materials were partially lost. To mitigate the surface area drop, we will optimize metalation and sample activation conditions.

Preparation of Mixed-Metal ZIFs. To improve H₂ storage capacity, the number of metals per volume is a very important factor to keep in mind. In most cases, ZIFs have higher metal density because the length of the imidazolate is short [5]. However, these metal ions (i.e. Zn²⁺ and Co²⁺) are fully coordinated to imidazolate linkers such that it is difficult to utilize these metals as strong H₂ binding sites. We believe it is possible to create open metal sites in ZIF structures, if we introduce another metal ion having different coordination geometry. To this end, we added another metal source (Cu²⁺) to reaction mixtures.

The as-synthesized product (ZnCu(imidazolate)) was washed with methanol and evacuated at room temperature. The permanent porosity of the activated sample was confirmed by N₂ adsorption at 77 K. The profile of the N₂ isotherm for evacuated samples is classified typical Type I isotherm, whose BET surface area is calculated to

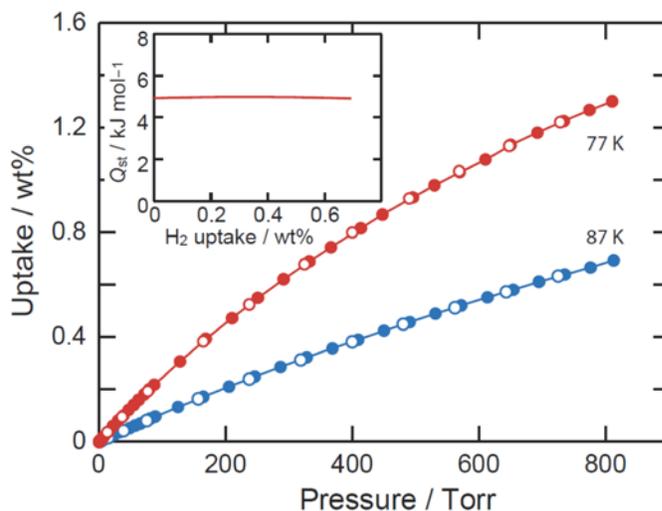

FIGURE 4. H₂ isotherms for the mixed metal ZIF at 77 K (red) and 87 K (blue). (Inset) Coverage dependence of the isosteric heat of adsorption (Q_{st}) for H₂ in the ZIF calculated from fits of its 77 and 87 K isotherms.

be 1,460 m²/g. This is one of the highest values in ZIF materials, although these are slightly smaller than ZIF-8 [6]. The H₂ isotherms for mixed metal ZIF are illustrated in Figure 4. The H₂ uptake at 1 bar and 77 K is 1.2 wt%. Considering that the isotherm is nearly straight in this region, the interaction between the framework and H₂ may not be strong. Indeed, the Q_{st} value did not change until 0.7 wt% of H₂ coverage (Figure 4, inset). Currently, we are studying the synthetic conditions for other mixed metal ZIFs with different metal ions with square planar geometry (e.g. Ni).

Conclusions and Future Directions

This year we experimentally demonstrated how to introduce potential metal binding moieties by connecting di-, tri-, and tetra-topic building units through condensation reactions (i.e. hydrazine and imine COFs). We started the metalation reactions using COF-301, although the metalation conditions are not optimized yet. We plan to screen candidates for metalation reactions of COFs through modeling studies, which will be experimentally evaluated. In addition, we will predict the binding energy between H₂ and metal unit.

- Material design assisted by the reticular synthesis.
- Calculate the H₂ isotherms for pristine and metalated COFs.
- Implement the metalation reaction based on the theoretical prediction.
- Calculate the free energy (ΔG) and enthalpy (ΔH) for the metalation processes.
- Calculate the diffusion coefficient of H₂ in the frameworks to estimate the kinetic factor.

- Synthesize mixed metal ZIFs with different metal ions.
- Begin calculation of H₂ isotherms for mixed metals ZIFs.

Contract Number: DE-FG36-08GO18142

Subcontractor:

Midwest Research Institute, Kansas City, MO

Project Start Date: September 1, 2008

Project End Date: January 31, 2013

(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

Technical Targets

This project aims at the development of surface-engineered carbons, made from corncob or other low-cost raw materials, which simultaneously host high surface areas, created in a multi-step process, and a large fraction of surface sites with high binding energies for hydrogen, created by surface functionalization with boron, iron, and lithium. Targets are surface areas in excess of 4,500 m²/g, average binding energies in excess of 12 kJ/mol, and porosities below 0.8, toward the design of materials that meet the following 2015 DOE hydrogen storage targets:

- Gravimetric storage capacity: 0.055 kg H₂/kg system
- Volumetric storage capacity: 0.040 kg H₂/liter system

FY 2011 Accomplishments

- Manufactured boron-substituted carbon by deposition and thermolysis of B₁₀H₁₄ on high-surface-area activated carbon, with B:C = 7-10 wt%, without compromising high surface areas (≥2,100 m²/g). Developed plans for automated apparatus.
- Maintained an oxygen- and water-free environment for the manipulation, characterization, and analysis of boron-substituted carbon, which was fundamental for the observation of enhanced hydrogen sorption characteristics.
- Observed an increase of 30% in areal excess adsorption (excess adsorption per surface area) of hydrogen, at $T = 303$ K and $P = 200$ bar, on boron-substituted carbon (B:C = 8.6 wt%) compared to its boron-free precursor. The increase in excess adsorption at high temperature and pressure demonstrates an increase in average binding energy due to boron substitution.
- Optimized pore structure of undoped carbons by varying the KOH:C ratio and temperature during activation. High KOH:C and T lead to larger surface area, pore volume, and porosity, but a reduced fraction of narrow pores. Optimal conditions for hydrogen storage are observed for activation with a 3.5 KOH:C ratio at 800°C, which represents the best balance between increasing the pore volume and loss of high-binding-energy sites in narrow pores.
- At low KOH:C and T , the pore structure is consistent with large graphene sheets closely stacked, whereas for more aggressive activation conditions the pores are formed by small graphene sheets loosely stacked (surface areas larger than that of graphene, 2,600 m²/g).

Fiscal Year (FY) 2011 Objectives

- Fabricate high-surface-area, multiply surface-functionalized carbon (“substituted materials”) for reversible hydrogen storage with superior storage capacity (strong physisorption).
- Characterize materials and storage performance. Evaluate efficacy of surface functionalization, experimentally and computationally, for fabrication of materials with deep potential wells for hydrogen sorption (high binding energies).
- Optimize gravimetric and volumetric storage capacity by optimizing pore architecture and surface composition (“engineered nanospaces”).

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (B) System Cost
- (E) Charging/Discharging Rates
- (J) Thermal Management

- Observed that carbon monoliths formed by activated carbon and polyvinylidene chloride (PVDC) binder outperforms powder samples at room temperature, consistent with findings that pyrolyzed PVDC is an attractive material for hydrogen storage (sample HS;0B) [1].
- Developed and applied a consistent method for the determination of isosteric heat of adsorption from the Clausius-Clapeyron equation. Validated by microcalorimetry measurements. The thermodynamic requirement that the isosteric heat cannot increase with increasing pressure and coverage gives a lower bound for the adsorbed film thickness (or volume).
- Established, via Fourier-transform infrared spectroscopy (FTIR), the presence of B-C bonds in boron-doped carbons ($1,022\text{ cm}^{-1}$ line).

Introduction

High-surface-area carbons from corncob, as developed by our team, show considerable promise for reversible onboard storage of hydrogen at high gravimetric and volumetric storage capacity. An earlier carbon exhibited a gravimetric storage capacity of $0.11\text{ kg H}_2/\text{kg carbon}$ at 80 K and 50 bar . This project is a systematic effort to achieve comparable results at 300 K , by increasing surface areas from currently $\sim 3,000\text{ m}^2/\text{g}$ to $\sim 6,000\text{ m}^2/\text{g}$, and substituting carbon with boron and other elements that increase the binding energy for hydrogen (electron donation from H_2 to electron-deficient B, and other charge-transfer mechanisms). Earlier high surface areas and high binding energies were hosted by sub-nm pores (“nanopores”) in narrowly spaced “stacks of graphene sheets.” New high-surface-area, boron-substituted materials are manufactured by thermolysis of volatile boron carriers in pores of stacks of graphene sheets. New surface area, created by fission tracks from boron neutron capture, in stacks of boron-substituted graphene sheets, or created in the form of stacks of small graphene sheets with large ratio of edge sites to in-plane sites, may add as much as another $3,000\text{ m}^2/\text{g}$.

Approach

The approach is an integrated fabrication, characterization, and computational effort. Structural characterization includes determination of surface areas, pore-size distributions, and pore shapes. Storage characterization includes measurements of hydrogen sorption isotherms and isosteric heats. Computational work includes adsorption potentials and simulations of adsorbed films for thermodynamic analysis of experimental isotherms. Comparison of computed and experimental isotherms validates theoretical adsorption potentials and experimental structural data.

Results

Observation of Enhanced Hydrogen Sorption on Boron-Doped Samples

Upgrades to the laboratory during the current year allowed us to process for the first time all boron-doped samples in oxygen- and water-free conditions. Activated carbon samples were degassed and coated with a monolayer or less of decaborane, $\text{B}_{10}\text{H}_{14}$, by liquid/vapor deposition (Figure 1), followed by pyrolysis and high-temperature annealing. This process creates the necessary boron substitution (FTIR indicates B-C bonds consistent with B-substitution in the C matrix). Table 1 shows selected samples manufactured and their characteristics. Hydrogen sorption isotherms for selected samples are shown in Figure 2. For B:C = $8.6\text{ wt}\%$, the areal excess adsorption at 303 K and 200 bar is 30% higher than on undoped material. The fact that the increase is observed at high temperature and pressure demonstrates an increase in the average binding energy, not highest binding energy. This is consistent with that sample 3K-H60 (I,A) was doped by Method I (liquid deposition), which deposits significant amounts of boron only in large pores. An increase in H_2 sorption is not observed at 90 K because unblocked pores in undoped material support H_2 multilayers, not available in the doped material. O_2 -free conditions were crucial for increased adsorption on B-doped samples (prior to the laboratory upgrade, no increase in H_2 sorption was observed in B-doped samples that had been exposed to air).

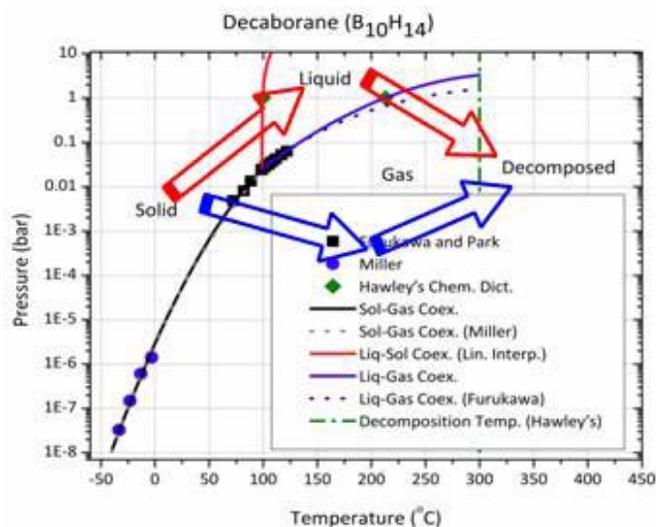

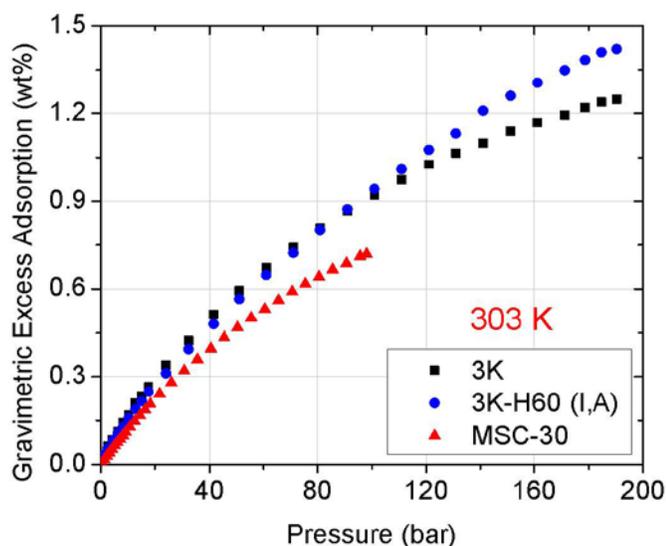

FIGURE 1. Schematic representation of deposition methods I (red, “liquid phase”) and III (blue, “vapor phase”). Higher deposition rates are possible with Method I, but since the process involves liquid decaborane, pore blocking may occur, as indicated by the reduction in Brunauer-Emmett-Teller (BET) surface area (Table 1).

TABLE 1. Sample characteristics of boron-doped carbons. B:C concentration was determined by prompt gamma neutron activation analysis.

Sample	Precursor	B:C (wt%)	Σ_{N_2} (m ² /g)	Φ_{N_2}	Notes
3K 3/3/10-B	Self	0.0	2,700	0.77	
3K-H30 (I,A)	3K 3/3/10-B	8.4	2,300	0.75	B-H decomp., 600°C
3K-H31 (III,A)	3K 3/3/10-B	10.0	2,000	0.73	B-H decomp., 600°C

3K-H60 (I,A)	3K 3/3/10-B degassed @ 600°C	8.6	2,100	0.73	B-H decomp., 600°C
3K-H60 (I,B)	3K 3/3/10-B degassed @ 600°C	6.7	2,100	0.72	B-H decomp., 1,000°C

**FIGURE 2.** Hydrogen sorption on boron-doped sample 3K-H60 (I,A), its boron-free precursor (3K 3/3/10-B), and reference sample MSC-30 (Maxsorb, Kansai Coke and Chemicals, Ltd). Experimental results are from 4-9 adsorption/desorption isotherms and are highly reproducible. Areal excess adsorption on 3K-H60 (not shown) is 30% higher than on 3K.

Optimization of Pore Geometry

Efforts to optimize the pore geometries of carbon precursors for hydrogen sorption were undertaken as follows. Ground corncob is soaked with phosphoric acid and charred at 480°C under nitrogen. The carbon is then activated by KOH in an oven, resulting in oxidation of some carbon by oxygen, and penetration of metallic potassium into the graphitic lattice. The intercalated potassium separates the graphene sheets/flakes and results in the formation of a highly porous material upon removal of the alkali. The resulting structure can be controlled by the weight ratio of KOH:C and activation temperature. Table 2 shows sample characteristics and H₂ sorption for various samples activated under different KOH:C ratios and temperatures (Figures 3-4). High KOH:C and temperature lead to larger surface area, pore volume, and porosity, but at the cost of a reduction of fraction of narrow pores. Optimal conditions for hydrogen storage are observed for activation with a KOH:C of 3.5 ratio at 800°C, which represents the best balance between a large pore volume and a small loss of high-binding-energy sites in narrow pores. At low KOH:C and temperature, the pore structure is consistent with large graphene sheets closely stacked, whereas for more aggressive

TABLE 2. Sample characteristics of carbon precursors. Names indicate KOH:C weight ratio and temperature during activation (e.g., 3K 900°C was activated with KOH:C = 3 at 900°C). Specific surface areas, Σ_{N_2} , from BET analysis of N₂ adsorption isotherms at 77 K and relative pressures 0.01-0.03, are rounded to nearest hundred. Porosities, Φ_{N_2} , were determined from N₂ adsorption at 77 K at relative pressure 0.995. Values for gravimetric excess adsorption are presented for $P = 100$ bar at 80 K, 194 K, and 303 K. Best performances in each column are highlighted in bold face.

activation conditions the pores are formed by small graphene sheets loosely stacked (edge sites generate surface areas larger than that of graphene, 2,600 m²/g).

Comparison of Powders and Monoliths (Briquettes)

One method to enhance the volumetric storage capacity is to increase the density the activated carbon. We have investigated this densification by “briquetting,” i.e., the production of monoliths. Powdered activated carbon was pressed into briquettes at 1,000 bar using PVDC as a binder (PVDC:carbon = 25-30 vol%), followed by pyrolysis of PVDC. The mass of a typical briquette was 70-100 g. Hydrogen sorption on briquettes was measured volumetrically for entire briquettes on a custom instrument with a 0.5-liter sample chamber (“Hydrogen Test Fixture,”

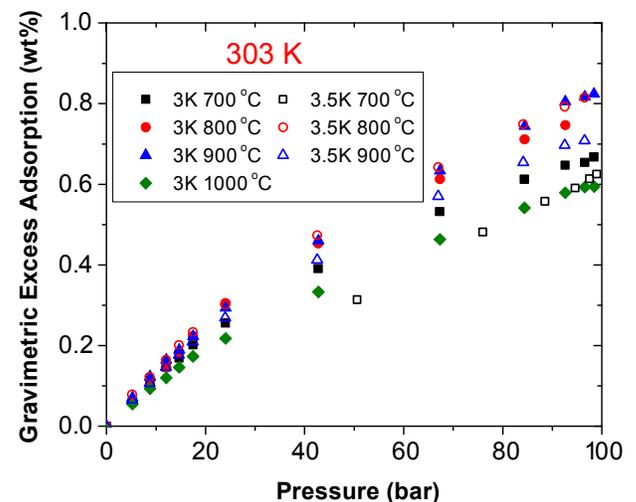

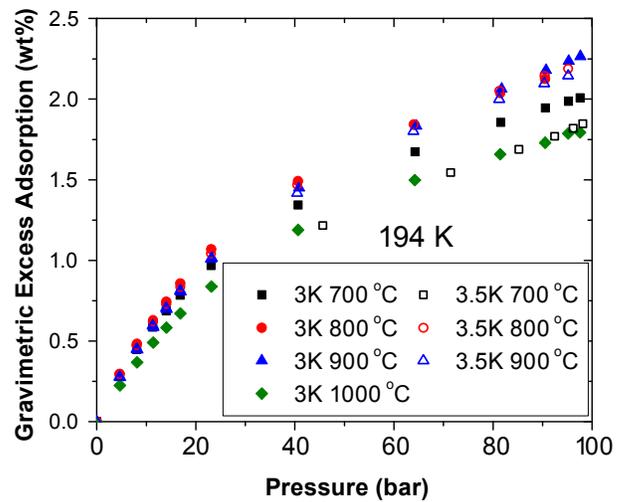

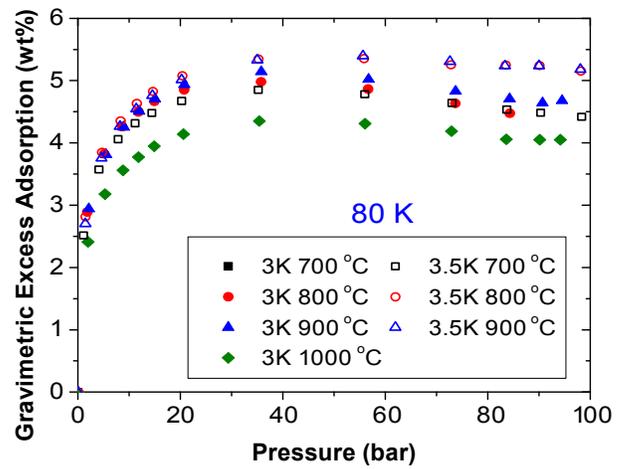

FIGURE 4. Gravimetric excess adsorption of H₂ on carbons produced with different KOH:C ratios and activation temperatures. Results are shown at T = 80 K, 194 K (dry-ice temperature), and 303 K.

TABLE 3. Comparison of powdered activated carbon and three carbon monoliths (briquettes). All hydrogen adsorption data are at room temperature, 297 K, and 100 bar. Gravimetric and volumetric storage capacities were calculated based on intragranular porosity (from N₂ adsorption at 77 K) for powders, and on intergranular porosity (from bulk density) for briquettes, respectively [2]. All hydrogen measurements on briquettes were performed on the HTF. Best performances are highlighted in bold face.

Sample	Σ_{N_2} (m ² /g)	Intragranular (intergranular) Density (g/cm ³)	Φ_{N_2}	Grav. Exc. Ads. (wt%)	Grav. Storage Cap. (wt%)	Vol. Storage Cap. (g/L)
2.5K powder	1,900	0.62	0.69	0.53	1.3	8.2
3K powder	2,600	0.44	0.78	0.93	2.2	9.6
4K powder	2,600	0.38	0.81	0.56	2.1	7.8
MSC-30	2,600	0.42	0.79	0.72	2.3	8.8
2.5K Briquette (30% binder)	2,000	0.74 (0.70)	0.63 (0.65)	0.67	1.4	9.7
3K Briquette (25% binder)	1,900	0.56 (0.47)	0.72 (0.77)	0.75	2.0	9.5
4K Briquette (25% binder)	2,100	0.53 (0.37)	0.74 (0.81)	0.86	2.6	9.5

HTF). Measurements on the HTF were validated on the Hiden HTP-1 instrument. Table 3 shows a comparison of four activated carbon powders and three briquettes. We observe that: (a) briquetting raises the density of samples by 20-40%, relative to the powder; (b) carbon made from PVDC exhibits superior hydrogen uptake at room temperature (HS;0B; very high areal excess adsorption [1]); (c) briquettes outperform most powder samples in terms of volumetric storage capacity because low porosity gives high volumetric storage capacity; (d) all briquettes outperform MSC-30 at room temperature in terms of volumetric storage capacity and areal excess adsorption. 4K briquette outperforms MSC-30 also in terms of gravimetric storage capacity; (e) entire briquettes, measured on the HTF, lead to robust averages over possible sample inhomogeneities. A 10-liter tank, recently completed [3], will permit studies of flow rates, thermal management, and operation at dry-ice temperature (194 K).

Observation of B-C Bonds by Fourier-Transform Infrared Spectroscopy

FTIR spectroscopy was used in transmission mode to identify the presence of boron-carbon bonds in boron-doped activated carbon. An infrared spectrum represents a fingerprint of a sample with absorption peaks, which correspond to vibrational frequencies of structural units making up the material. The samples were prepared using KBr pellets with a sample/KBr ratio of 0.033 wt%. Each FTIR spectrum was collected as an average of 32 interferometric scans with a spectral resolution of 1 cm⁻¹. An aperture was used to limit the sampling size and select the sampling area (>10 μm). Figure 5 shows the microscopic FTIR spectra for boron-free and boron-containing carbons. The FTIR spectrum of boron-free sample 3K shows only carbon-related bands, including the C-OH stretch mode at 3,429 cm⁻¹, C-OH bend mode at 1,630 cm⁻¹, C=C double-bond stretch mode at 1,430 cm⁻¹, and C-O bond stretch mode at 1,050 cm⁻¹. B-C bonds in boron-doped samples, 3K-H30 (not shown) and 3K-H31 (Figure 5), were identified

by comparing spectra with the spectrum of an activated boron carbide (not shown), a reference with the 1,022 cm⁻¹ band characteristic of B-C bonds. The band at 1,022 cm⁻¹ demonstrates the successful creation of boron-carbon bonds. Samples 3K-H30 and 3K-31, in addition to exhibiting C-OH and C-O modes seen in boron-free sample 3K, also exhibit a B-OH stretch mode at 3,220 cm⁻¹ and B-O stretch mode 1,327 cm⁻¹, consistent with the fact that the samples were not kept in an oxygen- and water-free environment for the FTIR experiment. To the best of our knowledge, this is the first time that the existence of B-C bonds in boron-doped carbons (liquid/vapor deposition of B₁₀H₁₄) has been observed and, hence, the successful incorporation of boron in the carbon matrix has been demonstrated.

Conclusions and Future Directions

- Observed enhanced hydrogen physisorption in boron-doped samples, enabled by equipment upgrades, with operations in an inert atmosphere.
- Optimized pore structure of samples by control of KOH:C ratio and temperature during activation.
- Performed comparison of powders and monoliths: increase in room-temperature performance of monoliths attributed to presence of pyrolyzed PVDC [1].
- Established B-C bonds by means of Fourier-transform infrared spectroscopy.
- Future work: (a) Continue production and characterization of B-doped samples, using B₁₀H₁₄ as boron carrier; investigate chemical pathways during the pyrolysis of B₁₀H₁₄ and annealing (mass spectroscopy of decomposition products) and effects on H₂ storage; optimize pathway of vapor/liquid deposition of B₁₀H₁₄; raise surface area of doped samples by removal of B via high-temperature reaction with H₂; optimize annealing. (b) Measure FTIR spectra of B-doped samples systematically; find number of B-C bonds per surface area. (c) Characterize B-doped materials produced from BCl₃ and compare with B-doping from

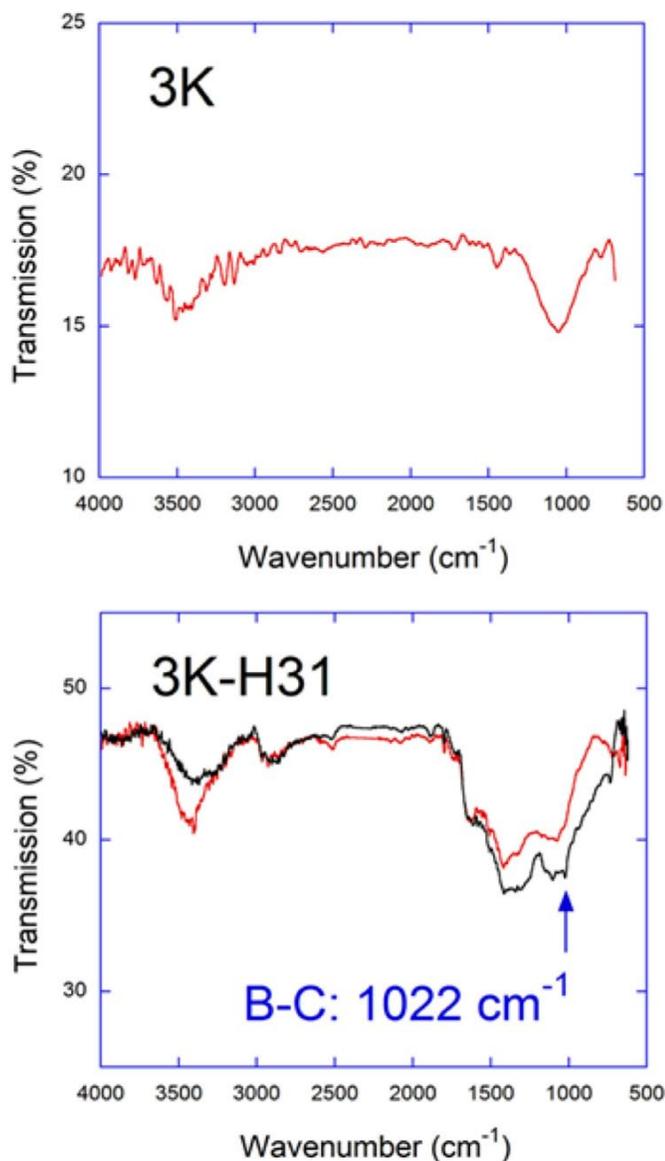

FIGURE 5. Microscopic FTIR spectra for samples 3K 3/3/10-B (boron-free) and 3K-H31 (III,A) (boron-doped). Each spectrum was obtained by limiting and selecting the sampling area through an aperture of an optical microscope (FTIR microscopy). The peak at $1,022\text{ cm}^{-1}$ is due to the B-C bond. The two spectra in 3K-H31 (III,A) correspond to different sampling locations.

$B_{10}H_{14}$. (d) Perform numerical simulations to investigate edge adsorption in finite pores, and compare results with experimental results on carbons activated at high KOH:C and high T . Determine pore structure and energetics from experimental H_2 isotherms. (e) Manufacture B-doped monoliths; test in 0.5-liter HTF and 10-liter tank; study flow rate and thermal management issues.

Project Start Date: September 1, 2008
Project End Date: August 31, 2012

Fiscal Year (FY) 2011 Objectives

Develop new materials to meet DOE gravimetric and volumetric targets for hydrogen storage:

- Develop and optimize strategies for introducing cations into metal-organic frameworks (MOFs).
- Synthesize new polymeric-organic frameworks (POFs) that contain cations.
- Use computational modeling to understand existing materials and design new materials for hydrogen storage.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (E) Charging/Discharging Rates
- (P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

Technical Targets

TABLE 1. Progress towards Meeting Technical Targets for Hydrogen Storage

Characteristic	2015 Targets	NU 2011 Status
System Gravimetric Capacity	0.055 kg H ₂ /kg system at ambient temperature and 100 bar	0.14 kg H ₂ /(kg sorbent + H ₂) at 77 K and 70 bar
System Volumetric Capacity	0.040 kg H ₂ /L system at ambient temperature and 100 bar	0.045 kg H ₂ /L sorbent at 77 K and 70 bar

FY 2011 Accomplishments

- Computationally screened MOFs functionalized with Li, Mg, Mn, Ni, and Cu alkoxides for their deliverable hydrogen storage capacity and found that Mg-alkoxide is the most promising.
- Synthesized a MOF containing protected catechol groups and investigated methods for deprotection and introduction of Mg²⁺ to form the alkoxide.
- Developed a new class of POFs based on click chemistry, with surface areas up to 1,440 m²/g.
- Developed POFs based on condensation of melamine and other building blocks and successfully incorporated up to 14 wt% Mg.

Introduction

One option for storing hydrogen on vehicles is to use tanks filled with porous materials that act as “sponges” to take up large quantities of hydrogen without the need for extremely high pressures. The materials must meet many requirements to make this possible. This project is developing two related classes of porous materials to meet these requirements. All materials are synthesized from molecular constituents in a building-block approach. This allows us to create a wide variety of materials in a tailorable fashion. The materials have extremely high surface areas, to provide many locations for hydrogen to adsorb. In addition, they are designed to contain cations that create large electric fields to bind hydrogen strongly but not too strongly.

Approach

The approach in this project is to introduce cations into MOFs and POFs to increase the hydrogen heats of adsorption, which will, in turn, increase the amount of

hydrogen that can be stored near room temperature. Many MOFs have enough surface area to meet the DOE hydrogen storage targets if the entire surface were covered with a monolayer of hydrogen. However, at room temperature, the energetic interactions between hydrogen and the surfaces are too weak to bind hydrogen. Thus, we are focused on increasing these energetic interactions. A variety of synthetic chemistries are being explored to increase the chances of success. In addition, molecular modeling is used to help explain experimental observations and provide guidance to the synthetic efforts.

Results

In FY 2010, we had developed a model for simulating hydrogen uptake in MOFs containing alkoxide groups. Briefly, second-order Moller-Plesset perturbation theory calculations with a large basis set (6-311+G**) were performed for a hydrogen molecule in ~200 different geometries near the alkoxide group, and these energies were fit with a combined Morse + Coulomb + Lennard-Jones potential. In FY 2011, we used this model in grand canonical Monte Carlo (GCMC) simulations to explore metal alkoxide functionalization for improving H₂ storage in isoreticular metal organic framework (IRMOF)-1, IRMOF-10, IRMOF-16, UiO-68, and UCMC-150, as some representative MOF structures [1]. We examined functionalization with lithium, magnesium, manganese, nickel, and copper alkoxides. We showed that lithium and magnesium alkoxides physically bind H₂ and manganese, nickel, and copper alkoxides chemically bind H₂. Hydrogen binding energies calculated with quantum mechanics are -10, -22, -20, -78, and -84 kJ mol⁻¹, respectively, for the first hydrogen molecule. Of these, lithium and manganese alkoxides bind H₂ too weakly to enhance adsorption at ambient temperature, even at 100 bar. Owing to the strong binding energies, Ni and Cu exhibit high uptake at low pressure, but metal alkoxide sites saturate at pressures as low as 1 bar. They thus exhibit poor deliverable capacities (calculated here as the wt% H₂ at 100 bar minus the wt% H₂ at 2 bar). The deliverable capacities from the simulations are shown in Figure 1 for MOFs with one functional group per linker. Magnesium alkoxide exhibits low uptake at low pressure and high uptake at high pressure and is a promising functional group for enhanced ambient-temperature hydrogen storage in all MOFs studied.

Additionally, we explored the effect of the number of alkoxide groups per MOF linker on hydrogen adsorption and the enthalpy of adsorption. We found that increasing the density of functional groups leads to an increase in hydrogen adsorption for a Mg-alkoxide-functionalized MOF but not for a Mn-alkoxide-functionalized MOF. The behavior can be explained by examining the enthalpies of adsorption in the different materials. These results show that increasing the number of alkoxide groups per linker significantly enhances the H₂ uptake and is thus a promising strategy for improving H₂ storage, but the strategy must be focused on the right metals.

Quantum mechanical results have also provided information on the nature of the hydrogen interactions

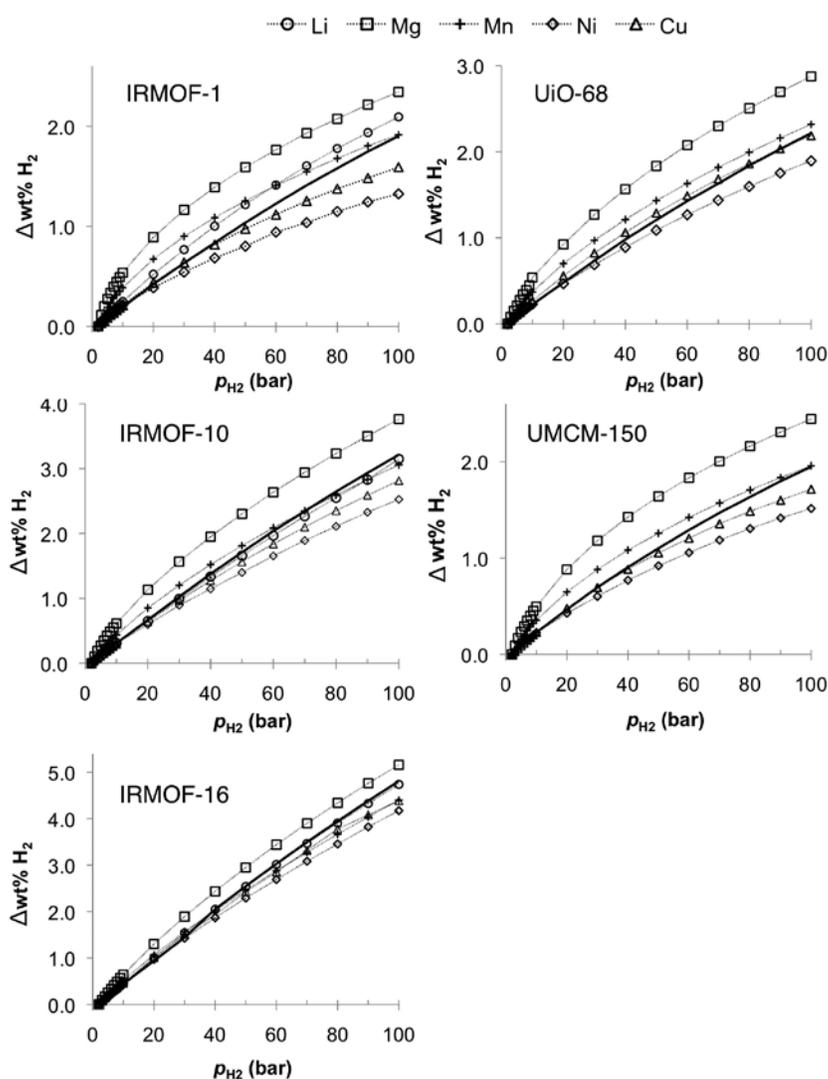

FIGURE 1. Deliverable hydrogen storage capacity [$\Delta\text{wt}\% = \text{wt}\%(p_{\text{H}_2}) - \text{wt}\%(2 \text{ bar})$] as predicted by GCMC simulations for metal alkoxide functionalized MOFs at 243 K. The MOFs are functionalized with one alkoxide site per linker. Deliverable capacities for unfunctionalized MOFs are depicted by thick solid lines without symbols.

with the exposed metal sites. (See Figure 2.) The average and differential hydrogen binding energies were also calculated for up to five H_2 molecules per metal atom. Results are shown in Figure 3. The binding energy on Li remains relatively constant for up to 3 H_2 molecules and then starts to weaken, whereas the binding energy on Mg weakens between $n = 1$ and $n = 2$ and then levels off before weakening again at $n = 4$. The binding energy to Mn alkoxide decreases between $n = 1$ and $n = 2$ and then remains relatively constant up to $n = 5$. (These trends are more easily seen in the differential binding energies of Figure 3.) In contrast, Ni and Cu bind H_2 very strongly initially, but the binding energies weaken dramatically as additional H_2 molecules adsorb.

Motivated by the modeling work, the experimental effort on MOFs this year has focused on synthesizing MOFs with divalent cations, especially Mg^{2+} , bound through a catecholate functionality. We synthesized a candidate MOF strut featuring a protected catechol group and successfully synthesized a MOF containing the strut in protected form. Suitable crystals for X-ray examination are in hand and awaiting analysis in our centralized X-ray characterization facility. Deprotecting the catechols once they are built into MOFs has proven challenging. We have tested several techniques. Preliminary studies (mainly with organic polymer analogues) indicate that high yields for deprotection are achievable with at least one of the techniques.

We have synthesized additional quantities of MOF NU-100, which will be sent to the National Renewable Energy Laboratory (NREL) for corroboration of our findings of high hydrogen uptake that were reported last year [2]. We also worked with NREL on validation and calibration of our own high-pressure sorption instrument.

In previous years of the project, we had developed microporous POFs using Schiff base and Bakelite chemistries. During FY 2011, we also reported a third class of highly stable, microporous POFs using “click chemistry.” They are synthesized via copper-catalyzed alkyne-azide coupling between two rigid tetrahedral building blocks. We investigated the effect of the amount of the reducing agent (sodium azide) used on the pore properties of these “click-based” POFs. The highest surface area achieved for this type of POF was $1,440 \text{ m}^2\text{g}^{-1}$ and the hydrogen uptake was also promising at low pressure (up to 1.6 wt% at 1 bar). Some effort this year was devoted to further optimizing the reaction conditions for the POF syntheses to enhance the microporosity and hydrogen uptake in these materials.

We have also attempted to attach metal cations in the phloroglucinol and “click-based” POFs to increase the hydrogen adsorption enthalpy. For example, phloroglucinol POFs have large numbers of OH groups that can react with alkyl metal compounds to produce metal functionalized POFs. We employed a variety of metal compounds and synthetic strategies to accomplish the metal introduction. In one case, we used POFs based on condensation reaction between melamine and different aromatic aldehyde

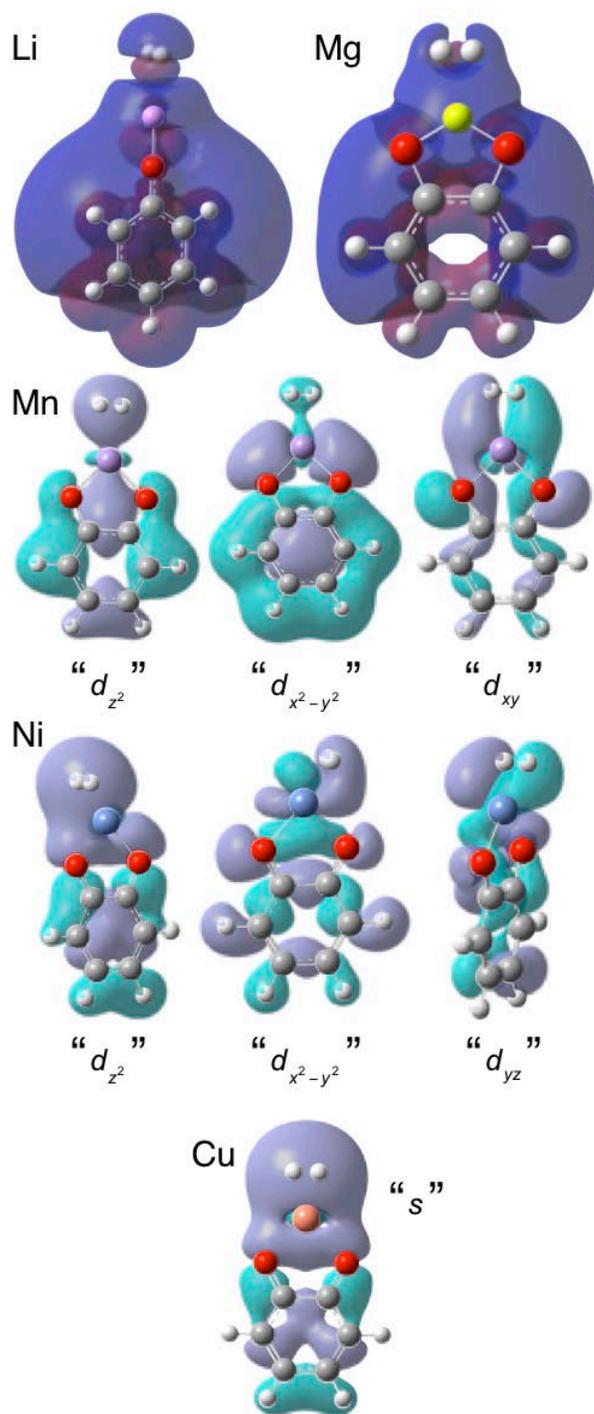

FIGURE 2. Binding properties for H_2 to metal alkoxide benzenes from quantum chemical calculations. (Top row) Charge density differences indicate Li and Mg polarize H_2 , resulting in charge density accumulation between the metal cations and H_2 . Regions of charge density accumulation and depletion are red and blue, respectively. (Second row) Molecular orbitals for H_2 adsorption to Mn alkoxide benzene indicate a variety of interactions between H_2 $1\sigma^*$ and Mn d orbitals. H_2 is strongly polarized and can interact with both spherical (d_{z^2}) and nonspherical (d_{xy}) orbitals. (Third row) Nickel alkoxide benzene has a variety of d orbitals for interaction with H_2 $1\sigma^*$, and a representative subset is shown here. (Bottom row) Copper alkoxide benzene forms a strong σ bond with H_2 .

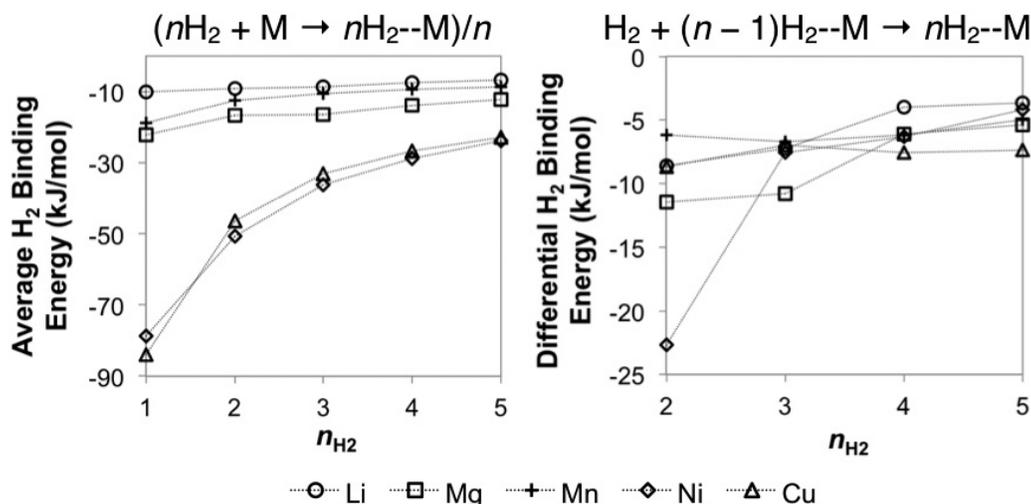

FIGURE 3. Average (left) and differential (right) binding energies for H₂ to metal alkoxide benzenes for 1–5 H₂ molecules, from quantum chemical calculations. Note that the average and differential energies are equal when $n = 1$.

building blocks with sites for metal binding. In our initial experiments we have successfully incorporated high amounts of metals like manganese (Mn) and magnesium (Mg) in our POFs (Table 2). Our next step is to study the effect of metal incorporation on the hydrogen uptake and the heats of adsorption in these POFs.

TABLE 2. Metal Loadings in POFs 2a and 2b

POF	Metal Source	wt% metal
POF 2a	Mn(CH ₃ COO) ₂	30 wt% Mn
POF 2a	Mg(CH ₃) ₂	14 wt% Mg
POF 2b	Mn(CH ₃ COO) ₂	23 wt% Mn

Conclusions and Future Directions

Conclusions

- We computationally screened Li, Mg, Mn, Ni, and Cu alkoxide-functionalized MOFs for their deliverable hydrogen storage capacity and found that Mg-alkoxide is the most promising of these metals.
- We synthesized a MOF containing protected catechol groups and found that the deprotection and introduction of Mg²⁺ is challenging. Preliminary studies with organic polymer analogs indicate that high yields for deprotection are achievable with at least one of the techniques investigated.
- We have developed a new class of POFs based on click chemistry, with surface areas up to 1,440 m²/g.
- We have developed POFs based on condensation of melamine and other building blocks. Levels of Mg incorporation up to 14 wt% can be achieved.

Future Directions

- Finish validation (with NREL) of very high cryogenic hydrogen uptake in MOF NU-100.
- Finish optimization of deprotection strategies for introducing alkaline earth alkoxide functional groups into MOFs.
- Explore other chemistries for introducing alkaline earth alkoxide functional groups into MOFs and POFs.
- Test hydrogen uptake in recently synthesized POFs with high metal loading.
- Combine strategies for introducing cations into MOFs and POFs with strategies for producing MOFs and POFs with very large surface areas.
- Model new functionalities for introducing cations into MOFs and POFs.

Project End Date: September 30, 2011

- Gravimetric density: 1.8 kWh/kg
- Volumetric density: 1.3 kWh/L
- Cost: \$2/kWh net

FY 2011 Accomplishments

- Successfully designed and synthesized a series of B-containing POPs with high specific surface areas (SSA) and narrow pore size distributions (PSD). Hydrogen uptake and isosteric heat of adsorption measurements found enhanced adsorption enthalpy for the POPs with higher boron-to-carbon ratio.
- Successfully designed and synthesized a series of metalloporphyrin POPs (PPOR) containing transition metals such as nickel, cobalt and iron. Excess H₂ storage capacities of 0.035 kgH₂/(kg_{Adsorbent}+H_{2adsorbed}) and 0.0026 kgH₂/L_{Adsorbent} were achieved. Hydrogen adsorption enthalpy over PPOR was found to be dependent on the type of metal exchanged into macrocyclic ring with Ni having the highest value.
- Successfully designed and synthesized two POPs incorporated with high level transition metals through hydroxyquinoline ligation. Both Co and Ni were used for the synthesis and the adsorption enthalpy of 9.9 kJ/mol was achieved.
- Conducted measurement for hydrogen adsorption/desorption kinetics over a representative POP at both ambient and liquid nitrogen temperatures. The result indicated the surface equilibrium can generally be reached within 10 to 20 seconds.

Fiscal Year (FY) 2011 Objectives

- To design, synthesize, and evaluate POPs as hydrogen storage adsorbents for transportation applications.
- To support POP development with in-depth understanding of hydrogen-adsorbent interactions through modeling/simulation and advanced characterization.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cells Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (B) System Cost
- (C) Efficiency
- (D) Durability/Operability

Technical Targets

The focus of this project is to prepare new POPs as hydrogen adsorbents with improved storage capacity and heat of adsorption through rational design, guided by computational modeling and advanced characterization. It supports DOE's initiative in developing adsorption-based storage technology with high uptake capacity, reversibility, and stability. The successful outcome of the project will produce a new storage material that meets DOE 2015 targets:

Introduction

On-board hydrogen storage represents a critical technology for implementing H₂-powered fuel cell vehicles. To achieve a practical driving range, the storage system must meet the gravimetric and volumetric densities set by DOE. Our team addresses these challenges by exploring a new class of hydrogen adsorbent, POPs. Compared with other adsorbents, POPs have excellent thermal stability and tolerance to contaminants such as moisture. POPs also have low skeleton density and high intrinsic porosity generated by covalent bonds, capable of maintaining SSA during high pressure pelletizing for better volumetric density. Furthermore, they can be produced at a commercial scale with the existing industrial infrastructure. Significant progress has been made with the focus on improving hydrogen uptake capacity and the heat of adsorption by enhancing SSA, porosity, and surface-adsorbate interactions through rational design at the molecular level [1-5].

Approach

A key technology challenge for the physisorption based hydrogen storage media, in addition to capacity and cost, is the heat of adsorption which should be in the range of 15 to 20 kJ/mol for practical applications. Our design principles of improving POP's storage capacity at ambient temperature include: (a) high SSA to provide sufficient interface with H₂; (b) narrow pore diameter to enhance van der Waals interactions through confined space; and (c) "metallic" characters, either through π -conjugation or metal doping, to promote electronic orbital interactions with H₂. Since the inception of this project, we have prepared over 100 different POPs targeting to these properties, including aromatic, hetero-aromatic and transition metal (TM)-doped systems, and investigated the surface structural and chemical impacts to the adsorption enthalpy. In FY 2011, we remain focused on H₂ isosteric heat of adsorption improvement. Several new POPs were systematically designed and synthesized. One series is polycarborane POPs. We developed a synthetic strategy to successfully incorporate high level of boron in form of carborane in POPs with high SSA narrow PSD. We found clearly the adsorption enthalpy improvement through inclusion of boron. Another example is a series of TM-doped PPORs prepared via several parallel crosslinking chemistries. We successfully added three TM ions (Co⁺², Fe⁺³, Ni⁺²) into PPORs through chelation with porphyrin's N₄ macrocycle. We identified different impacts

to the heat of adsorption depending on the type of TM. To increase the level of TM in POP therefore higher adsorption enthalpy, we also developed a new synthetic approach in preparing stable, porous framework through ligation between Co⁺² or Ni⁺² with hydroxyquinoline. We found indeed the enhanced hydrogen adsorption enthalpy over the new POP systems.

Results

From our cumulative experiences of over hundred synthesized POPs under three property categories, we conclude that the adsorbent pore size, within synthetically achievable sub-nanometer range, has relatively low influence to the hydrogen adsorption enthalpy [2]. Surface modification by introducing selected non-C main group elements or metals, on the other hand, does improve the interaction between hydrogen and POPs. Polycarborane POP represents an example of main-group elemental substitution. Boron-doped carbon cluster is known to promote non-dissociative hydrogen binding with adsorption energy of 19 kJ/mol was predicated [6]. Experimentally, improved adsorption energy was found in B-doped carbon produced by pyrolysis although the surface area was somewhat limited [7]. In our laboratory, we designed three different carborane-containing POPs, BPOP-1, 2 and 3 using trimerization and Friedel Crafts alkylation reactions. An example of the reaction scheme for BPOP-2 is shown in Figure 1. These

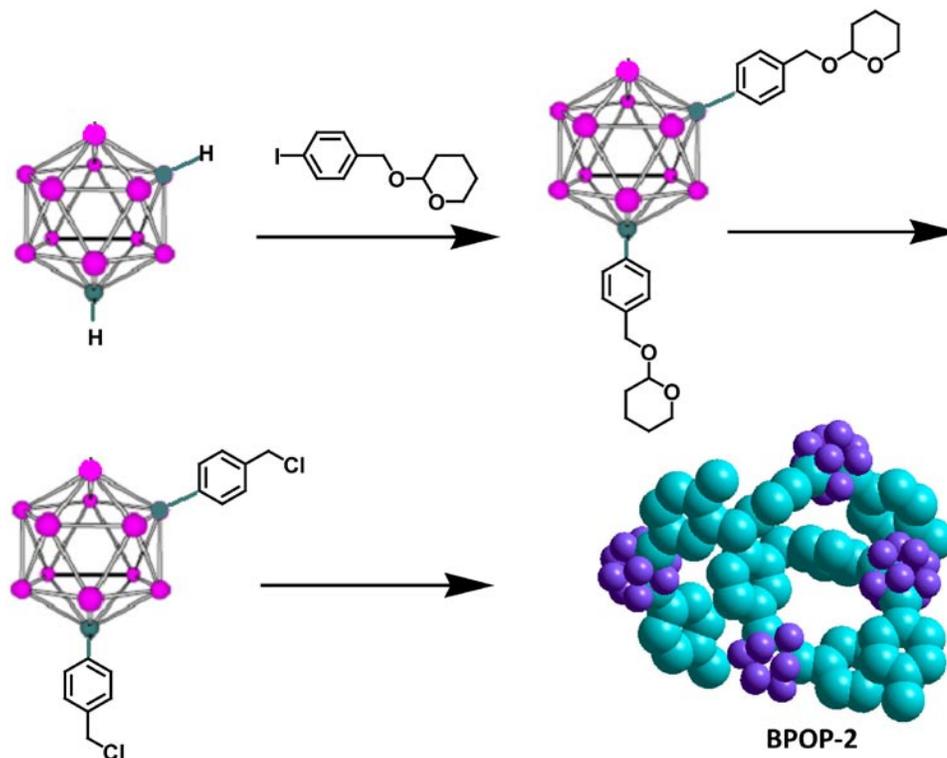

FIGURE 1. Synthetic Scheme for Preparing BPOP-2

cross-linking reactions yielded B-containing POPs with relatively high SSA from 400 to 1,100 m²/g, narrow PSD, and perhaps most importantly, high B/C ratio in the composition. Table 1 lists the surface properties, hydrogen storage uptake and isosteric heat of adsorption obtained from N₂-Brunauer-Emmett-Teller (BET) and Sievert isotherm measurements. It demonstrates a positive correlation between B/C ratio and the adsorption enthalpy.

A second series we investigated is PPOR with different TMs exchanged into the macrocyclic ring. In such system, the TM ions are ligated by four nitrogens in a square-planar

configuration, leaving the metals exposed to the interaction with hydrogen at both sides. We successfully prepared a variety of PPORs using several synthetic schemes, as are shown by the examples in Figure 2, and incorporated ionic Fe, Co and Ni into the POPs. We also measured surface property, excess hydrogen storage capacity and isosteric heat of adsorption. We found that while the impact to enthalpy by metal is limited with values in the range of 8 to 9 kJ/mol, their inclusion clearly enhances POPs interaction with hydrogen. The difference in adsorption enthalpy is relatively minor with respect to TM type used in this

TABLE 1. Surface Properties, Hydrogen Adsorption Capacities and Enthalpies of Different BPOPs

	BET SSA (m ² /g)	Langr. SSA (m ² /g)	Tot Pore Vol (cm ³ /g)	μ-pore Volume (cm ³ /g)	Pore Diameter (nm)	H ₂ Gr. Uptake @ 77 K (kgH ₂ /kgAds+H ₂)	B/C ratio	ΔH _{ads} (kJ/mol)

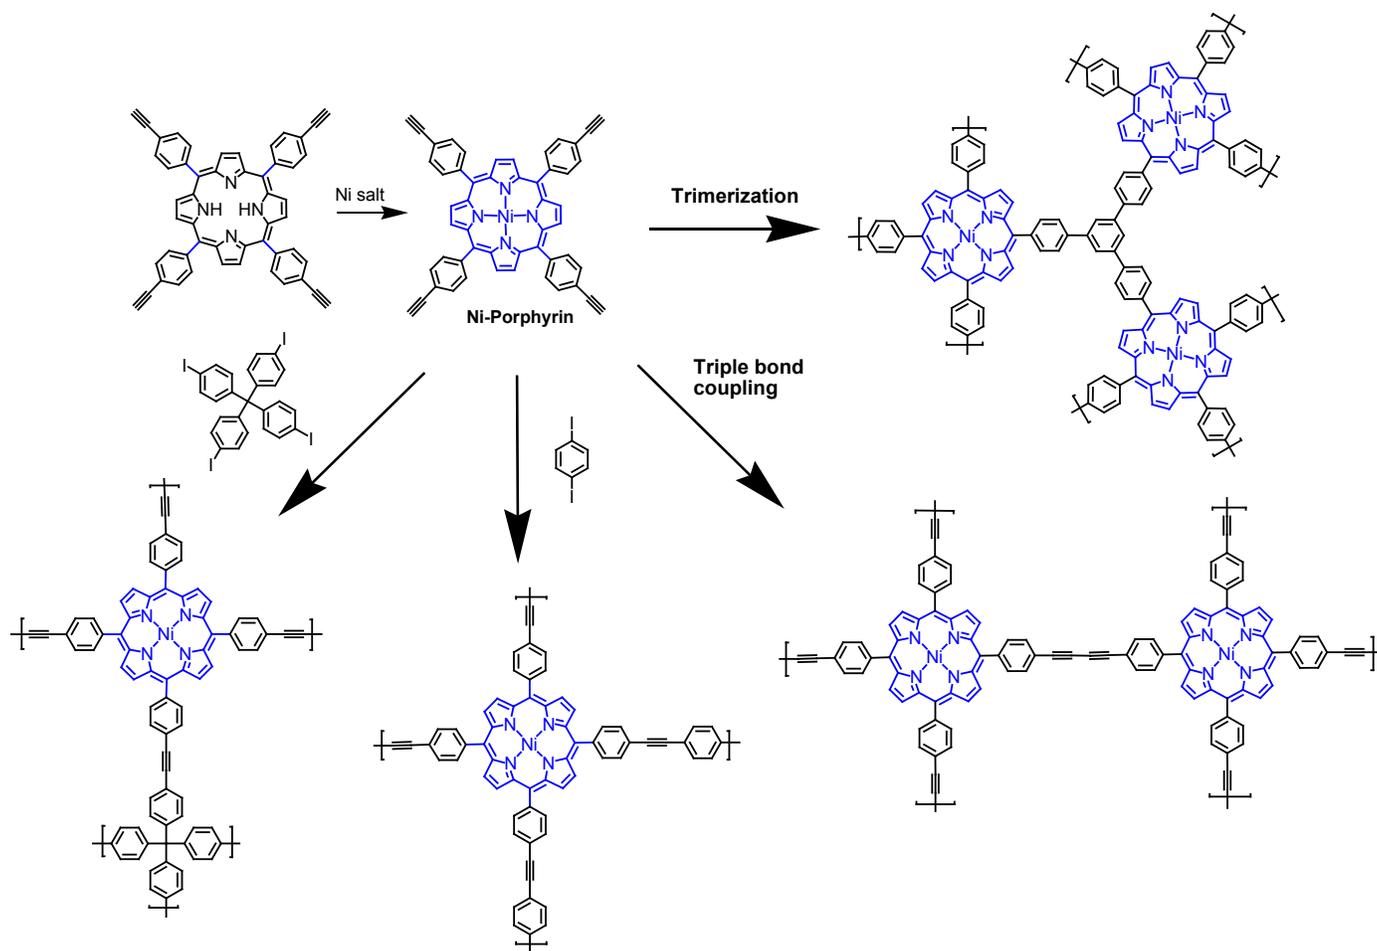

FIGURE 2. Four Parallel Synthetic Schemes for Preparing Different Ni-PPORs

study. The storage capacity is still mainly dominated by the SSA of the PPORs. To verify if the heat of adsorption behaves differently under different TM coordination, we also conducted a parallel study of two TM-containing POPs, prepared through chelation of Ni⁺² or Co⁺² with hydroxyquinoline. Both POPs have high metal contents (~14% by weight) and similar SSAs (~600 m²/g). The key difference is that one is connected through square-planer (nickel) and the other through tetrahedral (cobalt) coordination. Our BET analysis showed that POP formed through the tetrahedral linkage has an average pore diameter of 0.8Å larger than that formed through the square-planer connection. Interestingly, the Co-based POP showed nearly 10 kJ/mol adsorption enthalpy, almost 2 kJ/mol higher than of Ni-based POP.

Conclusions and Future Directions

In summary, we produced a broad range of POP-based adsorbents with high SSA, narrow PSD, and excellent chemical stability. These POPs, particularly those with metal exchange capability or B-incorporated backbone, could serve as excellent platforms for further development of materials with better adsorption enthalpy for ambient temperature applications:

- New metal elements, from both transition and main groups, could be exchanged into POPs through chemical or physical means, to achieve sufficient adsorption enthalpy suitable for near-ambient temperature application as predicated by theory.
- New surface modification techniques, departing from the conventional synthetic approaches, could have the potential to produce high binding energy sites.
- New POP designs with tailored surface property and chemical composition could serve as the precursors for further chemical/physical processing to improve H₂ binding energy.

Fiscal Year (FY) 2011 Objectives

- Synthesize designer microporous metal-organic frameworks (MMOFs) mixed with catalysts to enable H-spillover for H₂ storage at 300 K-400 K and moderate pressures.
- Optimize volumetric analyzer to increase precision and accuracy at high-pressure.
- Improve better dispersion of nano-metal catalysts, and examine uptake of MMOFs mixed with catalysts. Vary catalyst mixing technique to ensure optimal interfacial contact for spillover.
- Demonstrate spectroscopic evidence for spilled over atomic hydrogen in a Pt/carbon system, to help resolve potential confusion regarding physisorption versus chemisorption in spillover materials.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume

FY 2011 Accomplishments

- Improved accuracy of differential volumetric equipment 12-fold.
- Validated system against National Renewable Energy Laboratory blind sample.
- Explored mixing conditions on reproducibility of spillover of PtC/IRMOF. Demonstrated catalyst-MMOF contact needs improvement.
- Began new catalyst-MMOF mixing techniques.
- Demonstrated 22% increase in Maxsorb activated carbon after incorporating well-dispersed Pt catalyst.
- Demonstrated 1.2 wt% uptake on Pt/AC-INER at 1 bar and 298 K (supplied from collaborator INER, Taiwan).
- Synthesized new MMOFs with variations in surface chemistry for spillover studies.
- Developed MMOFs of high thermal and water stability by eliminating M-N bonds.

- Explored conditions to produce nanocrystals of MMOF samples for more efficient and uniform mixing with Pt/carbon catalyst.
- Raman in situ spectroscopy for the evidence of spilled over atomic hydrogen in Pt/carbon system and clarification of physisorption vs. chemisorption issue.
- Identified hydrogenation site for PtC/CuBTC via Fourier transform infrared and Raman spectroscopy.

Introduction

The term hydrogen spillover has been used to describe a synergistic effect between high-surface area adsorbents and associated catalysts. The associated catalyst may act to dissociate molecular H₂ into atomic H species. The atomic H is then free to migrate to surface sites on the high-surface area support; the net surface H concentration is a function of the relative rates of surface migration versus desorption from the surface. This process occurs at moderate temperature (i.e. 300 K) and generally leads to a much higher uptake than expected for the metal catalyst or high-surface area adsorbent alone. Spillover materials using MMOFs have been reported to have high uptake at ambient temperature: bridged ('br') PtC/IRMOF8 achieved 4 wt% excess adsorption at 100 bar and 298 K [1]. Independent groups have demonstrated up to 4.2 wt% at 6.9 MPa after extended equilibration for brPt/C/IRMOF-8 [2]. Subsequent reports on spillover materials at room temperature have varied from less than physisorption to almost 9 wt%, demonstrating difficulties in reproducibility and invoking controversy. These uptakes approach DOE goals; however, as the process is highly dependent upon synthesis, measurement, and catalytic particle size [3,4], the process remains poorly understood. It is anticipated that optimization of the MMOF structure, surface chemistry, and porosity will further increase uptake via spillover. Meeting DOE hydrogen storage targets at moderate temperature will have significant engineering advantages for mobile applications, as temperature of operation has implications for system weight.

Approach

The project relates to materials development and optimization of catalyst, surface chemistry, crystal and pore structure, and system parameters for the hydrogen spillover phenomenon. To optimize catalyst, platinum nanoparticle wet precipitation method [5] was used to get better metal dispersion. For surface chemistry, different MMOFs were mixed with catalyst to test hydrogen storage and the effect of functional groups. In addition, acid, base, and high temperature after-treatments were used in metal/carbon catalyst systems to have various surface functional groups and to test hydrogen uptake afterwards. We also scrutinized the effect of MMOF structural change on spillover hydrogen

adsorption via different mixing strategy with Pt/C catalysts. The project is currently exploring materials without bridging, as bridging has unknown effects on the surface chemistry and structural parameters we hope to optimize.

As discrepancy and debates in spillover hydrogen storage arise, we have spent considerable effort improving our differential volumetric measurement method for better precision and accuracy. We have demonstrated that simple differences in data processing, volume calibration, pumping, and He blank treatment have a drastic effect on the precision of measurement. Validation against published data [6] for GX-31 superactivated carbon and multiple measurements for PtC/IRMOF8 demonstrates better reliability. Moreover, in situ high-pressure spectroscopy is currently being incorporated into the project to characterize spilled over atomic hydrogen.

Results

The measurement instrument employed for our sorption studies is a custom-built volumetric differential Sievert's apparatus with two high-accuracy pressure transducers; an absolute pressure transducer and a differential pressure transducer. Single-sided Sievert's apparatus are broadly used in hydrogen adsorption measurements [7], and a differential unit provides greater accuracy due to simultaneous collection of a blank, a measurement that is highly insensitive to temperature gradients, and generally a higher accuracy of the differential pressure reading relative to the absolute pressure reading. In all volumetric methods, the moles adsorbed are calculated via a mass balance, assuming mass loss from the gas phase is solely due to adsorption to the sample. The accuracy of the measurement relies on an accurate volume calibration, which in turn, relies on the accuracy of the pressure transducers. At 80 bar, 298 K, 100 mg sample measurement, the 'base' error in the measurement of our system (based on mathematical propagation of error using measured variations in volume calibration) is 1 ± 0.6 wt%, which would also be typical for a single-sided measurement. By using the more accurate differential pressure-transducer to calibrate the volume, the error is reduced 12-fold to 1 ± 0.05 wt% (obtained by error propagation with the same inputs, but different operating equation). Nonetheless, since high pressure He is used in this new improved method, it is expected to be prone to systematic error if He adsorbs or if trace residual H₂ is present in the system. The latter may lead to large error for spillover samples, so we are developing a new method that circumvents the high-pressure He calibration, but with a precision of the same level. Current data reported herein is subject to possible He adsorption and/or H₂/He cross-contamination and thus represents highly conservative values. All the methods were validated against published data for GX-31 [8].

Reports from Tsao et al. and Yang et al. [9] state that small catalyst size ($d < 2$ nm) is essential for high uptakes via spillover. For a better platinum dispersion in Pt/C catalysts,

wet precipitation method was used as described in a recent publication [5]. Platinum on carbon Maxsorb (Pt/M) was synthesized with good metal dispersion and it confirms the spillover hydrogen uptake data (0.97 wt% at 71 bar, 300 K) published by Yang et al. [5].

With commercial Pt/C and custom synthesized Pt/M, we focused on reproducibility, preparation, and introduction of oxygen functional groups of MMOFs mixed with catalysts. In IRMOF-8 series, different ball milling ratios were used to alter structure. X-ray diffraction (XRD) of the resulting materials shows subtle difference, which can be attributed to damage induced from the mixing procedure [10]. The highest uptake was observed for a material with distorted—but still intact—XRD. Improved catalyst (Pt/M versus commercial Pt/C) did not consistently increase uptake of the mixed Pt/M/IRMOF8 (Table 1 and Figure 1), suggesting our current mixing procedure is insufficient for spillover to populate the IRMOF8. Thus, methods by which to directly incorporate catalysts into various MMOF structures are in progress. Also, frameworks made solely of strong M-O bonds are being developed which prove to have significantly enhanced thermal and water stability. We are currently exploring MMOFs with incorporated NH_2 groups, which serve as an anchoring site for direct metal-doping for H_2PtCl_6 [11]. Separately, carbonyl or hydroxyl groups functional groups were induced into MMOFs (MMOF=O

and MMOF-OH) to test the role of these groups on spillover. After mixing, subtle changes are seen in XRD, but MMOFs remains largely intact. The adsorption amounts are still low (Table 1), but changes in MMOF surface chemistry is not likely to increase uptake until the catalyst MMOF interfacial contact issue can be addressed.

We also examined the effect of surface chemistry on carbon, when carbon serves as the receptor in primary spillover materials. Surface chemistry on Maxsorb was varied using different after-treatments, including high temperature anneal, acid oxidation, and basic oxidation. The removal or increase of surface oxygen groups affected the size of the supported metal: oxidation increased metal crystal size and reduced dispersion (Figure 2a), in certain cases, cations led to pre-precipitation of Pt particles and led to large metal particles. The best uptake achieved for this series of materials was 1.0 wt% for Pt/M_v (Table 1), which is a material that has been annealed to remove oxygen groups. The uptake represents a 22% increase over the undoped Maxsorb precursor.

A Pt-doped activated carbon (Pt/C-INER) provided by C.S. Tsao (INER, Institute of Nuclear Energy Research, Taiwan) showed high low-pressure gravimetric uptake of H_2 (i.e. 1.2 wt% at 298 K and 1 bar [measured at Penn State]; >5 wt% at 69 bar and 298 K [measured in Taiwan] [9]). It was used to probe the interactions between the carbon surface and dissociated hydrogen (H^*) when the H^* was

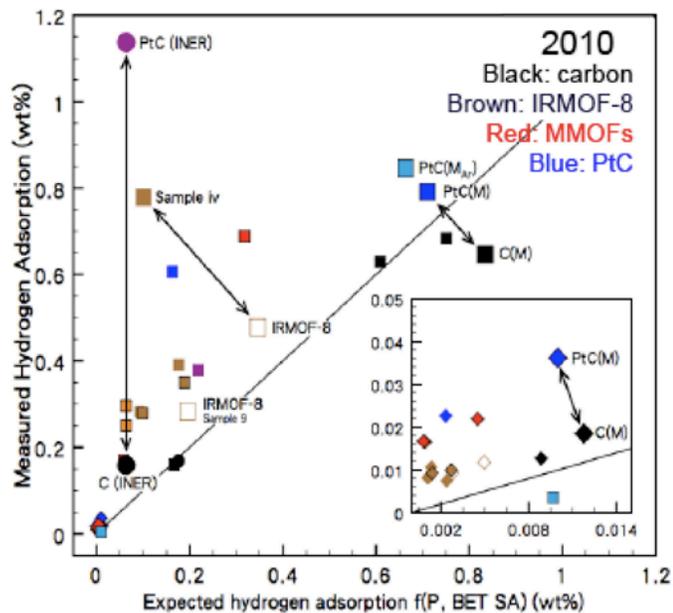

FIGURE 1. Summary of all 2010 H_2 uptake data (excess; relative to He blank at same conditions). H_2 uptake is plotted against uptake “Expected adsorption”, which assumes uptake is linearly proportional to both surface area and pressure, i.e. an adapted Chahine Rule [12]. Data is plotted in this way to summarize multiple data at various adsorption pressures in one plot. MMOF samples (IRMOF8 in brown; modified surface chemistry in red) are physically mixed with PtC catalyst. Arrows are used to connect undoped precursor samples with those with catalyst, e.g. carbon (black) and Pt-doped carbon (blue).

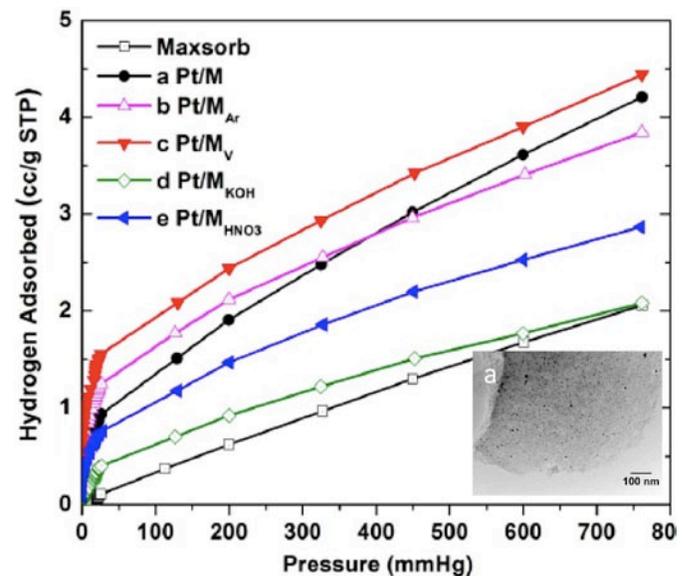

FIGURE 2. Effect of carbon surface chemistry on metal dispersion (low-pressure knee) and low-pressure H_2 isotherms at 1 bar for: (M) Maxsorb (M) activated carbon (a) Pt-doped M, following procedures of Yang et al.; (b) Pt/M_{Ar}: M is annealed at 950 °C in Ar prior to Pt-doping; (c) Pt/M_v: M is annealed in vacuum at 1,000 K for 3 hours prior to Pt-doping; (d) Pt/M_{KOH}: M is oxidized with KOH prior to Pt-doping; (e) Pt/M_{HNO3}: M is oxidized with concentrated (~70%) HNO_3 prior to Pt-doping. Inset (a): transmission electron microscope image of Pt/M shows high dispersion, which was not obtained prior to following the doping procedure of Yang et al.

provided by the adjacent Pt catalyst. In situ Raman (514 nm, 2 mW) measurements of Pt/C-INER were conducted within a silica fiber (wall thickness of 30 μm and center hole of 100 μm ; see right, Figure 3) to allow for sequential He and H₂ gas exposures with intermittent degas). A series of sequential He and H₂ exposures were then performed, with a 72 hour vacuum degassing process at 300 K with the turbo pump between each gas introduction (Figure 3). Pt/C-INER in He shows features characteristic of a solid carbon, including a D-band ($\sim 1,350\text{ cm}^{-1}$), G-band ($\sim 1,590\text{ cm}^{-1}$). After He removal and pumping, Pt/C-INER in H₂ at the same spot shows additional bands at $1,180\text{ cm}^{-1}$. These new features vanish after H₂ gas is removed under vacuum and reappear on a second H₂ exposure. The features were not found in Pt, activated carbon precursor, unactivated carbon, or fiber. Thus, the features at $1,180\text{ cm}^{-1}$ are consistent with a hydrogen spillover process, and given the frequency, can be assigned to a wagging mode coming from weakly bonded atomic hydrogen and the carbon substrate.

Conclusions and Future Directions

- Improvements are made in differential volumetric measurements. Current accuracy is at least 1 ± 0.05 wt% when a 100 mg sample is used.

- Pt-doped AC provided by INER had high uptake at low pressure (1.2 wt% at 1 bar), demonstrating continued promise of spillover mechanism.
- In situ spectroscopy for Pt/AC-INER shows a reversible Raman feature at $1,180\text{ cm}^{-1}$ in hydrogen only, associated with C-H chemical bond. The mode is reversible when H₂ is removed at 298 K. Reversibility is dependent upon carbon structure.
- Type and form of oxygen groups on carbon substrate affects Pt particle size and ultimate spillover.
- Current studies for spillover to MMOF are limited by interfacial contact. Future work will focus on methods to direct dope MMOFs with catalyst. MMOF structure is also an important parameter in obtaining uptake via spillover, and is dictated by mixing technique.
- Future work will explore new methods to facilitate catalyst-carbon-MMOF contact, including doping of MMOF-NH₂; effect of particle size; addition of terminal ligand/solvent for surface amino modification for catalyst anchoring; addition of carbon aerogel for pre-formed bridge.
- Future work will alter MMOF structure to introduce high density hydrogenation sites, open metal sites and separately, introduce holes that may facilitate spillover.

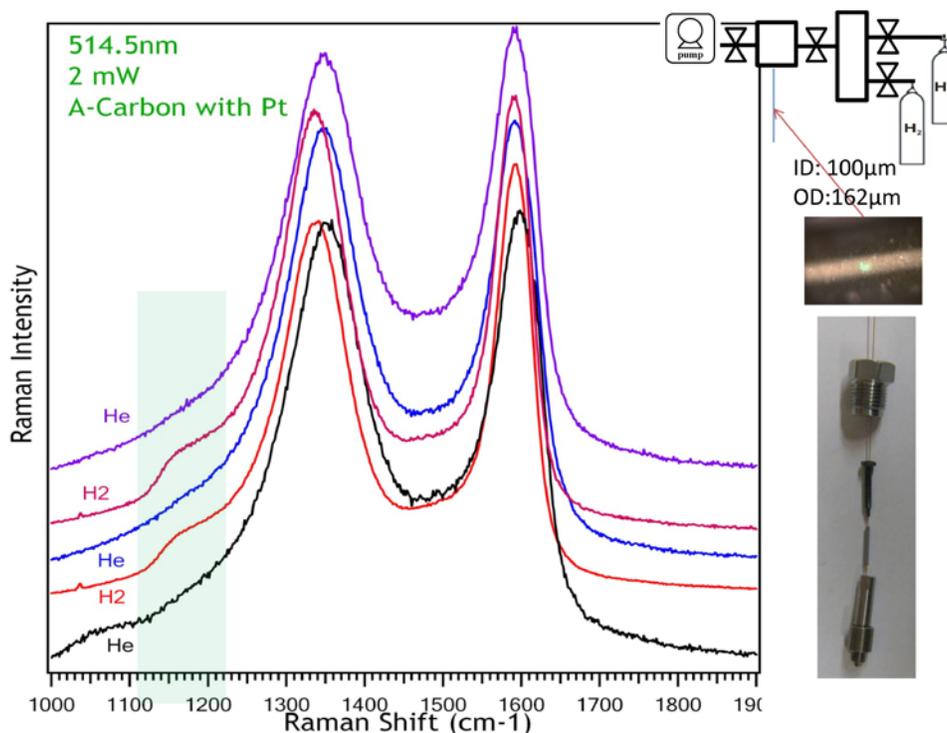

FIGURE 3. Raman spectra of Pt/C-INER at 298 K in a fiber (A) showing D-band ($\sim 1,350\text{ cm}^{-1}$), G-band ($\sim 1,590\text{ cm}^{-1}$), 2D-band ($2,700\text{ cm}^{-1}$) and a D+G band ($\sim 2,940\text{ cm}^{-1}$), exposed sequentially (after intermittent degas at 298 K) to (a) He gas (b) H₂ (c) He (d) H₂, and (e) He. Reversible bands at $1,180$ and $2,500\text{ cm}^{-1}$ are seen only in the presence of H₂ gas, and are removed after pressure reduction at 298 K (B).

- Future work will include a systematic study of introduced functional groups on MMOF-4,4'-bypyridine series with in situ spectroscopy.
- Write and submit papers on: (1) methods validation and reproducibility in differential volumetric analyzer; (2) hydrogen spillover on PtC/CuBTC; and (3) variation of MMOF structure/chemistry with secondary spillover studies.

Subcontractors:

- Craig M. Jensen, University of Hawaii, Honolulu, HI
- Plamen Atanassov, University of New Mexico, Albuquerque, NM
- Michael Hirscher, Max Planck Institute, Stuttgart, Germany
- Michel Latroche, Institut de Chimie et des Matériaux (ICPME), Paris, France
- Karl Gross, H2 Technology Consulting LLC, Newark, CA

Project Start Date: October 1, 2010

Project End Date: Project continuation and direction determined annually by DOE

Fiscal Year (FY) 2011 Objectives

- Evaluate the weak chemisorption/spillover process as a means to achieve DOE 2015 Hydrogen Storage goals.
 - Lead sample exchange and measurement validation efforts for weak chemisorption.
 - Perform round robin with “standard” high specific surface area sorbents to ensure all participating laboratories are measuring similar hydrogen storage capacities.
 - Evaluate universal reproducibility of enhanced adsorption weak chemisorption/spillover effects.
 - Determine type of interaction of the support with the spillover hydrogen.
 - Establish if weak chemisorption/spillover is a viable process for hydrogen storage.
 - Communicate validated results to the community at large.
- Provide highly accurate hydrogen storage measurement support to the sorption community in order to validate exceptional results.
- Coordinate additional work for the Best Practices Document.

Technical Barriers

This project addresses the following technical barriers from the Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) Cost
- (B) Weight and Volume
- (C) Efficiency
- (E) Refueling Time
- (M) Hydrogen Capacity and Reversibility
- (N) Understanding of Hydrogen Physi- and Chemisorption
- (O) Test Protocols and Evaluation Facilities

Technical Targets

This project is validating experimentally observed weak chemisorption. Insights gained from this work may be applied toward the future design and synthesis of hydrogen storage materials that meet the following DOE 2015 hydrogen storage targets:

- Cost: \$4/kWh net
- Specific energy: 1.5 kWh/kg
- Energy density: 0.9 kWh/L

The specific technical objectives include:

- Verify at least 15% increase in hydrogen uptake over baseline sorbent material at room temperature conditions based on the effects of weak chemisorption/spillover.
- Via spectroscopic techniques, determine the type of hydrogen-substrate interactions from the enhanced spillover hydrogen using diffuse reflectance infrared fourier transform spectroscopy (DRIFTS), nuclear magnetic resonance spectroscopy (NMR), RAMAN spectroscopy, and neutron scattering.

FY 2011 Accomplishments

- Completed round-robin analysis of standard samples:
 - Achieved <5% error on hydrogen capacity measurements on the same standard sorbents (two were distributed) at three different laboratories. Completing the standard measurements at three others.
- Completed synthesis of three different spillover samples and distributed the initial set to the different labs for evaluation.

- Verified a >15% enhancement of hydrogen storage in Pd catalyst on template carbon (Pd/TC) materials via volumetric measurements (NREL and ICPME)
- Synthesized weak chemisorption/spillover materials at three different laboratories.
- Demonstrated spectroscopic evidence for spillover C-H bonds.
 - DRIFTS measurements where both Pt-C and Pd/TC showed a unique stretch that was tentatively assigned to spillover hydrogen.
 - Neutron scattering (Ru-BCx), revealed apparent hydrogen wagging modes which correlated to those energies predicted by theory.
 - Reported detailed findings and recommendations on hydrogen spillover results.
 - International Energy Agency Hydrogen Implementing Agreement (IEA-HIA) Task 22 meeting Freemantle, Australia.
 - DOE Fuel Cell Technologies Annual Merit Review, Washington, D.C.
 - Gordon Research Conference, Easton, MA (included a workshop meeting).
 - Pending: American Chemical Society (ACS) Meeting, (August 2011) and IEA-HIA Task 22 Hydrogen Storage Meeting (September 2011).
- Completed four out of five drafts for the Best Practices Document: 515 pgs, seven sections: Introduction, Capacity, Kinetics, Thermodynamics, Cycle-Life, Thermal Properties, Mechanical Properties Measurements.
- Evaluated the hydrogen sorption characteristics of two unique >5,000 M²/g high surface area metal-organic frameworks from Northwestern and Texas A&M Universities.

Introduction

The ultimate goal of the Hydrogen Storage subprogram is the development of hydrogen storage systems that meet or exceed the DOE's goals for the onboard hydrogen storage in hydrogen powered vehicles. With the tremendous interest in weak chemisorption materials for hydrogen storage, NREL and DOE have dedicated considerable resources working with partner institutions to synthesize specific materials and to develop/perform the requisite measurements in order to establish the capacity, kinetics and overall performance of these materials. The key critical issues that must be resolved for these materials include reproducibility of material synthesis, understanding the kinetics of H transport on receptor surfaces, and which chemical reactions are desired and which are not. In addition, weak chemisorption properties are intricately linked to more standard H₂ storage mechanisms, so information gained on the hydrogen-

substrate interactions should help accelerate viable sorbent development.

Approach

Organized and led an international group with IEA and International Partnership for the Hydrogen Economy members to validate weak chemisorption synthesis and measurement results. Participants include: Angela Lueking (Pennsylvania State University), Michael Hirscher (Germany), Michel Latroche (France), Thomas Gennett (NREL), Craig Brown (National Institute for Standards and Technology, NIST) Craig Jensen (University of Hawaii), Evan Gray (Griffith University), Craig Buckley (Curtin University), Mike Miller (Southwest Research Institute®), Channing Ahn (California Institute of Technology), and Tony Burrell (Argonne National Laboratory).

Our approach includes the synthesis and characterization of a series of materials with an unexplained enhancement of hydrogen sorption in the presence of catalysts, that is thought to be caused by hydrogen spillover. The materials selected are Pd/templated carbon, Pt/templated carbon, and Ru/BCx. These materials are being synthesized and validated across laboratories. As we move forward we will utilize volumetric measurements for verified capacity measurements. Then through spectroscopic evaluation of the materials with DRIFTS, neutron scattering and NMR we will determine correct peak assignments in order to determine if spillover hydrogen spectroscopic modes are in regions expected for room temperature hydrogen desorption. There will then be a coordination of efforts for inter-laboratory comparison of characterization of results and eventually a reconciliation of spillover propagation mechanisms to thermodynamic parameters.

Results

- **Validation of volumetric analysis of standards across laboratories.** NREL was the lead and distributed a series of samples to various laboratories for testing, Figure 1. As is evident in the isotherms we were able to coordinate and establish an approximate 5% absolute variation in results across six laboratories. The variations in the data were found to be caused by calculation error, skeletal density assumptions and/or null volume assumptions.
- **Confirmation of hydrogen sorption enhancement in Pd-Templated carbon materials.** NREL and ICPME were able to achieve a similar enhancement in hydrogen sorption on Pd incorporated into a templated carbon matrix. This adsorption was beyond that expected for palladium hydride formation, Pd-H₂, possibly from the addition of the Pd. This was confirmed on two separate samples. A large batch synthesis by ICPME was completed, and those samples are under analysis by other laboratories. NREL is currently synthesizing

Data normalized until the inter-laboratory comparison is complete.

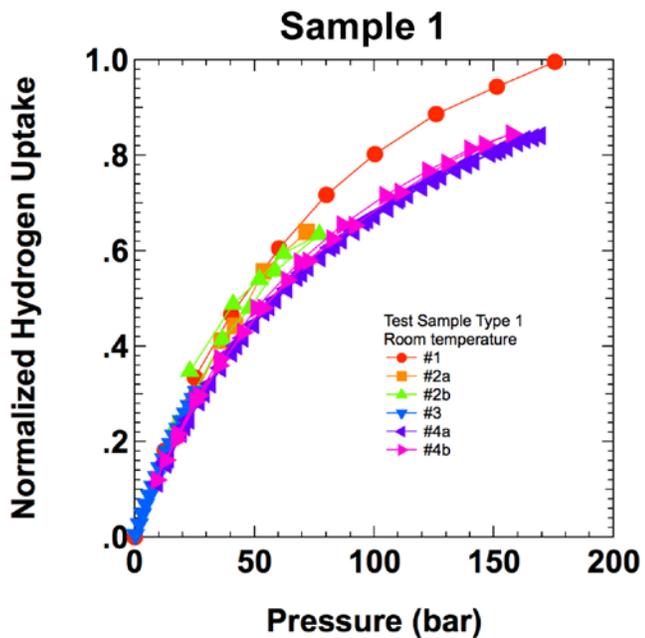

FIGURE 1. Inter-Laboratory Comparison of Volumetric Data for Two Distinct Samples

an independent batch of materials in order to confirm ability to synthesize in two distinct laboratories.

- **DRIFTS determination of new hydrogen-substrate interactions for an apparent spillover material.** Using infrared spectroscopy to identify distinct substrate-hydrogen interactions is an essential component of our work as we look to establish the energetics associated

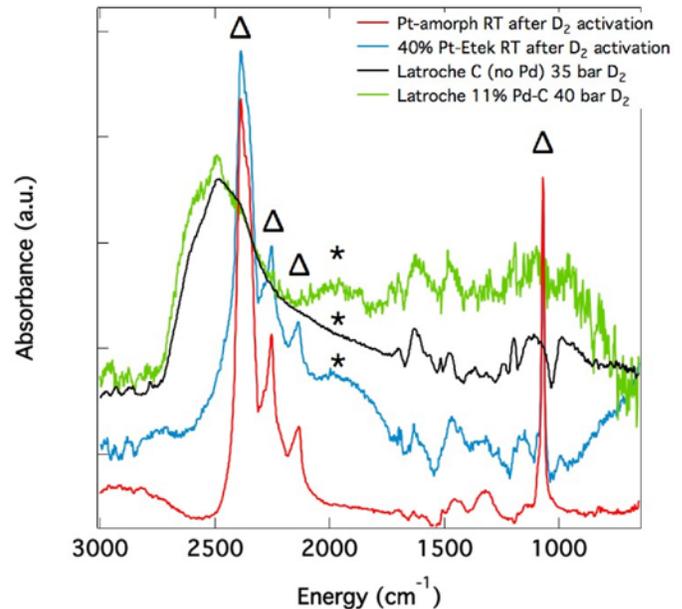

FIGURE 2. DRIFTS Spectra for Various Samples Charged with D_2 at Room Temperature

with the spillover hydrogen. Figure 2 shows DRIFTS spectra for several samples charged with D_2 and treated at two different temperatures. In one experiment, labeled “ D_2 activation”, the sample is charged with ~ 200 psi (~ 14 bar) of D_2 at room temperature, and then heated up to 200°C in the D_2 atmosphere. The other experiment is simply a room temperature D_2 charge with no heat treatment. Three samples in Figure 2 were subjected to a D_2 activation: an amorphous platinum sample (Pt-amorph), an activated carbon sample with 40% platinum (40% Pt-Etek), and a carbon sample from one of our partners, loaded with 11% Pd (Latroche 11% Pd-C). Interestingly, the D_2 activation procedure yields the same four sharp peaks, labeled by the triangles, for all three of these samples. A group of three sharp peaks occur at 2,386, 2,254, and 2,135 cm^{-1} , along with an isolated peak at 1,068 cm^{-1} . The three higher energy peaks are in the range expected for surface hydroxyl (O-D) and/or alkane (C-D) vibrations. Because these higher energy peaks are also observed for the amorphous Pt sample, a sample that contains no carbon, the possibility that these peaks are related to the formation of C-D bonds is ruled out. Instead, we propose that these peaks correspond to the possible formation of isolated surface hydroxyl species on the metal nano- or microparticles. Additionally, the isolated and strongly bound nature of the surface hydroxyl species precludes the hydrogen bonding observed for loosely bound water (H_2O or D_2O) that typically results in a broad featureless peak. The narrow peak at 1,068 cm^{-1} would then most likely correspond to a bending motion of the surface-bound hydroxyls. We note that none of these peaks are observed for activation of a carbon sample that contains no metal catalyst.

Finally, we also note that the energies observed for the grouping of peaks in the range of 2,100 to 2,400 cm^{-1} are significantly higher than what is expected for Pt-D bonds, which are expected to fall in the range of $\sim 1,688 \text{ cm}^{-1}$.

For the samples treated with a room temperature D_2 charge, we evaluated the Pd-TC sample, along with a control carbon sample prepared by the same method, but without Pd incorporation (Latroche C, no Pd). This sample has shown reproducible adsorption capacity enhancement at room temperature, which is presumably due to spillover hydrogen. The main feature observed for the control experiment (Latroche C, no Pd) is a broad absorption feature in the range of 2,000 to 2,800 cm^{-1} . This feature is assigned to loosely bound D_2O on the surface that most likely forms by the reaction of D_2 with surface-bound oxygen or hydroxyls. The same broad peak forms for the Pd-containing sample (Latroche 11% Pd-C), but a new broad feature also appears at $\sim 1,900 \text{ cm}^{-1}$, which is noted with an asterisk (*). Interestingly, a similar peak is observed for all samples containing both a catalyst metal and carbon, and not observed for the activated Pt-amorph sample. Thus, we tentatively assign the broad peak in the range of 1,800–1,900 cm^{-1} to C-D peaks formed by spillover of deuterium from catalyst particles (Pt or Pd) to the carbon surface. Further experiments must be done to confirm this assignment. Finally, we note the presence of many small peaks in the range of 900 to 1,700 cm^{-1} . Several of these peaks are similar amongst the samples investigated, while some samples possess unique peaks within the range above. With the recent results from neutron scattering experiments, we are calculating the corresponding infrared energy peak and look for it in this region (900–1,400 cm^{-1}) to see if we can correlate the spectroscopic data.

- **Neutron scattering evidence for spillover hydrogen on a ruthenium-BCx material.** NREL synthesized over 4 grams of ruthenium decorated BCx templated carbon materials for neutron scattering studies. The remarkable results are illustrated in Figure 3. This is by far the strongest hydrogen signal NIST has seen for a spillover type material. Interestingly the peaks in the spectrum appear to correspond directly with those predicted by Boris Yakospn at the University of Texas at Austin (private communication). This same sample is now undergoing a series of DRIFTS measurements to verify the peaks with a second spectroscopic method.

Conclusions and Future Direction

- Complete synthesis of the different spillover samples and distribute round-robin sets to the different labs for evaluation.
- Down select validated spillover materials and distribute samples to other labs for validation and additional spectroscopic characterization. This will include a synthesis of validated spillover materials by other labs.

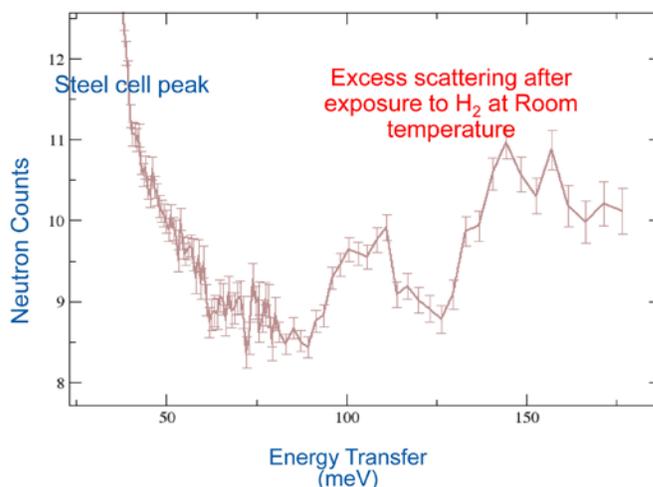

FIGURE 3. Neutron Scattering Data of BCx Material that Contains 6% w/w Ru

- Validate and assign specific types of interactions that have been observed from the spectroscopic evidence for spillover C-H bonds in DRIFTS, and neutron scattering.
- Develop and utilize NMR and possibly near edge X-ray absorption fine structure absorption spectroscopy to further elucidate and confirm the presence of the spillover hydrogen observed in DRIFTS and neutron scattering.
- Complete the remaining section, (Thermal Properties) and update the other sections within Best Practices.
- Report detailing findings and recommendations at ACS Meeting, (August 2011) and IEA-HIA Task 22 Hydrogen Storage Meeting (September 2011), final analysis will be presented at the 2012 Annual Merit Review meeting.

Validation and recommendations of weak chemisorption processes from this project will enable the hydrogen sorption community to accelerate development of room temperature hydrogen storage materials for light-duty vehicle and other early market applications.

Projected End Date: June 30, 2010 (no-cost
extension to December 31, 2011)

Fiscal Year (FY) 2011 Objectives

Develop and demonstrate reversible nanostructured activated carbon hydrogen storage material which has at least a 5.5 wt% materials-based gravimetric capacity and a 40 gH₂/L material-based volumetric capacity at 235–358 K, and potential to meet the DOE 2015 system-level targets.

- Prepare and characterize nanostructured polymer derivatives as carbon precursors.
- Initiate the production of nanostructured activated carbon for hydrogen storage.
- Develop methods for sorbent-based doped polymer/carbon.

Technical Barriers

This project addresses the following On-Board Hydrogen Storage technical barriers (2007) section 3.3.4 outlined in the Fuel Cell Technologies Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume

(C) Efficiency

(E) Charging/Discharging Rate

(P) Lack of Understanding of Hydrogen Physisorption and Chemisorption

(Q) Reproducibility of Performance

Technical Targets

The research and development of novel high surface area nanostructured carbons for hydrogen storage has been conducted in this project. The project aims to address the critical need that has been recognized by DOE, which has established a national effort to develop new and advanced high-capacity hydrogen storage materials and technologies. This project is applied toward the synthesis of inexpensive carbon-based, high surface area sorbents that can be combined with chemical-interacting organic, and/or inorganic materials, to yield high storage materials. These new materials and concepts have been designed to meet the DOE 2015 goals concerning the production of low-cost, high specific hydrogen binding energy hydrogen storage materials.

TABLE 1. On-Board Hydrogen Storage System Targets

Storage Parameter	Units	2015 System Target	SUNY-Syracuse**
System Gravimetric Capacity	kWh/kg (wt% H ₂)	1.8 (5.5 wt%)	2.4 (7.2 wt%)
System Volumetric Capacity	kWh/L (gH ₂ /L system)	1.3 (40)	1.2 (40)
Min/Max Delivery Temperature	K	233–358	77
Max Delivery Pressure	bar	100	60

** Data is based on material only, not system value

FY 2011 Accomplishments

- New type of polymer-based carbons that incorporate the metal (or metal ion) with high surface area and narrow pore size distribution has been developed with a hydrogen storage capacity of ~3.0 at 77K, 1 bar.
- Demonstrate the synthesis of modified polymer-based carbons with high surface area and low average pore width. Accomplished gravimetric storage capacity of ~6.7-7.0 wt% (77 K, 60 bar) and volumetric capacity 8 g H₂/L (237 K, 60 bar) with a high reproducibility on production in laboratory scale!
- Detail study on composition and morphology of new type of carbon nanotube with Fe and other metal into organocyclic-CN_n macromolecules rich with unsaturated bonds that should be available for room

temperature (RT) application at moderate pressures for H₂ storage systems.

- Products with an unlimited self-life! (Stable to extreme whether condition, including high humidity and temperature variation.)
- Products perform well at relatively low pressure (<20 bar).

Introduction

The State University of New York (esf) and PoroGen, LLC, have initiated a collaborative effort to develop superior high surface area nanostructured carbons for hydrogen storage. Synthesis of the carbon starts with the preparation of a nanoporous semicrystalline oriented polymer precursor having nanosize pores, with a uniform pore size distribution. This semicrystalline nanoporous polymer precursor is subsequently tailored to form high surface area activated carbons with slit-like microporous structure (pore width ~7-20 Å). The high surface area of the polymeric precursor aids in preparation of this unique carbon (Brunauer-Emmett-Teller surface area, $S_{\text{BET}} > 3,000 \text{ m}^2/\text{g}$) and enables doping initial material with chemical agents, which, upon carbonization, introduces specific interaction sites that significantly increase the hydrogen storage capacity of the nanostructured carbon material.

Approach

To achieve the project objectives, polymer-based nanostructured carbons have been synthesized by engineering the structure of the polymer precursors to produce carbon with the designed morphology for activation to high surface area and controlled micropores. Thus, polymer precursors (modified poly(phenylene oxide), MPEEK, poly(etherimide)) are spun at high melt shear rates further to controlled the morphology and orientation of crystalline regions. High orientation of polymer chains and alignment of crystalline lamellar regions leads to the formation of a porous material from oriented nano-size pores that upon carbonization, with specific activation agents, produce high surface area, high microporosity activated carbon. Consequently, procedures (including parameters such as heating rate, temperature and time) were developed to properly carbonize polymer precursors. In the activation (pore creation) step, the activation kinetics, including the reactivity size of activation agents, and the homogeneity of activation system, were addressed to control the carbons texture. Interaction of carbon with hydrogen is relatively low and may reach up to 6-7 kJ/mol. Since organocyclic-CNHN macromolecules with unsaturated bonds that exhibit rigid planar configuration and are abundant in electronegative nitrogen atoms, can complex metal-salt and are enable for RT application for H₂ storage systems in moderate pressure. Thus the synthetic methods

are expanded to incorporate reactive sites into the carbon nanostructures by doping polymerized unsaturated functionalized polycyclic complexes (Melem, Fe-Melem, and Nit-Melem). Alloying activated carbon with unsaturated functionalized polycyclic complex(ed) with Melem, the proper compositions, and the ratio of carbon/alloy and other components, is needed. Also, surface modifications of the nanostructures of polymer based carbons (by blending different polymer precursors) and control of hydrogen's binding energy with the carbon/alloys have been part of this study. Extensive physisorption and chemisorptions (of H₂ adsorption) characterizations have been performed to verify the synthetic effort.

Results

In FY 2010-2011, the main focus still remains the exploration of new polymer-based materials and synthetic routes by tailoring the morphology of polymer precursor to produce high surface area, higher microporosity and small pore size nanostructured carbons. Besides our laboratories, hydrogen storage measurement has been tested at other several industrial and government facilities. The porous textures and hydrogen storage capacity at 1 bar and 77 K are summarized in Table 2. These carbons gave S_{BET} from 1,000 to 3,200 m²/g. All carbons (beside APKI-1 and APKI-4) have microporosity >90%, with average pore diameter $d_{\text{DR}} \sim 10\text{--}20 \text{ \AA}$. A hydrogen gravimetric storage capacity $W(\text{H}_2) \sim 2.98 \text{ wt\%}$ and $V(\text{H}_2) \sim 25 \text{ g/L}$ was obtained at 77K and 1 bar.

A new type of polymer-based carbons that incorporate metal ions with high surface area and narrow pore size distribution were developed. Figure 1 compares the 77

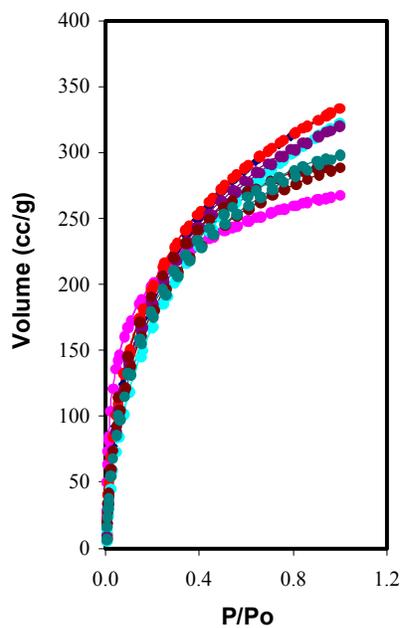

FIGURE 1. Hydrogen uptake (77 K, 1 bar) of polymer-based carbon (●) ACP-113; (●) NitACP-121; (●) ACP-127; (●) ACP-123; (●) NiACP-127; (●) ACP-136; (●) NitACP-136.

K hydrogen isotherms of nanostructured polymer-based (different polymer precursors) carbons synthesized under various conditions. Scanning electron microscope (SEM) images (Figure 2) of the carbon (NitCP-89) synthesis with metal gives nanotube structures (Figure 2a) with a diameter about 30 nm. Without metal ions, the carbon (APKI-1) shows a layer stack structure with small pores on the wall (Figure 2b). Although the BET surface area of NitCP-89 is lower at $\sim 420 \text{ m}^2/\text{g}$ compared with APKI-1 which is $3,225 \text{ m}^2/\text{g}$, the volumetric hydrogen uptake of NitCp-89 is 15.79 g/L (at 77K, 1 bar) higher than APKI-1 ($\sim 13.02 \text{ g/L}$).

Figure 3 shows a set of these carbons that were subjected to H_2 uptake at a pressure up to 20 bar at 77 K and 273 K up to 60 bar. At 273 K and 60 bar, the carbons made from phenyl phosphine oxide (NitACP-109 has $S_{\text{BET}} \sim 2,224 \text{ m}^2/\text{g}$, $V_{\text{pore}} \sim 0.97 \text{ cc/g}$ and $d_{\text{DR}} \sim 13.5 \text{ \AA}$) shows the highest volumetric hydrogen capacity $\sim 8 \text{ g H}_2/\text{L}$. However, at 77 K and 20 bar, polyether ether ether ketone (APKI-1 has $S_{\text{BET}} \sim 3,225 \text{ m}^2/\text{g}$, $V_{\text{pore}} \sim 1.7 \text{ cc/g}$ and $d_{\text{DR}} \sim 20.0 \text{ \AA}$) carbons have the same hydrogen storage capacity of $\sim 5.8 \text{ wt}\%$ at 20 bar, and 77 K.

In the past year, we continued to focus on the synthesis of nanotube multicyclic ligand carbon. These carbons carbonized at 600°C with different pyrolysis times from 2 h to 60 hours giving a different morphology than were observed by transmission electron microscope images. The surface area and hydrogen storage capacity of melem-based carbon at 77 K, 1 bar are shown in the Table 2.

Conclusions

- A new type of polymer-based carbons with the incorporation of metal ions with high surface area and narrow pore size distribution were developed. The hydrogen storage capacity was ~3.0 at 77 K, 1 bar.
- Detailed study of composition and morphology of new type of carbon nanotube with Fe and other metal into organocyclic-CNHn macromolecules rich with unsaturated bonds that should be available for RT application at moderate pressures for H₂ storage systems.
- Demonstrated synthesis of modified polymer-based carbons with high surface area and low average pore width. Accomplished gravimetric storage capacity of ~6.7-7.0 wt% (77 K, 60 bar) and volumetric capacity 8 gH₂/L (237 K, 60 bar) with a high reproducibly on production in laboratory scale!

Fiscal Year (FY) 2011 Objectives

- Expand the framework while keeping strong H₂ binding sites:
 - Design new porphyrin metal-organic frameworks (MOFs) to increase the storage space.
 - Expand Mg-MOF-74; high Q_{st} and Brunauer-Emmett-Teller (BET) surface area to achieve high H₂ density at room temperature.
- Preparation of high-surface area MOFs:
 - Large storage space, with minimization of dead space (*i.e.* high BET surface area).
 - Evaluate room temperature H₂ storage capacity by new high surface area MOFs.

Technical Barriers

This project addresses the following technical barriers from the Storage section (3.3.4.2) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (C) Efficiency
- (E) Charging/Discharging Rates

Technical Targets

This project consists of conducting fundamental studies of MOFs. Insights gained from these investigations will be applied toward the design and synthesis of hydrogen

storage materials that meet the following DOE 2015 revised hydrogen storage targets:

- Volumetric density: 40 g L⁻¹
- Gravimetric density: 4.5 wt%

FY 2011 Accomplishments

- Preparation of novel MOFs with metals.
- Highest BET surface area among porous solids.
- Fifteen and 2.7 wt% H₂ uptake by MOF-210 at 77 and 298 K.

Introduction

Conventional storage of large amounts of hydrogen in its molecular form is difficult and expensive because it requires employing either extremely high pressure as a gas or very low temperature as a liquid. Due to the described importance of hydrogen as a fuel, the DOE has set system targets for H₂ storage for the gravimetric (5.5 wt%) and volumetric (40 g L⁻¹) densities to be achieved by 2015. MOFs exhibit the highest hydrogen uptake of any porous materials and clearly demonstrate that the DOE targets are possible to achieve at 77 K. However, the implementation of room temperature hydrogen storage in MOF materials will require the design of new porous solids. Therefore, we are currently focusing our efforts on discovering novel highly porous materials with strong affinity for hydrogen.

Approach

To meet the DOE 2015 revised targets via physisorption, adsorbents must have high surface area (>3,500 m² g⁻¹) and relatively high density (>0.75 g cm⁻³). We have already demonstrated how to design high surface area materials. However, in most cases these materials do not demonstrate steep H₂ uptake in the low pressure region, which is indicative of the weak interaction with H₂. Therefore, we aimed at increasing strong binding sites for maximum H₂ uptake capacity without losing pore volume. More specifically, we prepared and tested the H₂ storage capacity of three types MOFs: (i) metalated MOFs, (ii) MOFs with open metal sites and large pore, and (iii) ultrahigh surface area MOFs, which are materials having the highest BET surface area.

Results

Preparation of Porphyrin MOFs. To achieve strong H₂-MOF interaction, we believe that utilization of open metal sites is essential and the most effective method.

Several metal ions are known to form coordinatively unsaturated sites; however, it is fair to say that only a limited number of metal units, e.g. $\text{Cu}_2(\text{CO}_2)_4$ are available in MOF structure. In other words, it is important to design novel MOFs whose organic linker has potential metal binding site. We have prepared MOFs with porphyrin linkers that are connected by zinc paddle wheel units. However, H_2 uptake in these porphyrin MOFs is not high, likely due to moderate surface areas. To overcome this drawback, we prepared a new MOF with Zr ions.

Based on the reticular chemistry of these systems, it is expected that the $\text{Zr}_6\text{O}_4(\text{OH})_4(\text{CO}_2)_{12}$ units (Figure 1A) are connected by tetratopic links to form new MOF structures, i.e. **ftw** net for square tetratopic link, **ith** net for tetrahedron. Therefore, we chose tetraphenylporphyrin as a square tetratopic link (Figure 1A) to synthesize a new free-base porphyrin MOF and its metalated versions (Cu and Pd ions). The porphyrin MOFs were prepared by a solvothermal reaction of a mixture of porphyrin link and zirconium chloride in *N,N*-dimethylformamide. Although, we did not finalize the structure, the powder X-ray diffraction pattern of this material is nearly identical to the simulated pattern of modeled material.

The permanent porosity was demonstrated by Ar adsorption isotherm for guest free samples. The compound shows typical type I isotherm, which indicates that the material has microporosity. The BET surface areas of

activated MOFs are estimated to be 2,100, 1,850, and 1,700 m^2/g for free-base, Cu and Pd porphyrin MOFs, respectively. To evaluate the pore size distribution of porphyrin MOF, the Ar isotherm was analyzed using nonlocal density functional theory. The distribution calculated by fitting the adsorption data (17 Å) is close to the pore diameter from modeled structure of each MOF.

The H_2 isotherms of porphyrin MOFs were measured at 77 and 87 K. The H_2 uptake of free-base, Cu and Pd porphyrin MOFs at 1 bar and 77 K is 1.6, 1.7, and 1.6 wt%, respectively. These uptakes are larger than that of MOF-177. We also estimated the heat of adsorption (Q_{st}) and the initial Q_{st} value of the free-base porphyrin MOF was calculated to be 6.4 kJ/mol, which is similar to MOF-199 having open metal sites (6.8 kJ/mol) [1]. More importantly, the initial Q_{st} values of metalated porphyrin MOFs (7.0 and 6.8 kJ/mol for Cu and Pd version) were higher than that of free-base porphyrin MOF, indicating that the metal ions in the large aromatic (porphyrin) cycle can improve the H_2 -MOF interaction. For the room temperature H_2 storage, further improvement of the Q_{st} is required; therefore, we plan to synthesize other metalloporphyrin MOFs.

Preparation of Expanded Version of Mg-MOF-74.

To achieve room temperature H_2 adsorption, density of strong H_2 binding site per volume is one of the key factors. We have demonstrated that rod-type metal building units (Figure 1B) are sufficient systems for increasing the metal/

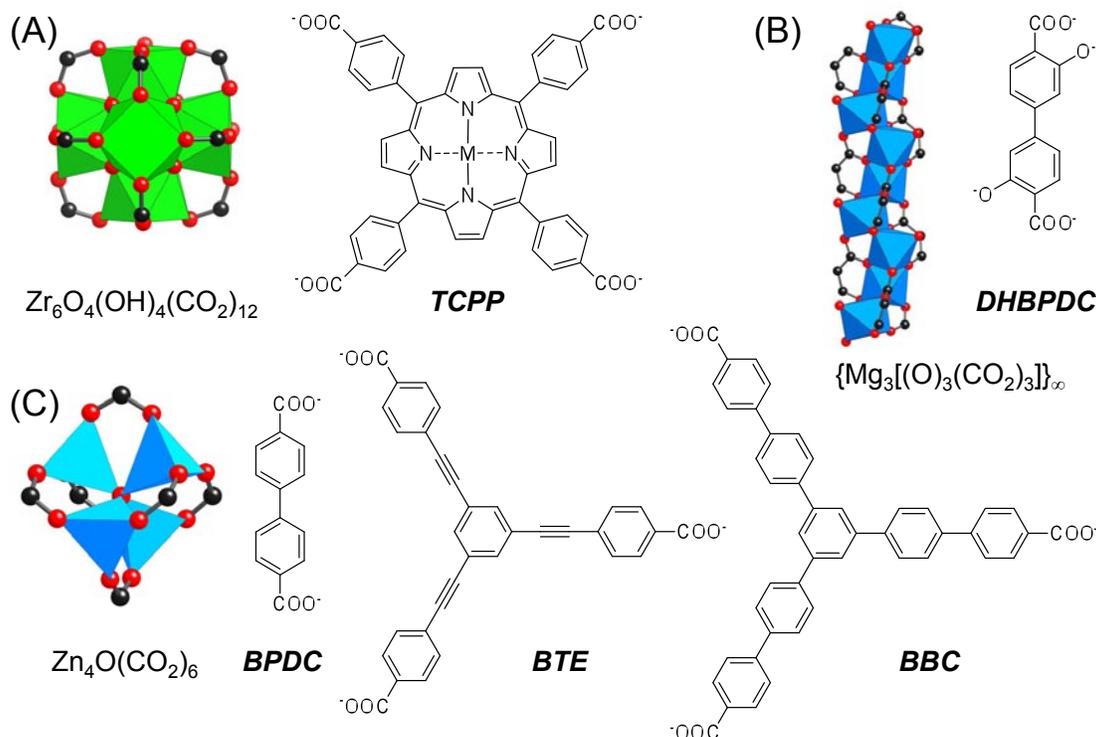

FIGURE 1. (A) $\text{Zr}_6\text{O}_4(\text{OH})_4(\text{CO}_2)_{12}$ -based MOFs with porphyrin linkers (TCPP, M = H_2 , Cu, or Pd). (B) Expanded version of Mg-MOF-74 is prepared using 3,3'-dihydroxy-[1,1'-biphenyl]-4,4'-dicarboxylate (DHPDC). (C) $\text{Zn}_4\text{O}(\text{CO}_2)_6$ unit is connected with organic linkers to form MOF-210 (BPDC and BTE) and MOF-200 (BBC).

ligand ratio (for example, MOF-74 shows excellent H_2 uptake behavior in the low pressure region at 77 K [1]). However, because of the moderate pore diameter of MOF-74, the surface area of MOF-74 is not high enough to meet the DOE targets of 5.5 wt%. We believe that expansion of the one-dimensional channel diameter would increase the total storage capacity. In this year, we prepared extended version of Mg-MOF-74 using 3,3'-dihydroxy-[1,1'-biphenyl]-4,4'-dicarboxylic acid (Figure 1B, this linker was provided by Prof. Stoddart group of Northwestern University) by a solvothermal reaction. Obtained micro crystals were analyzed by powder X-ray diffraction (PXRD) measurements.

To confirm the porosity and estimate the pore size distribution, we recorded Ar isotherm for the activated sample of expanded Mg-MOF-74 at 87 K. The compound shows a step at $P/P_0 = 0.05$, which indicates that the material has relatively large pore. The Langmuir and BET surface areas of activated MOF are estimated to be 3,200 and 2,740 $m^2 g^{-1}$, respectively. The pore size distribution calculated by fitting the Ar adsorption data (19 Å) is close to the pore diameter from the crystal structure.

To calculate the Q_{st} for this MOF, low-pressure H_2 isotherms were recorded at 77 and 87 K. The initial Q_{st} value (10.1 kJ/mol) is almost the same as that of Mg-MOF-74 (10.1 kJ/mol [2]). The Q_{st} curves are sometimes influenced by the pore geometry with smaller pore materials tending to show better Q_{st} data. However in this case, it seems the initial Q_{st} value just reflects the Mg- H_2 interaction.

Figure 2 demonstrates a high-pressure excess H_2 isotherm of expanded MOF-74 at 77 K (red circles). The isotherm showed a steep raise below 10 bar, the excess uptake was saturated around 45 bar where the H_2 uptake was 4.5 wt%. As expected, the profile of high-pressure

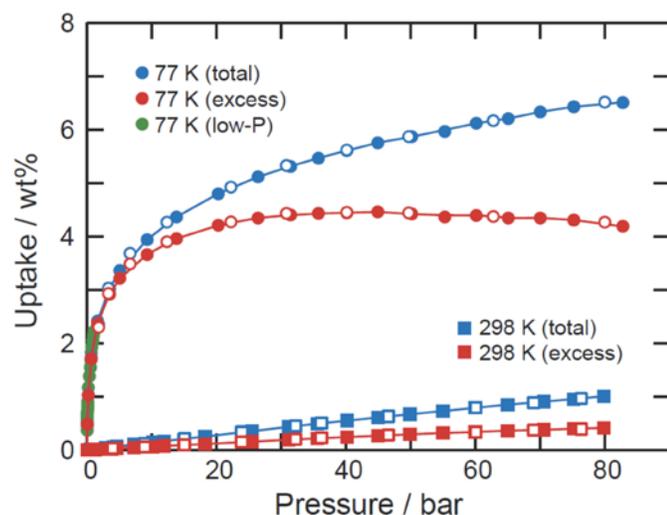

FIGURE 2. High-pressure H_2 isotherms of expanded Mg-MOF-74 at 77 K (red circles) and at 298 K (red squares). Calculated total uptake data were overlaid (blue symbols).

isotherm matches with the low-pressure data indicating that the measurements were properly carried out. Although the surface excess mass is a useful concept, the total amount that a material is able to store is more relevant to the practicality of using H_2 as a fuel. Therefore, we estimated this value by using a pore volume and bulk H_2 density ($N_{total} = N_{ex} + \rho_{bulk} V_p$). Estimated total H_2 uptake was plotted in Figure 2 (blue circles). Total uptake at 80 bar was calculated to be 6.5 wt%, which corresponds to 43 g/L. Due to the moderate BET surface area of expanded MOF-74, the total gravimetric uptake is not overwhelmingly exceptional. However, the volumetric uptake is well within the realm of the DOE system target albeit at 77 K.

We also measured H_2 isotherms of the same sample at 298 K (Figure 2). The excess uptake at 80 bar was 0.41 wt%, which was unfortunately smaller than the H_2 uptake at 87 K and 1 bar (1.5 wt%). This implies that a higher Q_{st} value is required to increase the H_2 density in MOFs even though the Q_{st} for expanded MOF-74 is ca. 10 kJ/mol. The estimated total H_2 uptake at 80 bar and 298 K was calculated to be 1.0 wt% (6.3 g/L). This volumetric uptake is slightly higher than the bulk density of H_2 at the same condition (6.2 g/L). In order to improve on these results, we plan to synthesize the isorecticular structures using Ni and Co ions instead, which are reported to have Q_{st} values greater than that of Mg-MOF [2].

Ultrahigh Porosity in MOF-200 and 210. One of the most important properties of MOFs is their high porosity and high specific surface area. An important consideration in maximizing the uptake of H_2 within MOFs is to increase the number of adsorptive sites within a given material. The simplest way to accomplish this is to use slim organic linkers in which the faces and edges of the constituent units are exposed for gas adsorption [3]. As shown in MOF-5 and MOF-177, the octahedral $Zn_4O(CO_2)_6$ (Figure 1C) has had a prominent role as a building unit in producing structures exhibiting exceptional porosity [1,3]. Therefore, we prepared the expanded forms of MOF-177 from 4,4',4''-(benzene-1,3,5-triyl-tris(benzene-4,1-diyl))tribenzoate (BBC) to give MOF-200, and used mixed 4,4',4''-(benzene-1,3,5-triyltris(ethyne-2,1-diyl))tribenzoate (BTE)/ biphenyl-4,4'-dicarboxylate (BPDC) links to obtain MOF-210 (Figure 1C).

MOF-200 and 210 were prepared from a solvothermal reaction of organic linkers and zinc nitrate, and obtained crystals were characterized single crystal X-ray diffraction. Considering the bulk density and void space calculated from the crystal structure analyses, MOF-200 and 210 are promising candidates to realize ultra-high surface area. However, preliminary trials revealed that the solvent exchange followed by pore evacuation under vacuum was not effective to activate MOF-200 and 210 without losing the porosity. Therefore, these crystals were fully exchanged with liquid CO_2 , kept under supercritical CO_2 atmosphere, followed by their pores being bled of CO_2 to yield activated samples. Successful guest removal was confirmed by PXRD measurements and elemental analyses.

As shown in Figure 3, these MOF samples show distinctive steps ($P/P_0 = 0.14$ and 0.27 for MOF-200 and 210), and the profiles for MOF-200 and 210 are nearly the same as the predicted isotherms by grand canonical Monte Carlo simulations (Prof. Snurr group at Northwestern University). The maximum N_2 uptake capacities at 77 K in MOF-200 and 210 are $2,340$ and $2,330 \text{ cm}^3 \text{ g}^{-1}$, respectively. More importantly, the measured values are near the values predicted based on the structure, indicating that these materials are well-activated. Because of the successful sample activation, extremely high BET (and Langmuir) surface areas were obtained: $4,530$ ($10,400$) and $6,240$ ($10,400$) $\text{m}^2 \text{ g}^{-1}$ for MOF-200 and 210. The BET surface area of MOF-210 is the highest reported for crystalline materials.

Given the exceptional properties of such materials, it is expected that these high surface area MOFs would exhibit exceptional H_2 storage capacity. These MOFs reach saturation uptakes, and the saturation pressure increases with an increase in the cavity size (Figure 4). The surface excess H_2 uptake in MOF-210 ($7.9 \text{ wt}\%$) was higher than MOF-177 and 200 (6.8 and $6.9 \text{ wt}\%$) [4]. Given the pore volume and density of H_2 at 77 K, the total H_2 uptake in MOF-210 is calculated to be $15 \text{ wt}\%$, which exceeds that of typical alternative fuels (methanol and ethanol) and hydrocarbons (pentane and hexane). MOF-200 also shows large total uptake ($14 \text{ wt}\%$); again, these values are higher than MOF-177 [4]. However, the volumetric total uptake (44 g/L for MOF-210; 36 g/L for MOF-200) was smaller than MOF-177 (50 g/L). The trend indicates that it is better to reduce the dead volume by introducing functionalities, which can interact positively with H_2 .

Figure 4 displays the room temperature H_2 isotherms of MOF-210. The excess uptake at 80 bar was $0.53 \text{ wt}\%$, which is similar to the room temperature H_2 uptake by MOF-177 ($0.54 \text{ wt}\%$). We believe that the excess H_2 uptake was not

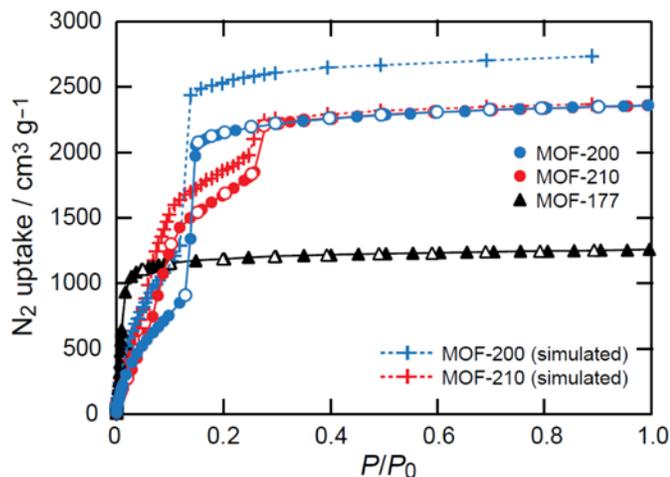

FIGURE 3. Low-pressure N_2 isotherms of MOF-177, -200, and -210 at 77 K. Simulated isotherms of MOF-200 and -210 were overlaid.

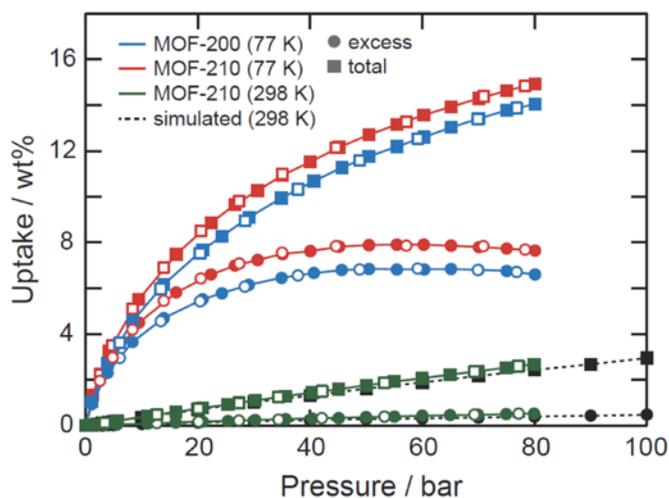

FIGURE 4. High-pressure H_2 isotherm of MOF-200 (blue circles) and 210 (red circles) measured at 77 K. Experimental (green) and simulated (black) H_2 isotherm of MOF-210 at room temperature are overlaid. Squares in the same color symbols represent calculated total uptake of H_2 under the same conditions.

improved because of the average pore diameter of MOF-210. The average pore diameter of MOF-210 is larger than the DOE recommendation for pore diameter size (0.7 - 1.2 nm to maximize the room temperature H_2 uptake capacity) with a significant storage space that still remains.

Calculated total H_2 isotherm is also shown in Figure 4. The total uptake at 80 bar was $2.7 \text{ wt}\%$, which is the highest number reported for physisorptive materials. When the bulk density of MOF is applied, the volumetric H_2 uptake is calculated to be 6.9 g/L at 80 bar. Although the majority of the total uptake is attributed to the large pore volume (i.e. the contribution from $\rho_{\text{bulk}} V_p$), the volumetric H_2 uptake by MOF-210 remains higher than the bulk density of H_2 under the same conditions. Worth noting is that this finding is in sharp contrast to the fact that MOFs with larger density typically show even smaller volumetric uptakes than the bulk H_2 density.

Through the collaborative work with the Prof. Goddard group of Caltech, room temperature H_2 uptake by MOF-210 was predicted. As shown in Figure 4, these room temperature high-pressure H_2 data are in good agreement with predicted excess and total isotherms. However, H_2 isotherms recorded at room temperature sometimes contain significant errors due to their smaller uptake (compared to 77 K data). Therefore, it is fair to say that the simulation data provides reassuring support for the excellent experimental room temperature H_2 uptake capacity by MOF-210.

Conclusions and Future Directions

In this project, we aimed at developing the next generations of MOFs. It is presumed that the organic functionalities alone were not enough to show strong

binding energy, therefore, we prepared novel MOFs with metals. These MOFs showed improved adsorption enthalpy albeit a large pore volume is still a prerequisite feature. From the viewpoint of the storage space, we aimed at discovering high surface area MOFs. After many trials we optimized the synthesis and subsequent activation conditions of MOF-210, leading to 15 and 2.7 wt% of total H₂ uptake at 80 bar at 77 and 298 K, respectively. Although this project has finished, we will continue to pursue practical storage targets by the combination of the isoreticular metalation and the isoreticular expansion.

Project Start Date: February 1, 2009

Project End Date: July 31, 2014

- Design, fabricate, test, and decommission the subscale prototype components and systems of each materials-based technology (adsorbents, metal hydrides, and chemical hydrogen storage materials).

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Hydrogen, Fuel Cells and Infrastructure Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (B) System Cost
- (C) Efficiency
- (D) Durability/Operability
- (E) Charging/Discharging Rates
- (G) Materials of Construction
- (H) Balance of Plant Components
- (J) Thermal Management
- (K) System Life Cycle Assessments
- (L) High Pressure Conformality
- (P) Lack of Understanding of Hydrogen Physisorption and Chemisorption
- (S) By-Product/Spent Material Removal

Technical Targets

This project directs the modeling, design, build and demonstration of prototype hydrogen storage systems for each metal hydride, chemical hydride and hydrogen sorption material meeting as many of the DOE Technical Targets for light-duty vehicular hydrogen storage. The current status of these systems vs. the Onboard Hydrogen Storage System Technical Targets are given in Table 1.

Fiscal Year (FY) 2011 Objectives

- Develop system models that will lend insight into overall fuel cycle efficiency.
- Compile all relevant materials data for candidate storage media and define future data requirements.
- Develop engineering and design models to further the understanding of on-board storage energy management requirements.
- Develop innovative on-board system concepts for metal hydride, chemical hydride, and adsorption hydride materials-based storage technologies.
- Design components and experimental test fixtures to evaluate the innovative storage devices and subsystem design concepts, validate model predictions, and improve both component design and predictive capability.

FY 2011 Accomplishments

- Completed all requirements for moving the Center into Phase 2.
- Performed quality functional deployment analysis on Hydrogen Storage Technical Targets at both the 2010 and 2015 metrics and identified the relative trade offs incurred balancing targets with ordered list of technical targets given in Table 1.
- A unified model was completed utilizing the MATLAB®/ SimuLink environment incorporating: (i) vehicle architecture and performance; (ii) fuel cell demands and requirements; and (iii) storage system demands and thermal management systems.

- Identified five drive cycles to be used in system analysis modeling.
- Systems analysis completed on metal hydride, chemical hydride and adsorbent systems resulting in:
 - Metal Hydride System
 - Completed system analysis on dual-bed NaAlH₄ system which was found to fully meet 10 targets, fall within 40% of six targets and below 40% of four targets (see Table 1).
 - Hydride compaction, enhanced hydride thermal conductivity and high temperature Type IV pressure vessels identified as critical technical barriers.
 - Chemical Hydride System
 - Completed system analysis on fluid ammonia borane (AB)/1-n-butyl-3-methylimidazolium chloride (BIMICl) system which was found to fully meet 13 targets, fall within 40% of four targets, below 40% of one target and two targets undefined (see Table 1).
 - Slurry identification/properties, flow through reactor control, low temperature fluid properties and reduced cost of balance-of-plant (BOP) components identified as critical technical barriers.
 - Adsorbent System
 - Completed system analysis on AX-21 system which was found to fully meet 14 targets, fall within 40% of gpit targets and below 40% of two targets (see Table 1).

- Reduced cost of Type IV cryo-pressure vessel and BOP components; demonstration of peripheral sealing for flow through cooling, adsorbent compaction and enhanced adsorbent thermal conductivity identified as critical technical barriers.

Introduction

The Hydrogen Storage Engineering Center of Excellence (HSECoE) brings together all of the materials and hydrogen storage technology efforts to address onboard hydrogen storage in light-duty vehicle applications. The effort began with a heavy emphasis on modeling and data gathering to determine the state of the art in hydrogen storage systems. This effort spanned the design space of vehicle requirements, power plant and BOP requirements, storage system components, and materials engineering efforts. These data and models will then be used to design components and sub-scale prototypes of hydrogen storage systems which will be evaluated and tested to determine the status of potential system against the DOE 2010 and 2015 technical targets for hydrogen storage systems for light-duty vehicles.

Approach

A team of leading North American national laboratories, universities, and industrial laboratories, each with a high degree of hydrogen storage engineering expertise cultivated

through prior DOE, international, and privately sponsored programs has been assembled to study and analyze the engineering aspects of condensed phase hydrogen storage as applied to automotive applications. The technical activities of the Center are divided into three system architectures: adsorbent, chemical hydride and metal hydride matrixed with six technologies areas: Performance Analysis, Integrated Power Plant/Storage System Analysis, Materials Operating Requirements, Transport Phenomena, Enabling Technologies and Subscale Prototype Construction, Testing and Evaluation. The project is divided into three phases; Phase 1: System Requirements and Novel Concepts, Phase 2: Novel Concept Modeling Design and Evaluation and Phase 3: Subscale System Design, Testing and Evaluation.

Results

Materials

One prototypical material was selected for each storage materials type. These prototypical materials were selected due to their relatively high degree of data identified by the center and their relevance to other similar materials. These materials are not intended to be a selection of materials, but rather used to identify the current state of the art for storage system technologies.

Drive Cycles

A number of drive cycles were implemented to identify storage system performance. This is particularly relevant in the case of transient system performance, where the DOE targets have not identified the duration for which the targets need to be met. In many instances, engineering solutions have been implemented to meet the targets not directly related to the storage system media used. A summary of the

drive cycles, and the targets which were determined by them are given in Table 2.

Systems

In order to determine the current state-of-the-art system performance, preliminary system architectures were designed and used in the unified modeling system run under MATLAB®-SimuLink and developed by the HSECoE. This SimuLink model included the hydrogen storage system, fuel cell system and vehicle system models.

Metal Hydride Systems

The baseline material used in this effort was sodium aluminum hydride (NaAlH_4), ball milled with 3 mole per cent TiCl_3 as a catalyst. The system used in this effort is given in Figure 1a and is composed of dual Type III NaAlH_4 tanks operational at 150 bar with an accompanying catalytic burner to supply the required enthalpy of dehydrogenation. A 150 bar buffer tank is included to facilitate cold-start and transient operations. The heat exchange system is a radial tube/fin design depicted in Figure 1a. The summary of these attributes is given in the spider diagram of Figure 1b where full realization of the target is denoted by filling in to the outer diameter.

Chemical Hydride Systems

The baseline material used in this effort was liquid AB composed of pure NH_3BH_3 , dissolved in the ionic liquid BIMICI to a mass fraction of 50% AB. The chemical hydride system used in this effort is given in Figure 2a and is composed of bladder tank feeding a flow through reactor and a gas liquid separator which serves to separate the gaseous species from the spent fuel and as a high pressure

TABLE 2. Drive Cycles Utilized in System Target Status

Drive Cycle	Test Schedule	Cycle	Description	Target	Temp. (°C)
1	Ambient Drive Cycle - Repeat the EPA FE cycles from full to empty and adjust for 5 cycle post-2008	UDDS	Low speeds in stop-and-go urban traffic	System Size	24

ballast tank to feed hydrogen to the fuel cell in start-up and transient conditions. A pump is included to maintain both fresh and spent fuel flow with a portion of the spent fuel recirculate to absorb excess heat generated at the reactor. The summary of these attributes is given in the spider diagram of Figure 2b where full realization of the target is denoted by filling in to the outer diameter.

Adsorbent Systems

The baseline material used in this effort was a super activated carbon commercially available and designated as AX-21. The adsorbent system used for this effort is given in Figure 3a. It is composed of a 200 bar high pressure Type III pressure vessel enclosed in a multilayer vacuum insulated jacket with a 5 W heat leak at 80 K. Charging is achieved

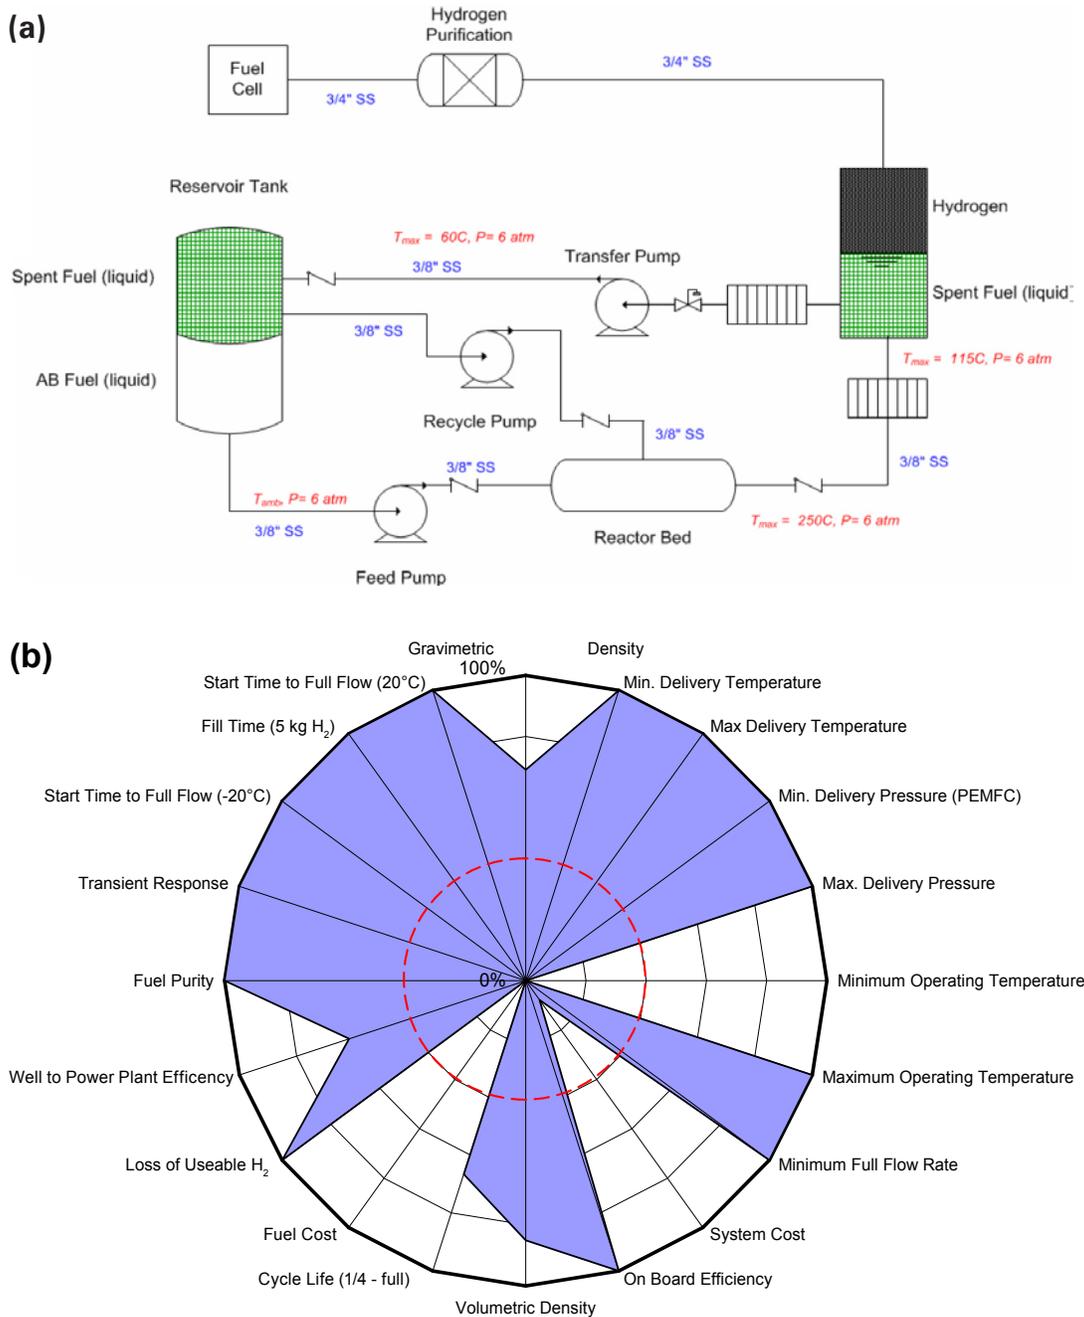

FIGURE 2. Chemical Hydride System (a) configuration and (b) spider chart depicting metal hydride system performance characteristics against the 2015 technical targets.

via flow-through cooling with an initial bed temperature 80 K. Desorption is achieved utilizing an in-tank electrical resistance heater. An external heat exchanger is utilized to heat the released hydrogen to ambient temperatures. The summary of these attributes is given in the spider diagram of Figure 3b where full realization of the target is denoted by filling in to the outer diameter.

Conclusions and Future Directions

The critical technical barriers identified to date and potential solutions being evaluated are given below for each of the storage system types.

- Metal Hydride System
 - Hydride compaction via mechanical constraint.

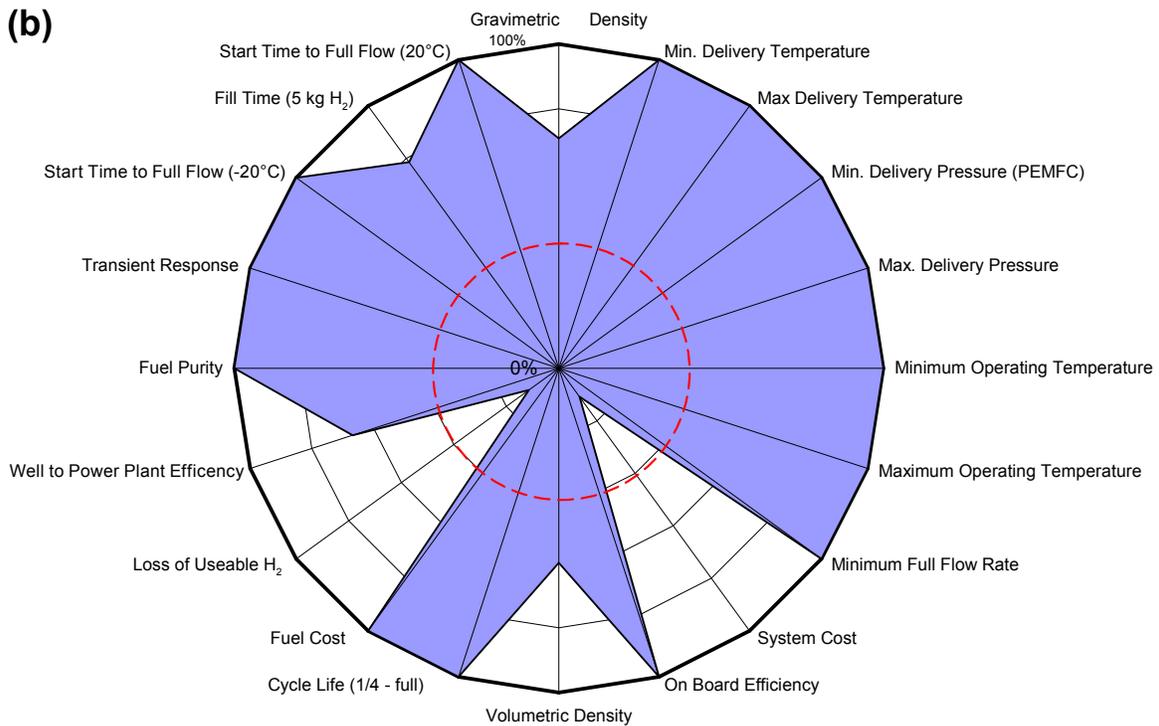

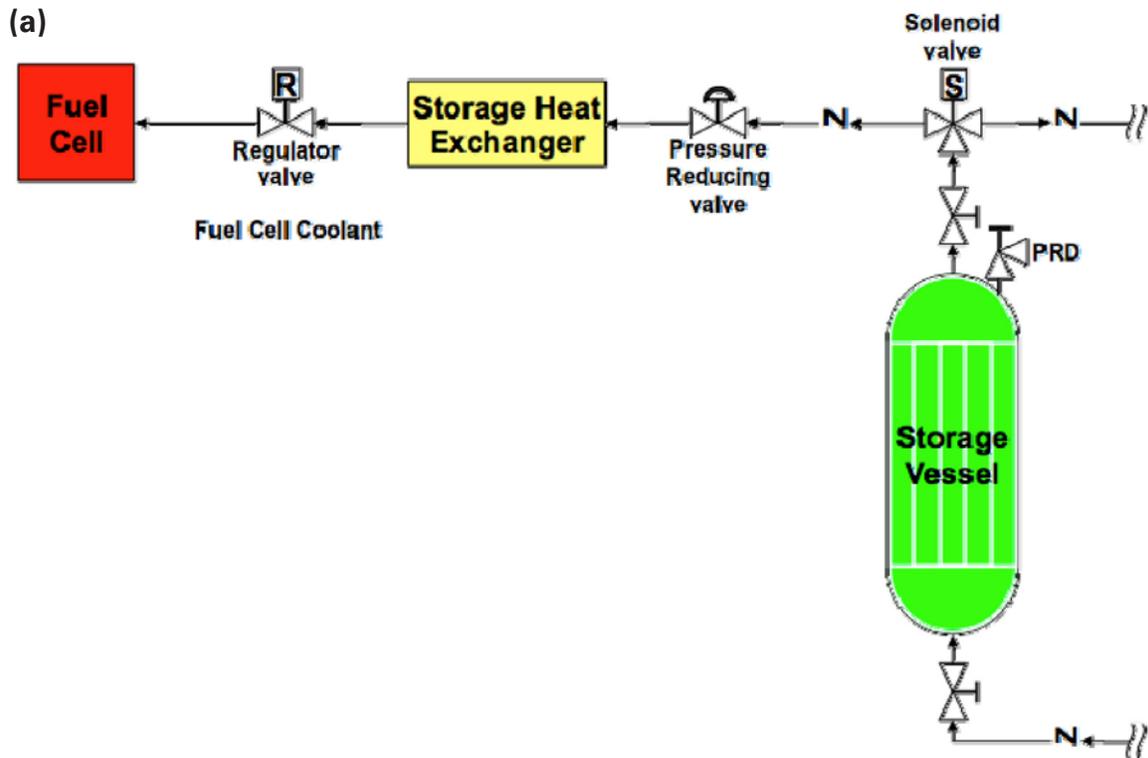

FIGURE 3. Adsorbent System (a) configuration and (b) spider chart depicting metal hydride system performance characteristics against the 2015 technical targets.

- Enhanced hydride thermal conductivity via additions of expanded natural graphite.
- High temperature Type IV pressure vessel development.

- Chemical Hydride System
 - Slurry/solvent identification/properties with nonreactive organic liquids/ionic, liquids.
 - Flow through reactor thermal control via spent fuel feedback.
 - Low temperature fluid properties.
- Adsorbent System
 - Type IV cryo-pressure vessel development.
 - Peripheral sealing for flow through cooling.
 - Adsorbent compaction via low temperature binderless techniques.
 - Enhanced adsorbent thermal conductivity via expanded natural graphite additions.

Project Start Date: February 2, 2009
Project End Date: September 30, 2014

- Energy density: 0.040 kg H₂/L system
- Charging/discharging rates: 3.3 min
- Well-to-power-plant (WTPP) efficiency: 60%

FY 2011 Accomplishments

- Developed a vehicle model framework and test cycle matrix to aid in the analysis and understanding of hydrogen storage system requirements for light-duty vehicles.
- Integrated the hydrogen storage simulator (HSSIM vehicle model) with the center fuel cell and hydrogen storage models to create a model framework that could be used across the center to evaluate all storage system designs on a common basis and with consistent assumptions.
- Used the vehicle model and the center modeling framework to evaluate the performance of specific storage system designs across all material classes and assess the impact on vehicle performance.
- Performed vehicle-level tradeoff analyses to better understand the impact of key engineering designs, for example, the tradeoff between mass, onboard hydrogen storage capacity, and vehicle range.
- Used the Hydrogen Delivery Scenario Analysis Model (HDSAM) to calculate preliminary greenhouse gas (GHG) emissions and WTPP efficiency figures for baseline physical storage systems and candidate solid-state storage systems for each material class.
- Identified potential materials for analysis and provided storage system design guidance to help meet DOE storage targets with adsorbent materials.

Fiscal Year (FY) 2011 Objectives

- Perform vehicle-level modeling and simulations of various storage systems configurations.
- Lead the storage system energy analysis and provide results.
- Compile and obtain media engineering properties for adsorbent materials.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (B) System Cost
- (C) Efficiency
- (E) Charging/Discharging Rates
- (I) Dispensing Technology
- (K) Systems Life-Cycle Assessments

Technical Targets

This project is conducting simulation and modeling studies of advanced onboard solid-state hydrogen storage technologies. Insights gleaned from these studies are being applied toward the design and synthesis of hydrogen storage vessels that meet the following DOE 2015 hydrogen storage for light-duty vehicle targets:

- Cost: to be determined
- Specific energy: 0.055 kg H₂/kg system

Introduction

Overcoming challenges associated with onboard hydrogen storage is critical to the widespread adoption of hydrogen-fueled vehicles. The overarching challenge is identifying a means to store enough hydrogen onboard to enable a driving range greater than 300 miles within vehicle-related packaging, cost, safety, and performance constraints. By means of systems analysis and modeling, hydrogen storage system requirements for light-duty vehicles can be assessed. With these findings and through collaboration with our Hydrogen Storage Engineering Center of Excellence (HSECoE) partners, optimal pathways for successful hydrogen storage system technology can be identified to enable future commercialization of hydrogen-fueled vehicles.

Approach

An array of tools and experience at NREL are being used to meet the objectives of the HSECoE. Specifically, extensive knowledge of multiple vehicle simulations, well-to-wheels (WTW) analysis, and optimization are being employed and integrated with fuel cell and material-based hydrogen storage system models developed by other HSECoE partners. This integrated model framework allows for the evaluation of various hydrogen storage options on a common basis. Engineering requirements are defined from these studies thus enabling the design of hydrogen storage vessels that could meet DOE performance and cost targets in a vehicle system context.

In the area of media engineering, attaining the objectives of the HSECoE relies on NREL's leadership in developing custom analytical instrumentation for hydrogen adsorbent analysis. These tools are used to thoroughly characterize hydrogen storage adsorbents so that an optimized storage vessel specific to the adsorbent material may be efficiently engineered. NREL will use these methods to analyze adsorbent materials identified by the HSECoE as holding promise for application in commercial on-vehicle refuelable hydrogen storage systems capable of meeting DOE targets.

Results

The following will provide results from work completed this year to support the HSECoE with a focus on five main tasks. In collaboration with our original equipment manufacturer (OEM) partners, NREL (1) worked on the development of a vehicle model (hydrogen storage simulator, HSSIM) and final structure of a test cycle matrix used to support the overall modeling effort; (2) worked on the integration of the vehicle model with the center fuel cell and hydrogen storage models to create a model framework; (3) worked with the systems architects to perform simulations and tradeoff studies to help with the high-level storage system design and engineering, including system sizing; (4) performed energy analysis on specific systems design being considered by the HSECoE; and (5) continued work in the area of adsorbent materials characterization and analysis.

A key result was working with the center OEMs on finalizing the test matrix that will be used to evaluate all the storage systems being considered across the center on a common basis. The test matrix was structured to evaluate the performance of the storage systems against the technical targets under standard and realistic transient driving condition. The matrix was also designed to exercise a given systems from full to empty to provide an understanding of its performance over the entire range of fill conditions. Therefore, the test cases were designed to repeat a drive cycle or set of drive cycles until the storage system being evaluated was empty. Standard drive cycles are typically not long enough to achieve this and would not even deplete

a buffer tank in some systems. The important point here is that when evaluating the complex dynamics of hydrogen storage systems, this approach of repeating drive cycles to create test cases is critical to gaining the feedback necessary to refine and improve the systems.

As shown in Table 1, the center test matrix includes five test cases:

The first case combines repeats of the urban dynamometer driving schedule (UDDS) and the highway fuel economy test (HWFET) until the storage systems is depleted. This is used to determine the vehicle-level fuel economy and from that figure the vehicle range. The fuel economy is calculated using the current Environmental Protection Agency (EPA) five-cycle procedure of adjusting and weighting the UDDS and HWFET to provide one fuel economy figure that represents real-world use—it is not the raw figures that come directly from running the cycles. Similarly, the range is then calculated from the adjusted and weighted UDDS and HWFET figure and not simply the cycles miles achieved until the storage systems is empty. Again, this test matrix is key to providing a means to evaluate the fuel economy, range, and other vehicle level performance feature of the storage systems on a common and comparable basis.

Secondly, NREL worked with other center partners on the integration of the vehicle model with the fuel cell and storage systems models within a single modeling framework. Figure 1 shows a representation of the modeling framework that allows for a common and consistent evaluation of given storage systems. The key is the integration of the various storage system models with a common vehicle and fuel cell model in Simulink[®]. NREL played a critical role in the development and structure of this framework and helped with the coding in Simulink[®] to ensure reliable, accurate, and validated results.

A third activity was working the center system architects to provide high-level feedback on the performance and design of their given material systems. Figure 2 shows an example of a tradeoff study quantifying the relative range impacts resulting from changes to the storage system capacity and reductions to the vehicle glider mass. Table 2 shows the example results from the application of this type of study to a NaAlH₄ system.

Fourth, NREL continued to support the HSECoE by performing energy analyses on various storage system designs that have become available. These analyses provide the center system architects and other partners with high-level estimates about the overall energy inputs required by a given system, including WTPP efficiency (%), hydrogen cost (\$/kg) and GHG emissions (carbon dioxide equivalent) on a gram per mile basis.

Fifth, the HDSAM I was used to estimate the above parameters for each system. To date the HDSAM model has been run for NaAlH₂ metal hydride system and the AX-21

TABLE 1. Test Matrix used Across the Center to Evaluate the Performance of all the Storage Systems

Case	Test Schedule	Cycles	Description	Test Temp (°F)	Distance per cycle (miles)	Duration per cycle (minutes)	Top Speed (mph)	Average Speed (mph)	Max. Acc. (mph /sec)	Stops	Idle	Avg. H2 Flow (g/s)*	Peak H2 Flow (g/s)*	Expected Usage

For media engineering, NREL provided the HSECoE with specific engineering properties on adsorbent materials that were recommended as potential candidates for which to perform additional engineering analyses. These included high specific surface area (SSA) materials with high bulk densities, and searching for materials with higher than 10 kJ/mol hydrogen binding energies. Initially, this involved investigating representative materials that have more idealized and controlled pore sizes (in the range of 0.7 to 1.5 nm) such as pyrolyzed polyether-ether-ketone (PEEK) materials. As shown in Figures 3 and 4, these types of materials can be pressed to very high pressures (100,000 psi) with no significant loss of specific surface area or hydrogen storage capacities. At these pressures, bulk densities ranging from 0.7 to 1.5 g/mL can be achieved (Figure 3), resulting in substantial increases in Gibbs excess volumetric capacities (i.e., 40 to 80 g-H₂/L, see Figure 4). Thus, even though these materials may not have as high of Gibbs excess gravimetric capacities as metal-organic frameworks (Figure 3), due to their bulk densities being 2 to 5 times higher, their Gibbs excess volumetric capacities can be 2 to 4 times higher.

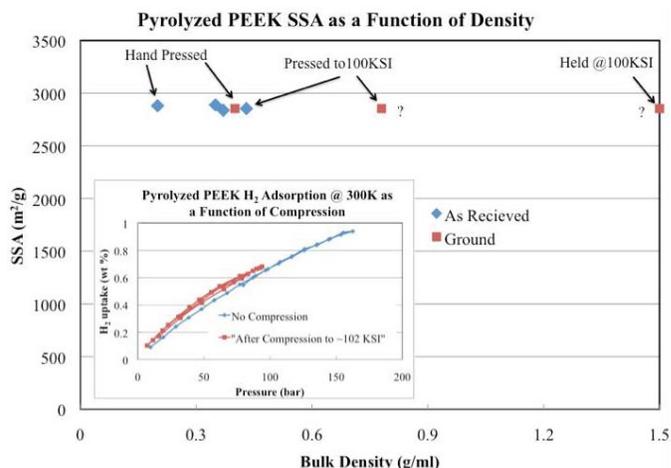

FIGURE 3. Engineering data of pyrolyzed PEEK materials demonstrating that very high bulk densities can be achieved with virtually no loss of SSA or hydrogen storage capacity.

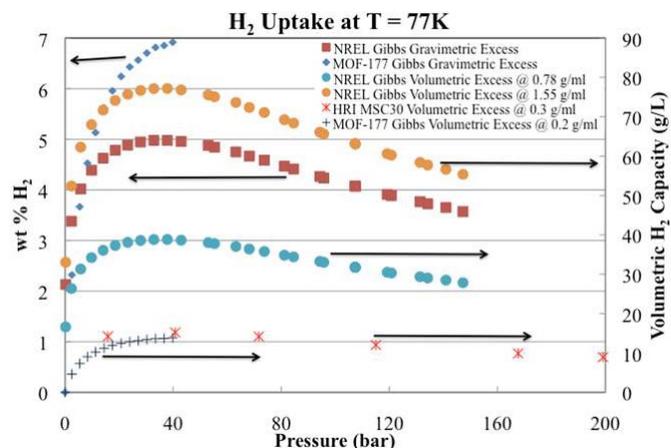

FIGURE 4. Engineering data for pyrolyzed PEEK that shows that volumetric capacity goals can be met with optimized pore size materials, much more easily than with lower bulk density materials such as MOFs.

Future Direction

- Continue to run vehicle simulations to support engineering design and support the center modeling framework refinements and enhancements:
 - Run vehicle simulations to support high-level storage system design and engineering tradeoffs.
 - Run vehicle simulations to support storage systems sizing analyses.
- Evaluate storage system impacts on vehicle performance (e.g., fuel economy, range).
- Evaluate storage system progress toward tech targets Run HDSAM to evaluate (liquid ammonia-borane and TiCr(Mn)H₂ systems):

- WTPP efficiency
- GHG emissions
- H₂ cost
- Investigate adsorbent materials that enable high near-ambient temperature storage capacities including Pt/AC-IRMOF 8.

Project End Date: February 2014

Introduction

Hydrogen storage systems based on chemical hydrides require a chemical reactor to release the hydrogen from the storage media, which is a fundamental difference from the other modes of hydrogen storage, adsorbents and metal hydrides. This hydrogen-release reactor is crucial to the performance of the overall storage system, especially in meeting the DOE targets for hydrogen generation rate, transient operation, and startup times. The reactor must be designed to achieve these targets while meeting the constraints of the overall system volume and weight targets.

LANL will also address the unique requirements of on-board automotive hydrogen storage systems. For example, these systems require fast startup, operation over a wide dynamic range (10:1 turndown or greater), and fast transient response to meet the demands of a drive cycle. The LANL team will develop novel reactor designs and operation strategies to meet these transient demands. In addition, the shelf life and stability of the hydrogen storage media is crucial for an automotive system, especially pertaining to safety and cost. Starting with the kinetics models, the LANL team will develop mathematical models for the aging characteristics of candidate hydrogen storage media (for example, complex metal hydrides or chemical hydrides) subjected to a range of environmental factors. These models can be incorporated into system-level models of performance and cost and also used for the development of accelerated aging protocols necessary for later testing.

Results

Fuel Gauge Sensor Development (Task 1)

Experiments were performed to determine the viability of employing acoustic sensor technology on metal hydrides as a fuel gauge sensor. Data were collected on commercial and noncommercial steel cylindrical pressure vessels containing metal hydride storage materials. In each case, the mass of metal hydride was small compared to the total mass of the system. However, large differences in the swept frequency response were observed, thus establishing a proof-of-principle that a hydrogen level sensor based on acoustic principles is feasible. Follow up experiments validated that the intermediate metal hydride state-of-charge can also be measured. Shown in Figure 1 are the resulting acoustic responses for various metal hydride states-of-charge. The acoustic response was observed to be inversely proportional to the metal hydride state-of-charge.

Fiscal Year (FY) 2011 Technical Objectives

- Develop fuel gauge sensors for solidstate hydrogen storage media.
- Mathematically model the aging characteristics (i.e., shelf-life) of candidate hydrogen storage materials.
- Develop rate models for hydrogen release on candidate chemical hydrides.
- Develop novel strategies for start-up and transient operation with candidate chemical hydrides.
- Identify hydrogen impurities and develop novel impurity mitigation strategies.
- Design, build, and demonstrate a subscale prototype reactor that releases hydrogen using chemical hydrides (technology area lead).
- Develop an on-board fluid-phase chemical hydrogen storage system; system designer.

FY 2011 Accomplishments

- Demonstrated novel acoustic fuel-gauge sensor is capable of tracking hydrogen states-of-charge for metal hydrides and metal hydride cycling.
- Performed preliminary fuel cell tolerance test with diborane impurity.
- Quantified borazine and diborane impurities generated from neat ammonia-borane (AB).
- Demonstrated that borazine and diborane can be scrubbed to produce fuel cell quality hydrogen.
- Developed base-case system designs for fluid-phase chemical hydrogen storage materials.
- Developed space filled model of base-case fluid-phase system design.

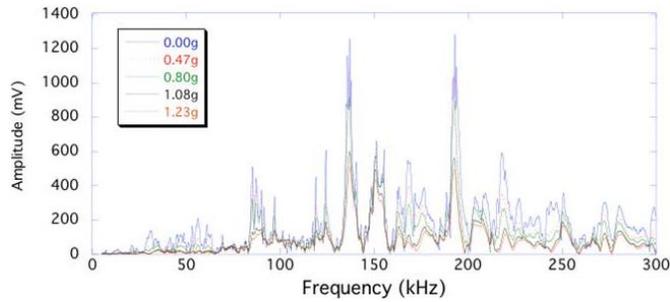

FIGURE 1. Acoustic Response as a Function of the Metal Hydride State-Of-Charge and Resonance Frequency

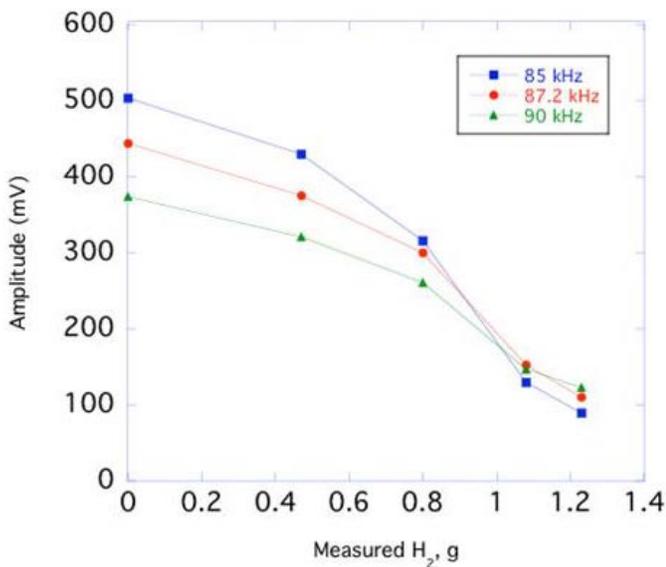

FIGURE 2. Acoustic Response for Three Resonance Frequencies as a Function of the Metal Hydride State-Of-Charge

The acoustic resonance frequencies were observed to be nonlinear with respect to the hydrogen state-of-charge. Figure 2 shows changes in three of the frequencies (85.0, 87.2, and 90.0 kHz) as a function of the metal hydride state-of-charge, with the lowest amplitudes occurring at the fully hydrided state-of-charge. The sensitivity in the acoustic amplitude was observed to be a function of not only the state-of-charge, but also the acoustic resonance frequency. The measured amplitude for a given resonance frequency exhibited monotonic behavior with respect to the state-of-charge, thus preventing multiple valued metal hydride states-of-charge.

Reproducibility of the state-of-charge is important if the sensor is to be commercialized. The sensor demonstrated reproducible results within 10%. The error is attributed to the fact that the metal hydride was in powder form. Performing acoustic measurements with engineered compacts will significantly lesson these errors.

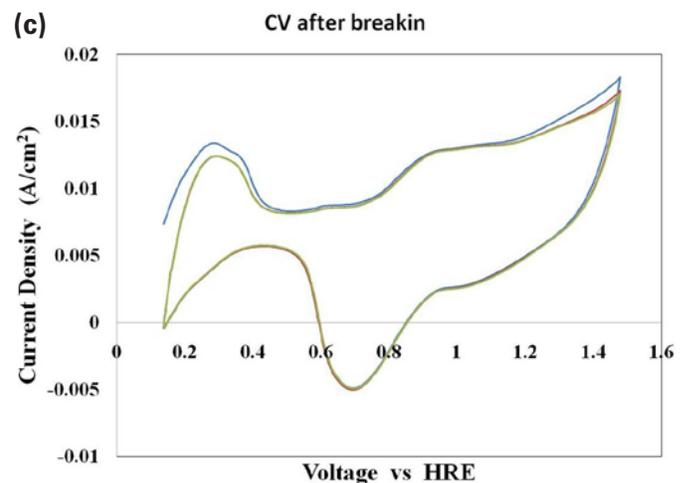

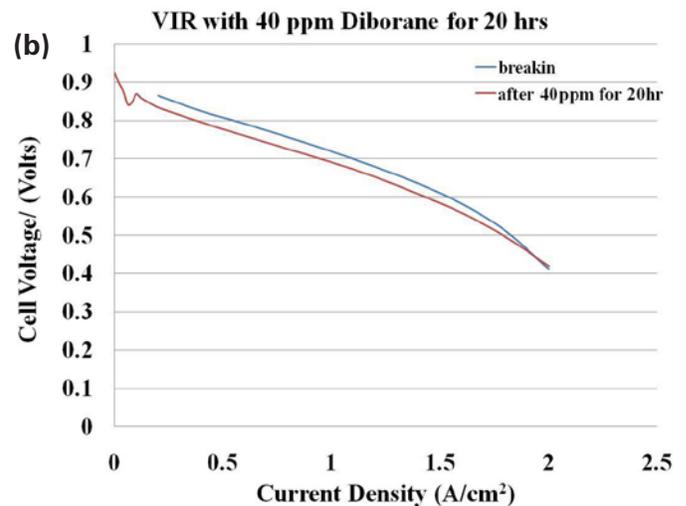

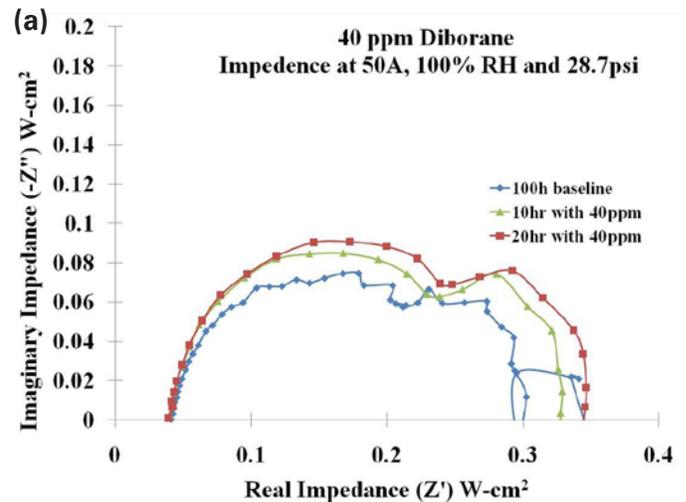

FIGURE 3. Fuel Cell Tolerance Test after 20 Hour Exposure with 40 ppm Diborane Impurity (a) Alternating Current Impedance, (b) Voltage-Current-Resistance Curve, and (c) Cyclic Voltammetry

Fuel Cell Tolerance Tests

In order accurately size an on-board hydrogen purification system for delivering fuel cell grade hydrogen, fuel cell tolerance levels for each of the impurities must be established. Diborane and borazine are known fuel cell impurities, but their levels for the safe and effective operation of a fuel cell are ill-defined. LANL performed preliminary fuel cell tolerance test with 2% diborane (balance ultra-high purity Ar) to investigate its effect on fuel cell performance. Shown in Figure 3 are the fuel cell tolerance test results after 20 hours of exposure with 40 ppm diborane. A decrease in fuel cell performance was observed after 20 hours of exposure to 40 ppm diborane, evidenced by a loss of 20 mV (Figure 3b). The electrochemical surface area remained constant throughout the preliminary 20 hour fuel cell tolerance test. The decrease in fuel cell performance can be attributed to an increase in the charge transfer resistance (Figure 3a). In addition, similar fuel cell tolerance tests are required for borazine.

Summary

- Successfully demonstrated that acoustic sensor technology can be used for tracking in real time the fully charged, fully discharged and the intermediate hydrogen state-of-charge of fixed metal hydride beds.
- Quantified impurities (diborane, ammonia, and borazine) generated from AB compositions.
- Performed preliminary fuel cell tolerance tests with diborane:
 - Fuel cell tolerance tests with 40 ppm diborane resulted in a 20 mV decrease in performance after 20 hours of exposure.
- Developed and designed automotive scale fluid-phase chemical hydrogen storage system.
- Developed and designed volume-based model of the automotive scale system design.
- Designed, built, and demonstrated a bench top fluid-phase chemical hydrogen validation test bed.

Future Directions

- Acoustic Fuel Gauge Sensor
 - Finish preliminary measurements on fluid-phase chemical hydrogen storage media
- Shelf-Life Modeling
 - Collect a complete set of shelf-life data on fluid-phase AB formulations.
 - Verify model accurately predicts shelf-life models for extended time periods.
- Reaction Rate Models for Hydrogen Release on Candidate Chemical Hydrides
 - Acquire complete set of kinetics data
 - Low temperature catalyst route
- Low Temperature Catalyst Development for Startup and Transient Operation
 - Continued efforts will focus on converting the room temperature homogeneous catalysts into heterogeneous form while maintaining room temperature activity.
- Hydrogen Impurities and Mitigation
 - In collaboration with LANL Chemical Hydrogen Storage Center of Excellence, quantify impurities from liquid AB formulations as a function of temperature.
- Subscale Component Design and Validation
 - Gas-liquid separator
 - Reactor
 - Hydrogen purification train

Project End Date: September 2014

- (I) Dispensing Technology
- (J) Thermal Management

Technical Targets

Regarding the technical barriers addressed by JPL's activities within the Hydrogen Storage Engineering Center of Excellence (HSECoE), the main areas that would be the focus of technical efforts would be the nature of loss of useable H_2 , thermal management, balance-of-plant components, efficiency, and durability/operability; the last of these will be evaluated directly by a phased effort of analysis and follow-on testing at JPL.

FY 2011 Accomplishments

Technical efforts at JPL during the previous year have been focused on the development and testing of novel thermal architectures for hydrogen storage systems. In particular, JPL's expertise with low-temperature system design and analysis has proved a good match for the unique demands presented by the cryo-adsorption system, which needs to operate at temperatures below 160 K, and as low as 60 K. The JPL project is a mixed approach of analytical modeling and follow-on experimental validation aimed at the development of thermal components and their interaction at the system level. JPL has also continued in the role of System Architect for cryo-adsorbent system technology development. In this role, JPL provides oversight and coordination of the various technology areas within the HSECoE that have responsibility for developing credible paths toward satisfying the DOE Hydrogen Storage targets (2010/2015/ultimate). This role also has direct responsibility toward system engineering outcomes, providing guidance and oversight for conceptual system design. Finally, JPL serves within the Center as Technology Area Lead for the Enabling Technologies team, providing technology management and coordination for overcoming technical gaps and incorporating emergent technologies and approaches.

Specific accomplishments:

- **High-Isolation Cryogenic Vessel Design:** In 2010, JPL identified multi-layer vacuum insulation (MLI) as a key design requirement for the cryo-adsorption storage vessel due to its high level of thermal isolation. Using analytical models validated by preliminary experiment, JPL demonstrated in 2011 a new design for a thermal architecture using MLI that improves thermal isolation, reducing heat loads on the storage medium by up to

Fiscal Year (FY) 2011 Objectives

- Apply an understanding of storage system requirements for light-duty vehicles.
- Develop innovative on-board system concepts for materials-based storage technologies.
- Develop and test innovative concepts for storage subsystems and component designs.
- Identify technology gaps and identify trajectories to overcome technical barriers.
- Design, fabricate, and test subscale prototypes for each material-based technology.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan (referenced to 2015 targets, as revised 2009):

- (A) System Weight and Volume: $5.5 \% \text{owt}_{\text{sys}}$, $55 \text{ gH}_2/\text{kg}_{\text{sys}}$, $40 \text{ gH}_2/\text{L}_{\text{sys}}$
- (C) Efficiency: 90% on-board/60% off-board
- (D) Durability/Operability: <1% degradation @ 1,500 cycles, etc.
- (E) Charging/Discharging Rates: 3.3 min fill, 0.02 g/kW-s minimum full flow
- (G) Materials of Construction
- (H) Balance-of-Plant Components

44% over current designs, increasing dormancy (“hold”) times for the idle vehicle.

- **Cryogenic Fuel Energy Management:** Via analytical modeling, JPL designed a compact onboard heat exchanger (“downstream H₂ HX”) for cryogenic hydrogen fuel conditioning. This crucial device will utilize fuel cell waste heat in a closed coolant loop to raise the temperature of fuel supplied to the fuel cell. The JPL model has been incorporated into the overall HSECoE model framework, and has been shown to operate as designed across the complete operating envelopes of both AX-21 and MOF-5-based storage system designs.
- **Loop Desorption Heating:** Developed a design criteria and initial analytical model for H₂-loop desorption heating, identifying additional onboard efficiency gains and promoting the H₂ circulator as a technology gap for further investigation in Phase II.
- **Cryo-Adsorbent System Phase 1 Transition:** In the role of System Architect, JPL assisted in guiding the cryo-adsorbent system design team through the Phase 1-2 transition, which involved standardizing performance metrics of defined baseline systems and identifying technology development opportunities and challenges.

Introduction

JPL is engaged in developing enabling technologies for vehicular hydrogen storage systems for meeting DOE/FreedomCAR technical targets. During this project year, the enabling technologies area has been primarily concerned with low-temperature thermal management for the cryo-adsorbent system with emphasis in three areas: 1) parasitic heat transfer reduction in pursuit of the 2015 loss of useable H₂ target of 0.05 g h⁻¹ kg⁻¹ useable H₂, 2) downstream hydrogen heating to achieve the -40°C target for hydrogen delivered by the storage system, and 3) controlled heating of the cryogenic vessel for desorption (i.e., desorption heating) to meet the required 1.6 g s⁻¹ requirement full flow rate for anticipated drive cycles. In each of these areas, the current state of the art was either extended in relation to the technical targets, or it was shown that the technical targets could be fully satisfied.

Approach

First-order heat and mass transfer models were constructed to quickly evaluate various technologies in the areas of dormancy, downstream hydrogen heating, and desorption heating. In the case of dormancy, detailed higher-order models were used for thermo-mechanical evaluation of cryogenic standoffs. In the dormancy area, the challenge is designing standoffs capable of withstanding shock loads exceeding 8 g while providing high conduction resistance. JPL has sought to improve on the state of the

art in vehicular cryogenic storage by adapting the baseline G10 system proposed by Lawrence Livermore National Laboratory and others for liquid H₂ storage to the cryo-adsorption system, and also by proposing a new method of insulation relying on fibrous suspension of the pressure vessel inside the vacuum jacket, which has led to significant reduction in H₂ loss rate. JPL has investigated various methods for accomplishing downstream H₂ heating with the objective of mitigating frost risks and minimizing heat exchanger volume. As of March 2011, JPL has begun construction on a cryogenic test facility capable of spanning the temperature range projected for cryo-adsorption storage. The first use of this facility is to validate the parasitic heat transfer model used for dormancy calculations. The cryogenic test facility will also be used in Phase II of the project for additional experiments.

Results

The primary benefits of cryogenic adsorption storage are increased gas phase density and increased adsorption mass fraction near 80 K. Unfortunately, this low temperature can yield large parasitic heat transfer rates; only a few watts of parasitic heat transfer are needed to induce H₂ venting after a few days of idle. Mechanical models of thermal standoffs were built to size supports for a rigid G10 design and a second Kevlar™ design such that the components did not yield when subjected to loads of 8 g perpendicular to the axis of the tank with a safety factor of 2. Kevlar™ cables were sized to support the same loading; because Kevlar™ rope is available in discrete sizes, only cables that met or exceeded the mechanical requirements were used for heat transfer calculations.

Heat transfer models were built to estimate conduction across standoffs, radiative exchange across MLI, and conduction through tubing. These models were parameterized as a function of cold-side temperature at a hot-side temperature of 26°C, representing a summertime diurnal average. The component-level heat transfer for the G10 architecture (Figure 1a) revealed that standoff heat transfer is the most significant constituent of the ~5 W total parasitic. By replacing the G10 standoff design with Kevlar™, it was estimated that the total parasitic heat transfer could be reduced by up to ~44% (Figure 1b).

The reduced parasitics of the Kevlar™ design lead to reduced H₂ losses by venting and longer dormancy. To quantify these improvements, a model was constructed to relate parasitic heat transfer to tank temperature and vent rate; para- to ortho- conversion during tank heating is accounted for. Figure 2 shows that the average vent rate over a 30-day period is about ~0.52 g h⁻¹ kg⁻¹ for the G10 design compared with ~0.35 g h⁻¹ kg⁻¹ for the Kevlar™ design, and that the dormancy for Kevlar™ is approximately 70% longer. Figures 1-2 document a 70 bar aluminum pressure vessel with AX-21 adsorbent. A 200 bar Type-III carbon fiber vessel with MOF-5 adsorbent has also been modeled. MOF-5 shows slightly lower vent losses and

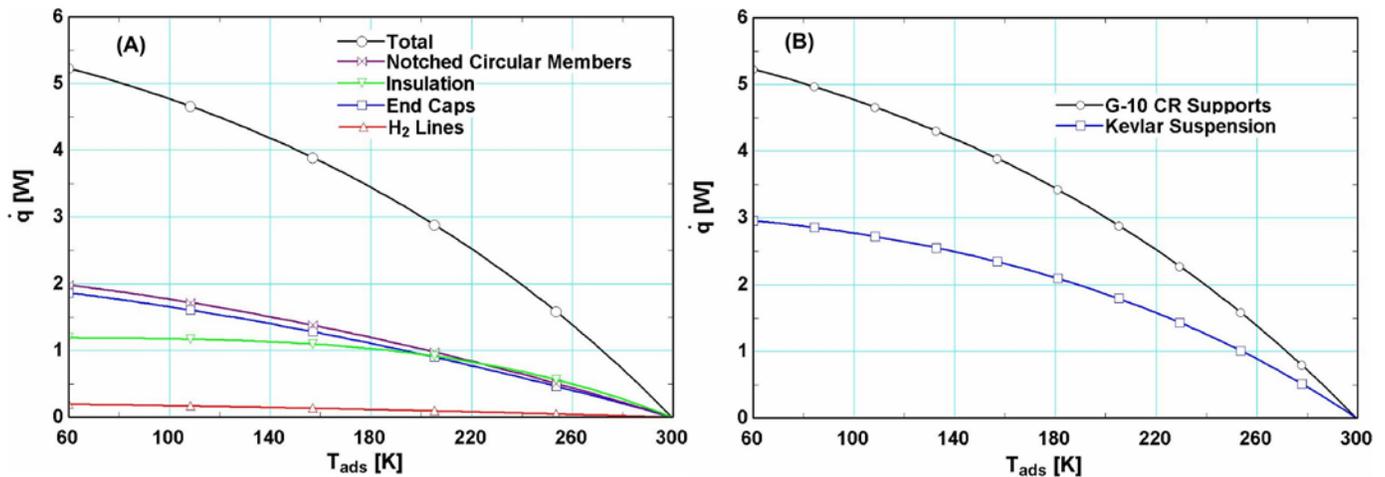

FIGURE 1. Breakout parasitic loads for G10 (state of art) and total parasitic loads for G10 and Kevlar™ (advanced) tank thermal isolation designs.

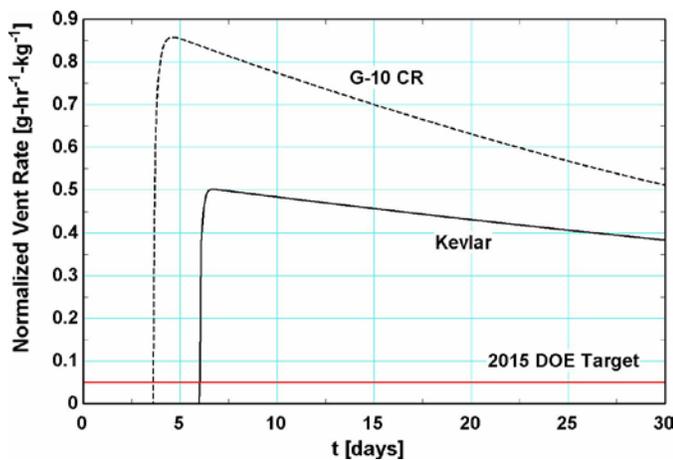

FIGURE 2. Vent rate histories for G10 (state of art) and Kevlar™ (advanced) thermal isolation designs.

longer dormancy times, but the relative improvement of Kevlar™ over G10 is generally similar to the AX-21 case. Nevertheless, even the Kevlar™ design gives dormancy performance that falls short of the 2015 hydrogen loss target; the projected mass of hydrogen lost to venting is appreciable (~1 kg over 30 days) with the improved design. However, it should be noted that the scenario exercised in this model is a worst case and does not account for natural pressure relief through driving; a small amount of daily driving can extend dormancy indefinitely in this type of system.

In the downstream heat exchange area, three types of downstream heat exchange sub-systems were modeled with the common objective of heating stored low-temperature hydrogen to allowable temperatures en-route to the fuel cell or internal combustion engine. The modeled sub-systems included a direct air-coupled hydrogen heat exchanger with an air-side heater, a hydronic loop coupled to air, and a fuel cell coolant-coupled loop. The obstacles for each of these

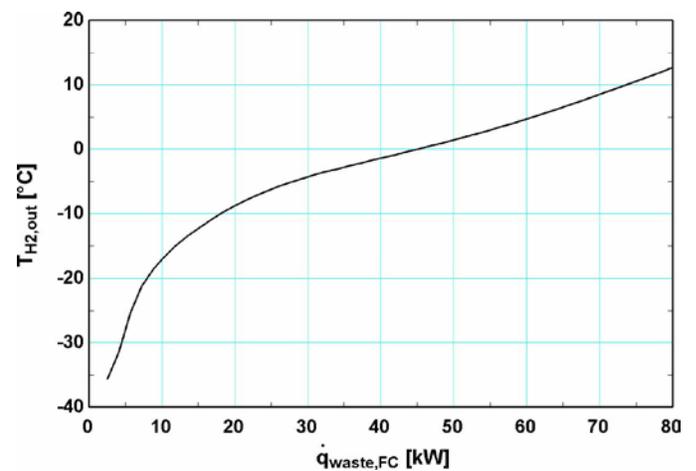

FIGURE 3. Delivered hydrogen temperature versus total fuel cell waste heat. Assumes 50% of waste heat is dissipated by coolant loop.

concepts were 1) the size and number of heat exchangers required, and 2) the potential for ice formation at various locations within the heat exchange equipment. The direct air-coupled heat exchanger model predicted frost build-up on the air side for most cases. The independent hydronic loop also showed the potential for icing at low temperatures in addition to requiring two dedicated heat exchangers. The fuel cell coolant-coupled loop is the leading design candidate. Waste heat from the fuel cell helps prevent icing on the coolant side, while the coolant loop axial flow fan and air-coupled heat exchanger are leveraged to reduce volume and parts count. At -30°C ambient and a hydrogen flow rate of 0.8 g s^{-1} , this system will deliver -40°C hydrogen with no waste heat input from the fuel cell. With a nominal amount of waste heat input, Figure 3 shows that this system exceeds the delivery target even in -40°C ambient conditions.

In desorption heating, a compressible flow network model was developed to model the flow-through heating

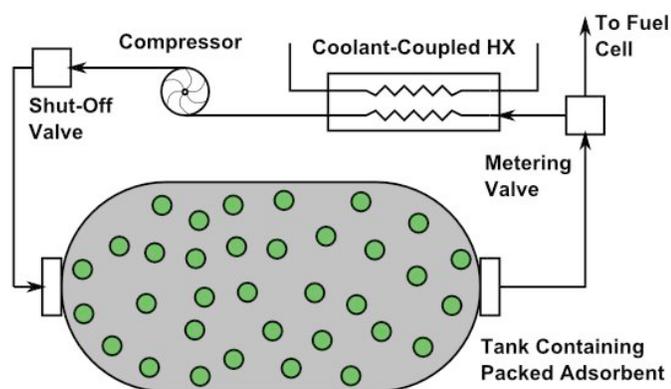

FIGURE 4. Flow-Through Desorption Loop Schematic

design shown in Figure 4. The most aggressive cases, delivering 1.6 g s^{-1} with a set point pressure of 20 bar, the H₂ circulation rate must be very large. For nominal quarter inch lines, pressure losses resulting from these flow rates can be significant; however, drive cycles incorporated into the framework model developed by Savannah River National Laboratory in conjunction with the United Technologies Research Center have suggested that such stringent cases do not exist in practice. Tank heating rates up to 1 kW should be realizable with this type of system. The model predicts that a circulator would need to provide 3 kPa of pressure rise in order to deliver $\sim 1 \text{ kW}$ of heating when transferring heat from fuel cell coolant at 52°C. The technology gap in this area, however, is procuring a circulator that is rated to operate at pressures exceeding 200 bar; investigations in this particular direction have already begun.

Conclusions and Future Directions

- Two thermal isolation architectures were studied in detail. A scaled parasitics experiment is being constructed to validate the predictive models, and in Phase II, a high-fidelity dormancy experiment based on the novel Kevlar™ architecture is planned. Pressure vessel outgassing experiments are also being developed, which will indicate the level of vacuum that is feasible.
- Various methods for downstream hydrogen heating were investigated, and it was determined that coupling to the fuel cell coolant loop offers the best protection against freezing while also meeting hydrogen conditioning requirements. JPL has started to develop higher-order models of this process and is in the planning stage of adapting an experimental facility to supplement those models.

- The HSECoE has identified flow-through heating as an alternative to Joule heating for desorption. A compressible flow network model was developed by JPL to model the flow-through design. Pressure-drops are reasonable current system configurations; however, the technology gap is the hydrogen circulator, which must operate at low temperature and high pressure. More work will be done to identify a path forward for desorption heating.
- During the next year, JPL plans to conduct a demonstration high-pressure burst test of a 200-350 bar composite pressure vessel at cryogenic ($\sim 77 \text{ K}$) temperatures. This proof-of-concept activity will begin a series of investigations that will include cryogenic pressure/temperature cycling as well as possible future burst tests. These investigations will be performed in conjunction with HSECoE partners Lincoln Composites, Pacific Northwest National Laboratory, and United Technologies Research Center, among others. The results will inform future investigations and safety/testing protocols during Phase II experimental work as well as eventual prototype storage system testing.

E-mail: Ned.Stetson@ee.doe.gov

Subcontractor:

Université du Québec à Trois-Rivières, Quebec, Canada

Start Date: February 1, 2009

Projected End Date: July 31, 2014

Fiscal Year (FY) 2011 Objectives

The Savannah River National Laboratory (SRNL) and its sub-recipient the Université du Québec à Trois-Rivières (UQTR) will:

- Collect property data for select metal hydrides and adsorbents.
- Compile list of available analytical techniques to support materials property data requirements.
- Develop and evaluate the acceptability envelope for storage media and vessels.
- Develop numerical models to adequately predict storage system behavior for metal hydride and adsorbent based storage systems.
- Use the models to design optimized storage systems based on NaAlH₄, other metal hydrides, AX-21, and other potential adsorbent materials.
- Direct metal hydride system testing and evaluations as the Metal Hydride System Architect for the Center.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section (3.3) of the Hydrogen, Fuel Cells and Infrastructure Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (C) Efficiency
- (E) Charging/Discharging Rate

Technical Targets

The goal of the entire Hydrogen Storage Engineering Center of Excellence (HSECoE) is to provide a system model for each material sub-class (metal hydrides, adsorption, chemical storage) which meets the “Technical System Targets: On-Board Hydrogen Storage for Light-Duty Vehicles”, Table 3.3.2 in the DOE Multi-Year Research and Development Plan – April 2009. The end-of-Phase I, Go/No-Go milestone which is set for February 2011 for the entire HSECoE project is that:

1. Four of the DOE 2010 numerical system storage targets are fully met and that,
2. The status of the remaining numerical targets must be at least 40% of the target or higher.

For SRNL's specific technical portion of HSECoE, SRNL will:

- Direct the testing and evaluations necessary for the specific Go/No-Go milestones for metal hydride systems.
- Compile thermochemical data.
- Bound media operating characteristics for metal and adsorption hydride material.
- Develop and apply numerical models that couple mass, momentum and energy balances with chemical kinetics and/or isotherms to simulate hydrogen uptake and discharge.
- Develop and run system models for candidate adsorbent material systems.
- Identify technology gaps.
- Identify preliminary system designs to achieve DOE 2015 hydrogen storage goals.

FY 2011 Accomplishments

- Collected material operating data for LiMg-amide metal hydride materials including developing engineering kinetic expressions.
- Applied Acceptability Envelope to select metal hydride materials and systems.
- Studied 50 bar, 100 bar, and 150 bar sodium alanate optimal systems.
- Estimated isenthalpic (Joule-Thompson) temperature change for hydrogen flow through a throttling valve, which can be as large as an 18 K drop.
- Developed methodology and estimated pressure drop losses for flow in piping of cryo-adsorbent system for a range of conditions (mass flow rates, temperatures, and pressures) for use in system models.

- Developed improved methodology to estimate heat transfer coefficient for turbulent (radial) flow in micro-channel between cooling plates for analysis and COMSOL optimization of modular cryo-adsorbent designs.
- Studied in-line heat exchangers for hydrogen feed to fuel cell.
- Completed System Architect analysis of sodium alanate as a model material vs. DOE 2010 Go/No-Go Decision.

Introduction

SRNL and its subrecipient, UQTR, are involved in several critical aspects of the HSECoE. SRNL is focused primarily on modeling, validating, and optimizing hydrogen storage designs for metal hydrides, adsorbents, and, to a lesser extent, chemical hydrides, and System Architect Analyses of metal hydride systems. SRNL is applying its expertise in modeling dynamic transport phenomena and chemical processes, materials testing, and system modeling to accomplish its objectives in the proposed effort—developing and applying models to identify viable subscale prototype designs, performing design calculations sufficiently accurate for engineering application, and defining the scope and required measurements for experiments with the selected prototypes.

UQTR is developing thermodynamic formulations for adsorbent isotherms that can be easily and efficiently implemented by SRNL into a numerical model that accurately predicts the behavior of an adsorption-based storage system over a range of operating conditions and system configurations. UQTR is extending its thermodynamic model, which currently applies to adsorption on activated carbons, to other adsorbents.

Relevance

The ultimate goals of the HSECoE are the design and testing of prototype hydrogen storage vessels, the interpretation of test data, and the implementation for full-scale vessels. Within the HSECoE, the Transport Phenomena Technology Area is responsible for the development and application of analyses for storage systems that are necessary to identify and design prototype media and vessel configurations having the best performance relative to the DOE Technical Targets. Storage vessel models developed by this Technology Area will be essential to interpret data obtained from prototype testing and to relate it to full scale systems.

Approach

In Phase I, SRNL and UQTR will:

- Evaluate, interpret, and assimilate data for media and vessel components.

- Develop and apply an “Acceptability Envelope” based on DOE targets.
- Develop, validate and test general models for scoping and detailed evaluation of storage system designs.
- Obtain material operating requirements for metal hydride and AX-21 materials.
- Perform System Architect analysis on candidate metal hydride systems for Phase I Go-No-Go decision.

Results

SRNL and its subrecipient UQTR to date have met and or exceeded their Phase I objectives for all of their major technical areas for the HSECoE. These major technical areas include: Transport Phenomena, Adsorbent Systems Modeling, Material Operating Requirements and System Architecture. Transport Phenomena and Adsorbent System Modeling results are shown below for adsorbents systems. Results for activities under Material Operating Requirements and System Architecture are shown for metal hydrides systems.

Transport Phenomena

- Developed Detailed and Thermodynamic Models for Adsorbent-Based Storage Vessels
 - Applied to MaxSorb™ (MSC-30™) and MOF-5™ (Basolite Z100-H)
 - Validated MaxSorb™ model against test data
- Applied Models for Charging and Discharging of Storage Vessel
 - Charging characteristics (see Figure 1)
 - Charging models were applied for DOE 2015 Technical Target time of 198 seconds (3.3 minutes)

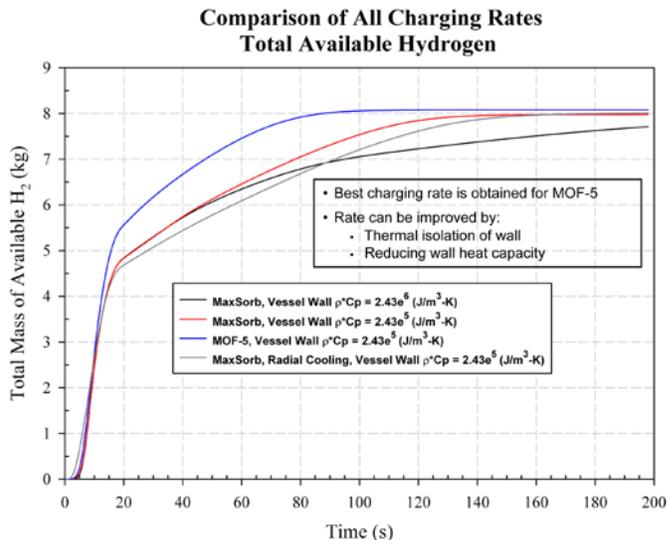

FIGURE 1. Comparison of system charging rate for different adsorbent materials and different wall thermal isolating conditions.

- Considered stored energy in vessel wall
- Heat removal by axial and radial convection via flow-through cooling
- Contributions of pressure work and heat of adsorption
- Discharging characteristics (see Figure 2)
 - Resistance heater
 - Flow-through cooling

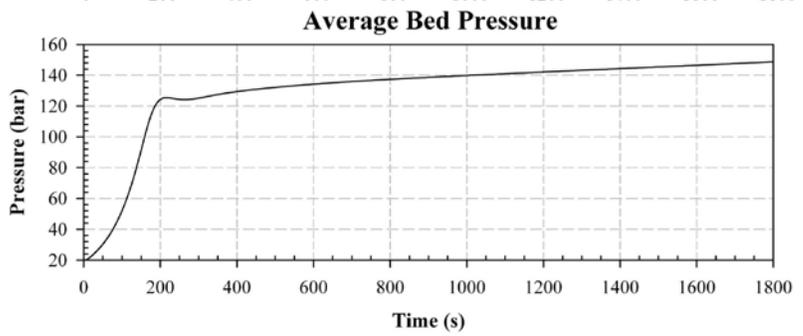

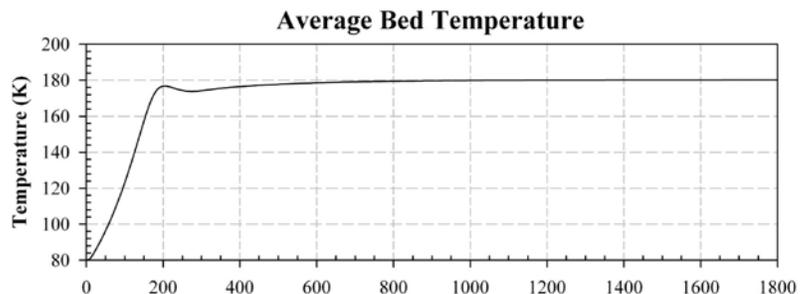

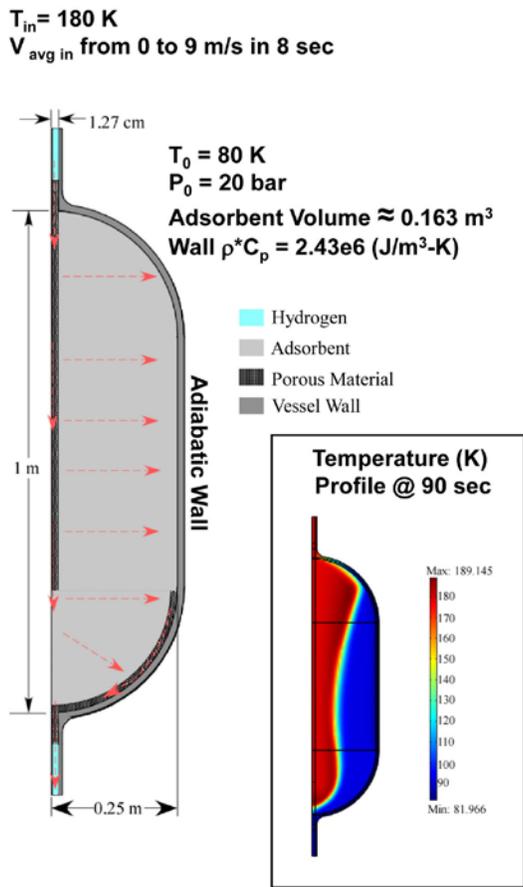

- None other than the exposed hydrogen piping
- Air-to-hydrogen vessel heat exchanger
- Air-to-fuel cell coolant heat exchanger (currently the base case system option)

Material Operating Requirements: Metal Hydrides

Adsorbent System Modeling

- Developed and ran baseline system models for four adsorbent systems (AX-21 at 60 and 200 bar and MOF-5 at 60 and 200 bar) in support of the baseline Adsorbent System Go/No-Go decision (see Figure 3)
- Evaluated several tank heating input methods using the adsorbent system model
 - Hot hydrogen recirculation line
 - Heat switches
 - Internal resistance heater (currently the base case system option)
- Evaluated various heat exchanger options

- Selected sodium aluminum hydride (NaAlH_4) material as initial baseline hydride candidate material for transport phenomena and system modeling development.
- Database updated for:
 - NaAlH_4 (with and without catalysts)
 - TiCrMn
 - Mg_2Ni
 - $8\text{LiH}:3\text{Mg}(\text{NH}_2)_2$
- Additional data added for:
 - 2:1 $\text{LiNH}_2:\text{MgH}_2$
 - 1:1 $\text{LiNH}_2:\text{MgH}_2$
 - MgH_2 (without catalysts)

▪ Flow through heating provides good time response

FIGURE 2. Average adsorbent bed temperature and pressure profiles with radial flow-through heating.

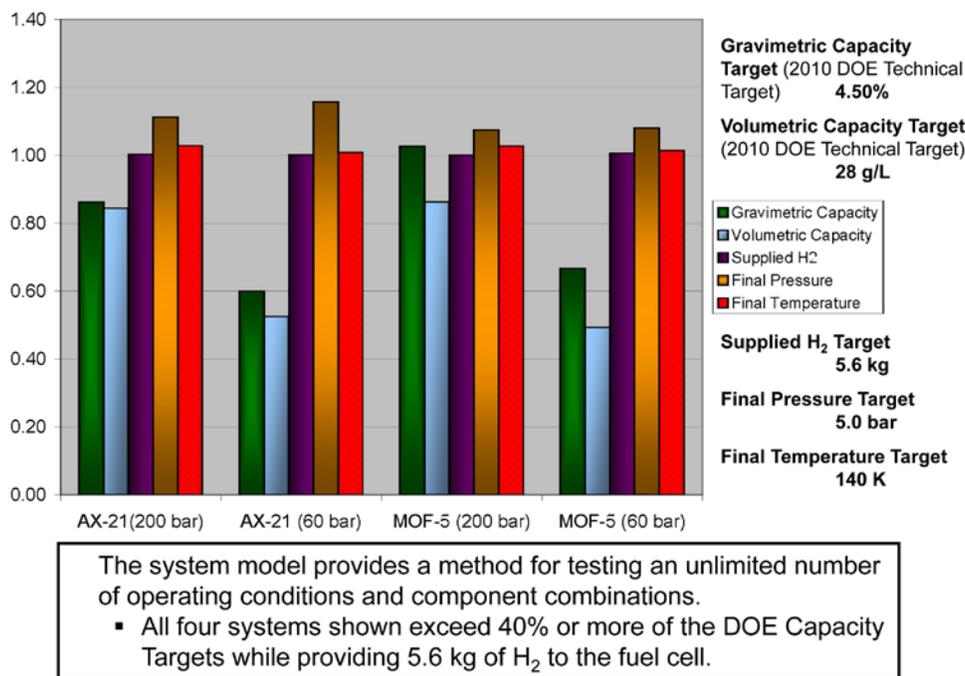

FIGURE 3. Adsorbent system modeling results compared to DOE 2010 system targets.

- Developed preliminary kinetic expressions for 2:1 LiNH₂:MgH₂ and 1:1 LiNH₂:MgH₂ to support system modeling analyses.
- Updated and improved the Acceptability Envelope to evaluate metal hydride materials for the Go/No-Go decision.

System Architect Analyses: Metal Hydride

- Selected Metal Hydride System for baseline Phase 1 Go/No-Go decision (see Figure 4).
- Documented selection criteria and assumptions for Metal Hydride Systems with respect to 2010 targets and Phase 1 Go/No-Go decision.
- Identified deficiencies and improvement areas for Metal Hydride Systems for Phase 2 development plan.

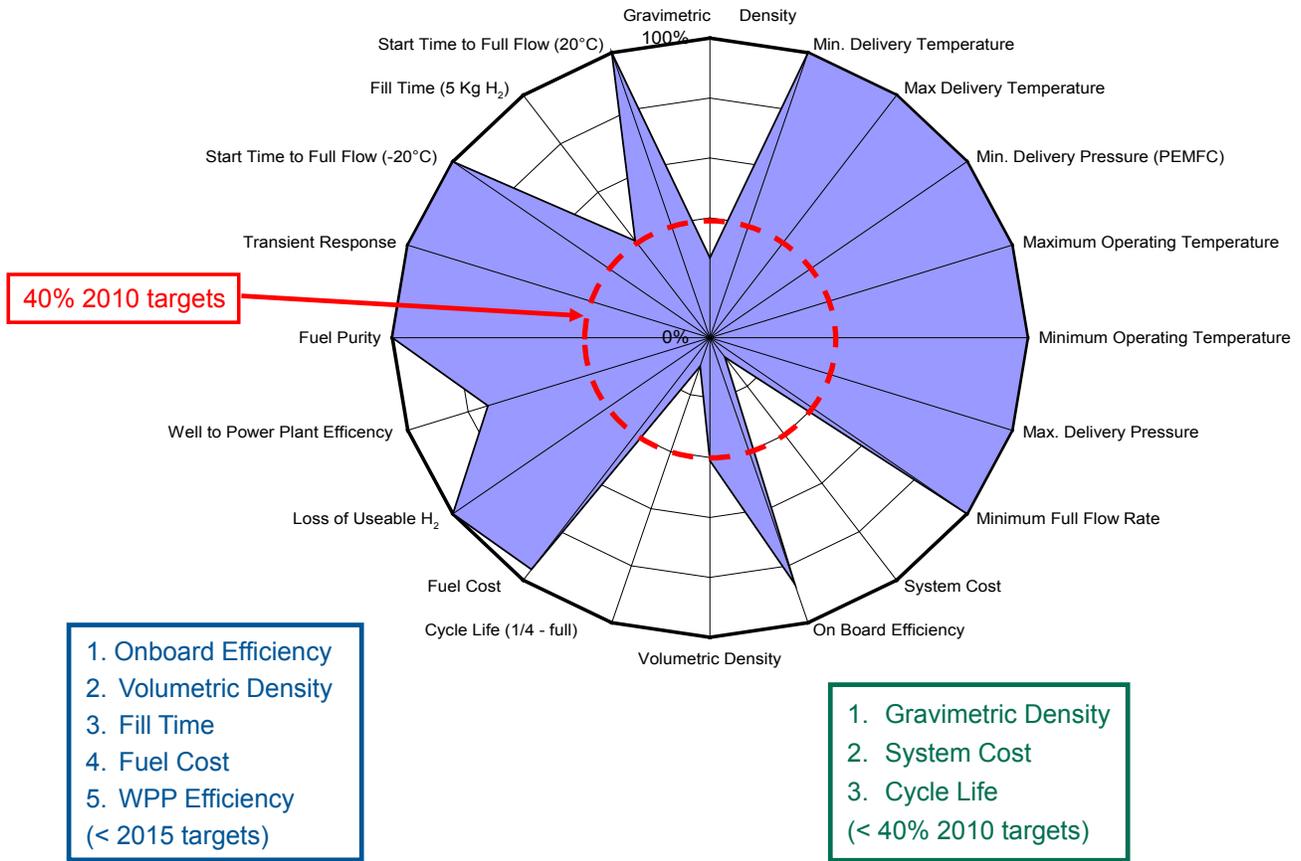

Conclusions and Future Directions

- Continue Metal Hydride System Architect analyses.
- Provide analyses for Phase 2 Go/No-Go decision.
- Investigate thermal and structural effects of bed expansion.
- Improve bed heat transfer for metal hydrides and adsorbents (expanded natural graphite addition and honeycomb lattice) - experiments will be guided by models.
- Investigate viability of flow-through concept for adsorbent systems.

- Optimize adsorbent system with respect to pressure work, enthalpy of hydrogen discharge flow, dormancy conditions and thermal interaction with container wall.

Project Start Date: February 1, 2009
Project End Date: January 31, 2014

Fiscal Year (FY) 2011 Objectives

The Pacific Northwest National Laboratory (PNNL) objectives address the critical engineering challenges currently limiting on-board hydrogen storage systems for light-duty fuel cell vehicles. Each of the project's objectives and tasks have been established to advance the state of the art in analysis, design and engineering for chemical hydride storage, pressure/containment vessel construction for metal hydride and cryogenic adsorbent systems, and component miniaturization for all systems to achieve PNNL, Hydrogen Storage Engineering Center of Excellence (HSECoE), and DOE goals.

- Demonstrate a high level of performance that meets DOE targets for key components (reactor, solids handling, and heat exchanger) of a solid chemical hydrogen storage system.
- Optimize the design of a chemical hydride storage bed and system performance through engineering including the establishment of bulk media and system kinetics data to aid in design activities.
- Reduce system volume and weight while optimizing system storage capability, fueling and dehydrating performance through application of microtechnology and associated architectures to the design of high-efficiency heat exchangers and balance-of-plant (BOP) components.
- Mitigate materials incompatibility issues associated with hydrogen embrittlement, corrosion, and permeability through suitable materials selection for vessel materials, heat exchangers, plumbing and BOP components.
- Demonstrate the performance of economical, compact lightweight vessels for a hybrid pressurized metal-hydride and adsorbent system, and containment vessel for a chemical hydride system.

- Guide design and technology down selection, Go/No-Go decision-making, and address vehicle and market impact through cost modeling and manufacturing tradeoff assessments of the three HSECoE prototype storage systems.

Achieving the objectives will enable PNNL, Savannah River National Laboratory (SRNL), and other HSECoE partners to demonstrate on-board hydrogen storage with the potential to meet 2015 DOE technical targets. This technology and design knowledge will be transferred to the participating automotive original equipment manufacturers and non-proprietary information and models will be made available to the fuel cell community, thus advancing the hydrogen market sector and production of future hydrogen-powered vehicles.

Technical Barriers

This project addresses the following technical barriers from the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

General to All Storage Approaches

- (A) System Weight and Volume
- (B) System Cost
- (C) Efficiency
- (D) Durability/Operability
- (E) Charging/Discharging Rates
- (G) Materials of Construction
- (H) Balance of Plant (BOP Components)
- (I) Dispensing Technology
- (J) Thermal Management
- (K) System Life-Cycle Assessments
- (O) Hydrogen Boil-Off

Off-Board Regenerable Specific

- (S) By-Product/Spent Material Removal

Technical Targets

The HSECoE activities being conducted at PNNL range from process and reactor modeling and component design/engineering to technology application and prototype fabrication for demonstration. The final ultimate goal for the PNNL scope is to demonstrate, with Los Alamos National Laboratory (LANL) partners, a (100-g) scaled chemical hydrogen storage system that meets all the 2015 DOE storage performance targets. As a snapshot of progress to date,

the spider chart in Figure 1 represents the principal 2010 DOE performance targets and status toward achieving those targets as a percentage. The DOE has established an initial in-process review gate of 40% for each of the targets except system cost; the dashed line represents this 40% threshold.

FY 2011 Accomplishments

- Demonstrated refueling feasibility using a solid hydrogen storage material with both pellets and powders. The pellets were capable of achieving 75-100% of the DOE's refueling (fill and drain) 2010 targets and the powders were capable of achieving 27-50% of the 2010 targets. Low density polyethylene was used as a surrogate of an 80:20 ammonia-borane (AB)/methyl cellulose (MC) mixture by weight. Based upon the results of these tests, pellet form factors are recommended for solid chemical hydride fuels over powders.
- Validated AB kinetic models using pressure-concentration-temperature (PCT) and larger scale testing.
- Demonstrated self-sustaining hydrogen release of AB/MC pellets without foaming at atmospheric pressure and at 10 bar (system design pressure).
- Validated and modeled a new design which combines the fuel storage tank with the reactor and hydrogen ballast tank into a single fixed-bed design. The simple design consists of a single tank with multiple beds. Each bed is thermally isolated from the others. Therefore as

hydrogen is needed, a single bed is heated to release the hydrogen. A single bed was used to validate the design. COMSOL and Simulink were used to predict and improve the reactor performance.

- Completed the Simulink modeling for eight system configurations including the fixed bed design, fluid system (AB dissolved in ionic liquids [IL] or a chemical hydride slurry), reactive transport systems such as an auger design, and a tape/roller system. The fixed bed system was modeled with AB/MC, the reactive transport and fluid systems were modeled with solid AB/MC, alane, AB slurries, alane slurries, and AB/ionic liquids.
- Predicted, using Simulink models integrated with the Vehicle Model that hydrogen storage technologies based upon solid and/or fluid chemical hydrides can meet the DOE delivery targets. Multiple cases were examined with the integrated models including: UDDS+HWFET, US06, and Cold FTP.
- Discontinued work on the reactive transport (or auger) concept based on concept validation tests. Hydrogen was successfully produced using an auger type reactor with AB/MC as the chemical hydride; however, the auger tended to clog. Based on the results, work on the reactive transport systems was discontinued.
- Down selected from greater than eight designs to one design for Phase II. Any design requiring replacement canisters or cassettes was discontinued due to safety concerns. Reactive transport concepts were

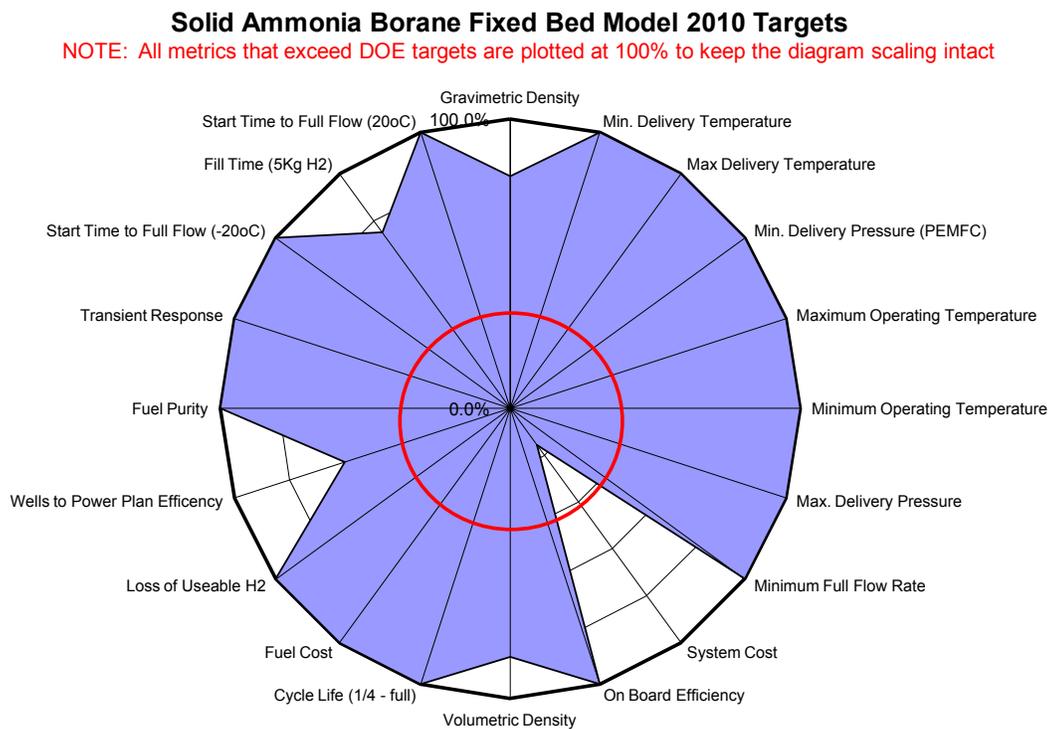

FIGURE 1. Progress toward achieving DOE performance targets for solid AB hydrogen storage. Fifteen targets are met at 100%, four targets met at >40% and system cost target at <40%.

discontinued based upon the results of the auger reactor testing. A fixed bed reactor concept was validated. The modeling and cost analysis revealed that a fixed bed reactor with a solid chemical hydride and fluid reactor (solid liquid slurry or AB in IL) would meet the DOE targets. Due to programmatic restraints, it was decided that only one design would go forward. After consultation with our HSECoE partners, including the manufacturers, it was decided to focus future efforts on the fluid system (slurries or AB in IL).

- Projected the mass and volume of four different systems including the metal hydride system, cryogenic adsorbent system, fixed bed reactor chemical hydride system and AB in IL system. As part of this work the heat exchangers and BOP components were sized, and vendors were identified. Care was taken to ensure that the materials were compatible with hydrogen, and the operational temperature and pressures. Value engineering to reduce the mass and volume of the BOP was begun.
- Completed the BOP catalogue which includes the vendor sources, materials of construction, mass, volume, operating temperatures, connection data (if applicable), and performance information (if applicable). This library will be made available to the public in FY 2012.
- Projected the storage system costs to be \$9,200 and \$4,800 for the metal hydride and chemical hydride systems when produced in high volumes (500,000 units/year). The cost of AX-21 material at high volumes was projected using models of the process as described in the literature. The projected cost was found to be ~\$4/kg when made at high volumes. The complete system cost for the cryogenic adsorbent system is not complete since we have not received all the vendor quotes. The single largest cost component for all the systems is the tank cost.
- Developed model to assess materials and design options for Tier 1-III pressure vessels.
- Assessed materials options and design options for Type IV liner materials.
- Developed experimental plan for burst testing Type IV pressure vessels under high and low temperature (cryogenic) thermal cycling.
- Optimized the vessel design in terms of cost and performance.
- Defined the geometry limitations for vessel size with manufacturers.

Introduction

To date there has been multiple on-board vehicle-scale hydrogen storage demonstrations, including several studies to examine phenomena and characteristics that impact the engineering of hydrogen storage systems. However, none of these demonstrations have simultaneously met all of the

DOE hydrogen storage sub-program goals. Additionally, engineering of new chemical hydride approaches specifically is in its infancy, with ample opportunity to develop novel systems capable of reaching the DOE targets for storage capacity. Toward this goal, PNNL is leading efforts as part of the HSECoE led by Savannah River National Laboratory (SRNL), to design and fabricate a 100 g of hydrogen scaled system based on solid or slurry chemical hydride storage media. This system is intended to be demonstrated at LANL at the conclusion of the HSECoE effort.

Approach

The PNNL actively contributes to the five technology areas established as part of the HSECoE led by SRNL. The goal of this center, and PNNL's role, is to develop and demonstrate low-cost, high-performing, on-board solid-state hydrogen storage through a fully integrated systems design and engineering approach.

PNNL targets six key objectives to optimize performance characteristics and reduce the size, weight, and cost of a solid-state hydrogen storage system. This is being accomplished through carefully engineering and integrating design approach, including application of advanced materials (structural and hydrogen storage), and assessments of manufacturing and cost impact based on established models/approaches for technology tradeoff or "viability" studies.

PNNL also serves multiple leadership roles within the HSECoE technology area structure to help facilitate collaboration across the center partnership and to feed technical results back through and disseminate to other center partners. Achieving the objectives enables PNNL, SRNL, and other HSECoE partners to demonstrate on-board hydrogen storage with the potential to meet 2015 DOE technical targets. This technology and design knowledge will be transferred to the participating automotive original equipment manufacturers, thus advancing the hydrogen market sector and production of future hydrogen-powered vehicles. As appropriate, the models, catalogues, and lessons learned will be made available to the general fuel cell community to accelerate fuel cell technology penetration into commercial applications.

Results

Chemical Hydride Modeling, Concept Validation, and Down Selection

Three types of models were under development in FY 2010: kinetic models, COMSOL, and Simulink models. During FY 2011 the kinetic models were validated, the COMSOL and Simulink models were completed, and the Simulink model was integrated with the Vehicle System Model.

The kinetic models were validated using PCT and large-scale experiments using neat AB and AB mixed with

MC. The results of the PCT tests indicated the amount of H₂ released and the rate of release were consistent with the predicted values (Figure 2). In addition, no foaming was observed on the AB/MC mixture. Since the PCT tests were limited to mg amounts of material, larger tests using gram quantities were done using a quartz tube with thermal imaging and in a stainless steel tube under pressure. The quantity and rate of release was consistent with the models. For the quartz tube testing a heating element was placed at the bottom of the tube with 2.5 g AB powder or pellets placed on top. The experiments revealed that heat did not sufficiently propagate in the AB powder to release all of the H₂ even when the heating element was raised to 400°C. We believe the AB in direct contact with the heating element reacted quickly, but also foamed. The foaming moved the AB out of the heated area and there was not sufficient thermal propagation for all of the AB to react. However, the AB/MC mixture completed reacted and there were no heat propagation issues. Approximately 3-4 minutes were required for the reaction to complete. To investigate the impact of pressure, 2.5 g of AB/MC was tested in a stainless steel tube under 10 bar of Argon. The reactor was heated in a furnace. The H₂ released at a faster rate (2.5 equivalents released in ~15 seconds). The spent AB/MC fuel was stickier than fresh fuel.

During FY 2011 we completed the initial chemical hydride reactor models and construct was completed. Four configurations were considered: solids reactor vessel, auger reactor, recirculating fluid system, and a new fixed bed reactor. The auger and fluid reactors were modeled using Simulink with solid AB, alane, AB slurries, alane slurries, and AB dissolved in an IL. The auger and fixed bed reactor models were integrated with the Vehicle Level Model and run through three cases: UDDS-HWFET, US06, and Cold FTP. The models indicated the H₂ demand could be met throughout the entire drive cycles for each of the cases studied (Figure 3).

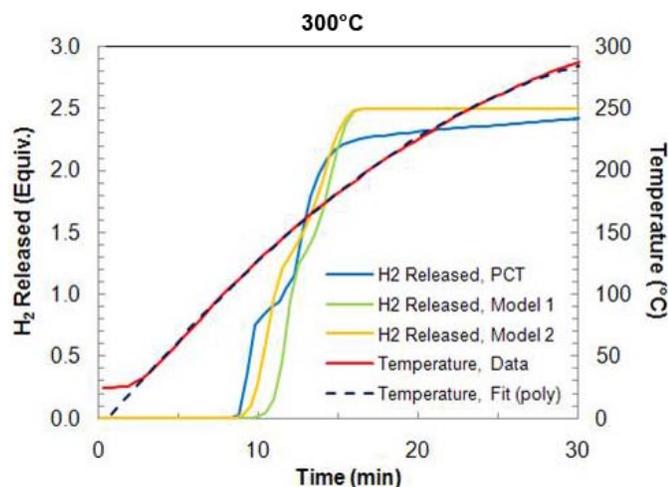

FIGURE 2. Kinetics of Solid AB/MC: Model Prediction vs. Experimental Results at 300°C

The fixed bed reactor concept was developed in FY 2011. The fixed bed reactor combined the hydrogen ballast tank, material storage tank and reactor into a single component. The fixed bed reactor consisted of eight thermally isolated sections in a single tank (Figure 4). The H₂ gas could flow freely between the sections to provide the ballast tank. When the H₂ pressure would decrease to a pre-specified level, a heat element would initiate the H₂ release reaction in one of the sections re-pressurizing the tank. At fueling the, AB beads could be pneumatically conveyed into and out of the bed and the tank re-pressurized. This reactor was modeled using COMSOL to predict pressure ranges, reaction rate, and reaction propagation to minimize the amount of heating required to initiate the reaction. The COMSOL model performance results were used in the Simulink models. The design concept was validated by the AB/MC experiments performed in a stainless steel tube at elevated pressure described previously.

In addition to the kinetic and fixed bed reactor experiments, auger reactor concept validation experiments

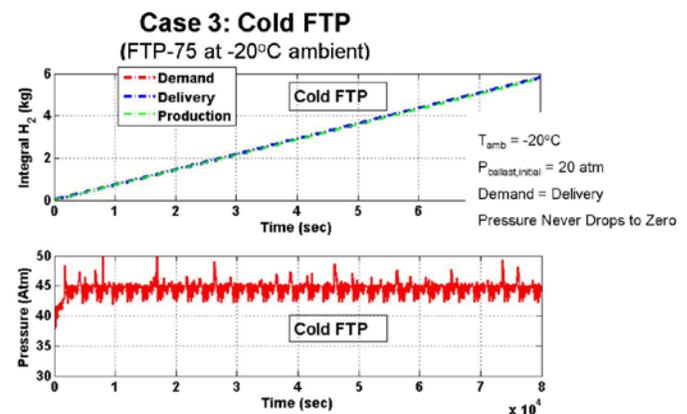

FIGURE 3. Results of AB in IL Chemical Hydride Simulink Model Integrated with the Vehicle Model Operating over the Cold FTP Case

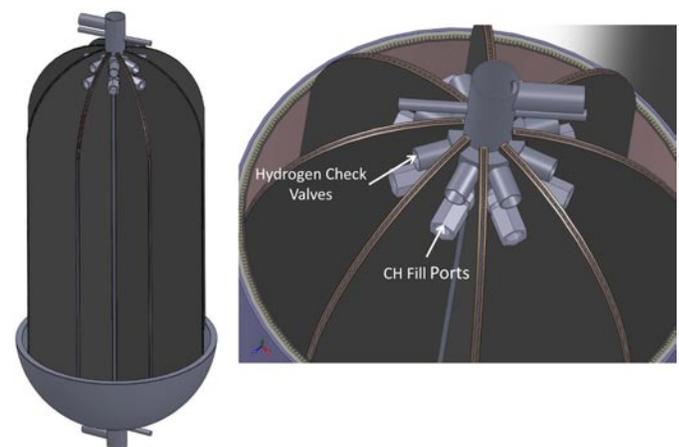

FIGURE 4. Conceptual Drawing of the Fixed Bed Reactor for Chemical Hydrides

were performed. An extruder for plastics was outfitted for hydrogen generation, by insulation, insertion of multiple thermocouples, and placed in a plastic case under an inert atmosphere to prevent any hydrogen generated from reacting with oxygen in the atmosphere. Hydrogen was successfully generated from the reactor with AB/MC as the chemical hydride simulant. However, the auger reactor consistently clogged. Due to the clogging issues, experimental and modeling work on this concept was discontinued early in FY 2011.

For a solid chemical hydride to be a viable solution for on-board hydrogen storage, material movement onto and off of the vehicle in a timely manner must be done. Movement of solid material onboard is being addressed by our partner United Technologies Research Center, or it can be avoided by using the fixed bed reactor. In FY 2010, we proposed using pneumatic conveyance for on/off boarding of the material. This concept was validated in FY 2011. The DOE target for fill time is 5.6 kg of H₂ in 4.7 minutes. Therefore, for AB/MC approximately 9.2 kg/minute must be transported to achieve the DOE target and >3.8 kg/min for the 40% requirement for the concept to be accepted to pass onto Phase II of the HSECoE project.¹ Since low density polyethylene (LDPE) has many of the same transport properties as AB and AB/MC, it was selected as a surrogate material for the tests. The pneumatic tests were done using a 2" heavy duty line vac (Exair) through 14–22 ft length of 2" plastic hose, either open ended or in/out of wedge shaped sections to simulate the fixed-bed tank. The tests were done with powder and beads of LDPE (Table 1). For the open-ended tests, both the powder and pellets exceeded the DOE 2010 targets. However, when filling or draining from a vessel, the pellets exceeded the 40% minimum, but the powder did not. Based on the results of the test we recommend that a pellet form factor be used.

TABLE 1. Refueling Feasibility Test Results with LDPE

	Powder	Pellets
	kg/min (% target)	kg/min (% target)
Open-Ended (22')	14-15 (>100%)	14-15 (>100%)
Fill (14' hose)	2.5 (~27%)	5.4-6.9 (60-75%)
Drain (14' hose)	4.5 (~49%)	4.8-9.2 (50-100%)

Finally, during FY 2011, the HSECoE had a Phase I to Phase II transition where only the most likely design would be selected for continued development. Obviously the auger design was not selected since it failed in concept validation. After consultation with HSECoE manufacturer partners and the DOE, it was determined that any concept requiring a tank exchange would not be acceptable since, among other reasons, the interlocks could not be guaranteed to operate safely over the life of the tank. However, both the fixed-bed

¹ This assumes simultaneous addition of fresh fuel and removal of spent fuel.

reactor with solid chemical hydrides and the fluid reactor² with either AB dissolved in IL or an AB liquid slurry would meet or surpass the 40% target threshold. Due to concerns over the slight increase in stickiness of the spent AB/MC fuel compared to fresh fuel, HSECoE manufacturer input, and using our engineering judgment on the most likely to succeed candidate, it was decided to focus Phase II efforts on the fluid chemical hydride system.

Vessels

During FY 2011 the main task was to design a series of carbon fiber and metal- and polymer-lined tanks for use in metal hydride and cryo-compressed storage applications, using an ANSYS finite element model. The center needed to determine a realistic range of weights and volumes for the tanks. The initial model was to develop tables comparing different liner materials and pressure combinations that would give the system architects an initial estimate of tank weight and volume. The model has continued to be refined by working with our center partner, Lincoln Composites, for a more detailed analysis as the center works to minimize the tank weight and volume. For example, the model needed to allow the carbon fiber to realistically slide relative to the liner. The temperature drop caused by the initial cryo-state cool down causes the liner to shrink faster than the carbon fiber, so the carbon fiber did not carry the intended load. A model refinement has the two dissimilar materials now working together in a load sharing mechanism which now allows for proper tank liner sizing that will help minimize the fatigue stresses in the type III metal lined tank.

BOP/Costing

Working with the other HSECoE partners, PNNL developed a baseline mass, volume, and cost estimates for the systems under consideration. During Phase II, work will be done to minimize the BOP components and reduce the mass, volume and cost. The system architects and modelers provided PNNL system schematics with predicted temperatures, pressures, and flow rates. PNNL then sized the appropriate components (valves, heat exchangers, etc) and identified specific components from vendors. Using this information, a BOP Catalogue was developed which lists the device, volume, mass, cost, operating parameters, model numbers, and links to vendors. Dimensions and materials of construction were used to estimate the mass or volume for components which did not have the information available. Based on comments from the manufacturers and the Storage Tech Team, the storage systems were designed to be stand alone, or in other words we did not assume that any components from the fuel cell (i.e. radiator) or other vehicle systems could be shared. This limitation made the mass and volume projections larger than if the fuel cell, storage systems, heating, ventilation, and air conditioning, etc. were integrated. Table 2 contains the

² See Annual Progress Report by HSECoE partner Troy Semelsberger of LANL.

mass and volume projections based on this bottoms-up approach (please note the 2010 targets were 0.045 kg H₂/kg and 0.028 kg H₂/L). In FY 2012 we plan on applying value engineering to minimize the largest, heaviest and most expensive components. For example, a pump for the coolant system for the metal hydride storage weighed 26 kg. We have identified an alternative which weighs only 2.3 kg, but requires an alternating current input and could not provide the needed flow. We are working with the vendor to project the size of a scaled up the system with a direct current input. This will need to be done with many of the BOP components, especially the storage vessels, in order to significantly reduce the mass of the system.

TABLE 2. Hydrogen Storage System Baseline Mass and Volume

	Calculated Mass/Volume	kg H ₂ /System	Fraction of 2010 DOE Goal
Metal Hydride System			
Gravimetric Density	457.5 kg	0.0122	27%
Volumetric Density	488.7 L	0.0115	41%
ABMC Fixed Bed System			
Gravimetric Density	155.4	0.036	80%
Volumetric Density	236	0.0237	85%
AB IL Fluid System			
Gravimetric Density	147.85 kg	0.0378	82.6%
Volumetric Density	163.3 L	0.0344	122%
Cryogenic Adsorbent			
Gravimetric Density	145	0.0388	86%
Volumetric Density	238	0.0236	84%

Cost estimates were similarly done by a bottoms-up approach. Vendors identified in the BOP catalogue were contacted and provided estimates at production amounts of 10, 1,000, 10,000, 130,000 and 500,000 units per year (Table 3). Discounts were applied to the vendor estimates if the cost estimate was from a distributor and not the manufacturer. Progress ratios were applied to account for scaling, learning, and manufacturer requirements. These progress ratios were analogous to those used by the DOE in their fuel cell and Quantum tank cost estimates [1-2]. Oregon State University provided the cost estimate from their software for the combustor they are designing. Dynatek provided the tank price estimate. The AB cost, from the Dow presentation from the 2010 Annual Merit Review meeting, was \$9/kg. For the metal hydride, sodium alanate plus a carbon additive to increase thermal conductivity was used as a surrogate with a cost range of \$126 to \$9/kg. For the cryogenic storage team directed us to use AX-21 for this cost estimate. Since there was no vendor source, we estimated the cost from the process described in the patent literature. The cost of AX-21 was estimated to be ~\$4/kg. Unfortunately, we did not receive all of the vendor quotes for the cryogenic adsorbent system

so the cost could not be calculated. For all the systems, the highest cost component was the storage vessel, with the hydrogen storage media a close second, and the BOP next. The HSECoE will be working on reducing the cost of the storage vessels in FY 2012.

TABLE 3. Estimated Storage System Baseline Costs

		Production Amount (\$k)				
		10	1,000	10,000	130,000	500,000
Metal Hydride	Total Costs	\$68.5k	\$46.9k	\$22.3k	\$16.5k	\$9.2k
	\$/kWh					\$49.3/kWh
Chem Hydride	Total Costs	\$234k	\$24.7k	\$11.6k	\$6.1k	\$4.8k
	\$/kWh					\$25.6/kWh
Cryogenic Adsorbent	Total Costs	In Progress				
	\$/kWh	In Progress				

Conclusions and Future Directions

- Solids and Materials Transport and System Design
 - Demonstrated on-off boarding of a solid material.
- Process Modeling and Engineering
 - Completed Simulink and COMSOL models:
 - Multiple designs
 - Multiple materials
 - Evaluated chemical hydride storage to predict that they can provide sufficient H₂ for the cold FTP drive cycle and the aggressive US06 drive cycles.
- Kinetics and Materials Property Measurements
 - Validated kinetic models with data.
 - Validated fixed bed reactor concept.
 - Discontinued Auger type reactor.
 - Completed reaction propagation tests.
 - Begun solid-liquid slurry work.
- BOP and Materials Reactivity and Compatibility
 - Completed BOP Library.
 - Detailed and sized BOP components for two chemical hydride systems, two metal hydride systems and cryogenic adsorbent systems.
 - Identified areas for decreasing mass and volume in BOP.
 - Identified technology gaps.
- Containment and Pressure Vessel Design
 - Developed cryogenic tank models:
 - Projected mass and volume of tanks.
 - Enables optimization of tank depending on pressure.

- Manufacturing and Cost Analysis
 - Completed cost analysis for metal hydride and chemical hydride systems.
 - Projected cost of AX-21 material \$4/kg to \$4.2/kg.
 - Initiated cost projection for cryo-sorbent system.

Future Work

For Phase II (FY 2012-FY 2013), the primary deliverable is detailed designs for a hydrogen storage system. To this end, we will:

Chemical Hydride System

- Detailed Design, Engineering and Analysis
 - Expand model to include additional physical properties.
 - Sensitivity analysis to determine the acceptable range of:
 - Viscosity
 - Settling/flocculation
 - Vapor pressure
 - Thermal stability
- Experimentally Validate Model Parameters
- Experimentally Validate Critical Components
- Solid-Liquid Slurry Development
 - Composition
 - Additives
- Work with HSECoE Partners in Detailed Design

BOP and Cost Analysis

- Value Engineering
 - Minimize mass and volume
 - Work with partners on BOP
 - Work with vendors to push limits on components
- Pressure Vessel Engineering
 - Reduce cost, mass
 - Maintain safety
- Materials Compatibility/Reactivity
 - H₂ wetted material compatibility in components
- Cost Analysis
 - Complete cryo-sorbent
 - Work with partners, vendors on reducing cost
 - Update analysis with detailed design

Contract Number: DE-FC36-09GO19006

Project Start Date: February 1, 2009
Project End Date: July 31, 2014

Fiscal Year (FY) 2011 Objectives

- Collaborate closely with the Hydrogen Storage Engineering Center of Excellence (HSECoE) partners to advance materials-based hydrogen storage system technologies.
- Develop vehicle/power plant/storage system integrated system modeling elements to improve specification of storage system requirements and to predict performance for candidate designs.
- Establish detailed heat and mass transfer modeling and apply to design improved internal heat exchange configurations.
- Design and evaluate compacted/structured hydride powder beds including integration into the above heat exchange configurations.
- Assess the viability of on-board purification for various storage material classes and purification approaches.
- Conduct risk assessments during the progression of the phased HSECoE efforts to evaluate concepts regarding the “Environmental Health and Safety” target.

Technical Barriers

This project addresses the following technical barriers from the Storage section (3.3.4) of the Fuel Cell

Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (C) Efficiency
- (D) Durability/Operability
- (E) Charging/Discharging Rates
- (H) Balance of Plant (BOP) Components
- (J) Thermal Management

Technical Targets

The goals of this project mirror those of the HSECoE which by the end of Phase I (March, 2011) seeks to define systems configurations which can fully meet four of the DOE 2010 numerical system storage targets as outlined in the Multi-Year Research, Development and Demonstration Plan (<http://www.eere.energy.gov/hydrogenandfuelcells/mypp/>) and partially meet the remaining numerical targets to at least 40% of the target or higher.

TABLE 1. Current Status of Four Key System Characteristics

Characteristic	Units	2010 Target	2015 Target	Compacted Material in System	UTRC 2011 Status
System Gravimetric Capacity	kg H ₂ /kg system	0.045	0.055	SAH	0.0142
				1:1 LAMH	0.0257
System Volumetric Capacity	kg H ₂ /L system	0.028	0.040	SAH	0.015
				1:1 LAMH	0.018
Efficiency	%	90	90	SAH	70
				1:1 LAMH	75
NH ₃ Content	ppm	0.1	0.1	1:1 LAMH or/AB	0.1

SAH - sodium aluminium hydride; LAMH - lithium amide and magnesium hydride; AB - ammonia borane

FY 2011 Accomplishments

Accomplishments of the current project comprise:

- Developed Simulink framework to compare all H₂ storage systems on a common basis.
- Implemented two on-board reversible metal hydride systems in Simulink framework.
- Optimized volumetric capacity and thermal conductivity of two on-board reversible metal hydride materials through compaction and additives.
- Designed compact heat exchanger for SAH pellets that enables a 10.5 minutes refueling time.

- Developed H₂ purification cartridge that enables NH₃ removal down to 0.1 ppm, as required by the SAE J2719 APR2008 guideline.
- Completed qualitative risk assessment of all three H₂ storage system types.
- Demonstrated solid transport of AB surrogate material along a complex path with a flexible screw feeder.
- Evaluated vibration packing of AX-21/MaxSorb in order to increase density of cryo-adsorbent AX-21/MaxSorb but resulting density was only 0.3 g/cm³ instead of the targeted 0.6 g/cm³.

Introduction

Physical storage of hydrogen through compressed gas and cryogenic liquid approaches is well established, but has drawbacks regarding weight, volume, cost and efficiency which motivate the development of alternative, materials-based methods of hydrogen storage. Recent worldwide research efforts for improved storage materials have produced novel candidates and continue in the pursuit of materials with overall viability. While the characteristics of the storage materials are of primary importance, the additional system components required for the materials to function as desired can have a significant impact on the overall performance. Definition, analysis and improvement of such systems components and architectures, both for specific materials and for generalized material classes, are important technical elements to advance in the development of superior methods of hydrogen storage.

Approach

UTRC's approach is to leverage in-house expertise in various engineering disciplines and prior experience with metal hydride system prototyping to advance materials-based H₂ storage for automotive applications. UTRC focused in the second year of the HSECoE project on screening H₂ storage system improvement ideas resulting from compaction, thermal conductivity enhancement, H₂ purification, compact and low weight heat exchanger design and system integration. Results contributed to the selection of storage systems that were more likely to meet DOE targets when further developed in Phase 2 during the Phase 1 to Phase 2 go/no-go meeting.

Results

Complex metal hydrides like Ti-doped SAH and mixtures of LAMH offer a higher gravimetric hydrogen storage capacity (e.g. SAH: 3.2 wt% H₂; 1:1 LAMH: 8.2 wt%) than interstitial metal hydrides (e.g. Ti_{1.1}CrMn: 1.7 wt% H₂) but have a relative low density which affects their volumetric capacity. Applying these materials in

powder form further reduces their volumetric capacity to levels below the 2015 volumetric capacity target (40 g H₂/L of system). It is therefore important to consider powder compaction.

The effect of powder compaction on the thermal conductivity of SAH was reported in the previous annual report and efforts in the second year focused on improving the thermal conductivity of SAH to 5-8 W/m/K by using additives. UTRC selected aluminum powder and expanded natural graphite (ENG). The results show that the effective thermal conductivity of the SAH/aluminum mixtures follows the series model for thermal conductivity which makes aluminum powder fairly ineffective in improving the thermal conductivity of SAH as a large aluminum volume fraction would be required [1]. It is better to apply aluminum in the form of fins in a fin and tube heat exchanger as an effective thermal conductivity of 4 W/m/K can be achieved with only 4 volume percent of aluminum and compacted SAH pellets. The effective thermal conductivity of SAH with expanded natural graphite followed the parallel model for thermal conductivity [1], which enabled high values of the thermal conductivity at a relatively low volume fraction of this additive. Best results were obtained when using ENG 'worms', kindly provided by SGL Carbon, that introduce thermal conductivity anisotropy upon uniaxial compaction with the highest value of the thermal conductivity perpendicular to the pressing direction and in the direction of the heat exchanger tube. A COMSOL model was developed in order to extract information about the thermal conductivity anisotropy from the thermal conductivity measurements. Heat exchanger tubes no longer require fins when using compacted SAH pellets with about 5 wt% ENG 'worms' to improve the thermal conductivity.

UTRC applied compaction know-how of SAH to the LAMH material in this second year of the HSECoE project. The LAMH material was much more difficult to compact than SAH and required the addition of expanded natural graphite binder in order to obtain samples with a sufficient strength. Thermal conductivity measurements showed that LAMH required a larger weight fraction of ENG 'worms' (e.g. 15 wt%) than SAH (e.g. 5 wt%) in order to obtain high thermal conductivity values in the direction of the heat exchanger tube that would allow a rapid refueling process when it would be possible to substantially improve the slow H₂ absorption kinetics and reversibility of the current LAMH material.

Kinetic measurements from Ti-doped SAH powders and pellets were analyzed in order to obtain values of the model parameters in the kinetic expressions that are used in the detailed COMSOL Multiphysics™ model [2,3], which was developed in the first year of the HSECoE project for obtaining a better understanding about the impact of thermal gradients during refueling upon the H₂ absorption rate. Results showed that one set of model parameters can be used for SAH in its powder and compacted form. The detailed COMSOL model was modified accordingly

and experimentally determined values of densities and thermal conductivities of SAH (without ENG ‘worms’) were implemented in order to optimize the heat exchanger configuration for a fast refueling time. The results are shown in Figure 1. Small diameter aluminum tubing with aluminum fins are projected to provide sufficient heat transfer in order to reach 90% of the materials H₂ storage gravimetric capacity in about 10.5 minutes, which was the maximum allowable refueling time for the Phase 1 to Phase 2 Go/No-Go decision. A faster refueling time will require materials development in order to improve the reaction kinetics and it will require an increase in the aluminum volume fraction of the heat exchanger in the metal hydride tank. Figure 1 clearly shows the benefit of compaction on the volumetric capacity of the SAH bed. Uncertainty about the heat transfer coefficient between the SAH pellet and the heat exchanger tube has driven the development of an experimental test apparatus which will be used to study H₂ absorption and heat transfer by SAH pellets stacked around a heat exchanger tube in Phase 2.

The H₂ storage system is expected to experience 1,500 cycles over its lifetime. A series of tests was performed in order to study the effect of H₂ absorption and desorption cycles on the strength of SAH pellets. SAH pellets with aluminum mesh reinforcement (Figure 2) have a higher strength than unreinforced SAH pellets but the strength of both types of pellets rapidly degrades upon cycling due to a substantial expansion of the SAH pellets.

UTRC leads the Integrated Power Plant Storage System Modeling technical area, which fostered a successful collaboration between the HSECoE partners. This resulted in a Simulink framework [4] that includes a vehicle level module (National Renewable Energy Laboratory), a fuel

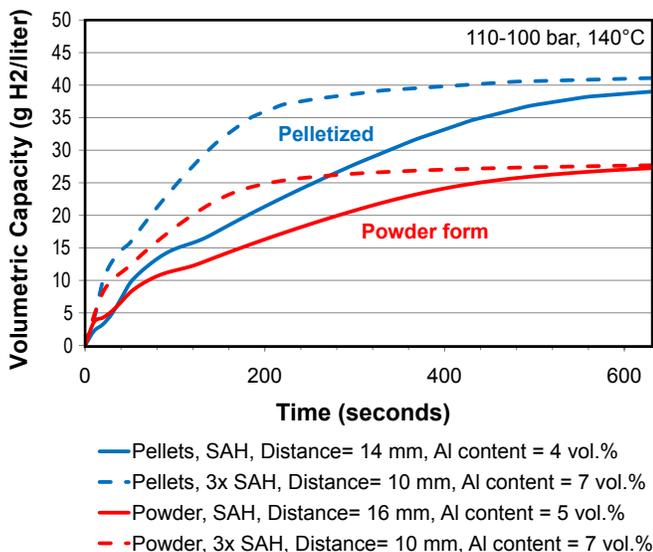

FIGURE 1. Volumetric capacity of the SAH bed, including the aluminum fin and tube heat exchanger, optimized for a 10.5-minute refueling time with SAH in powder or compacted form.

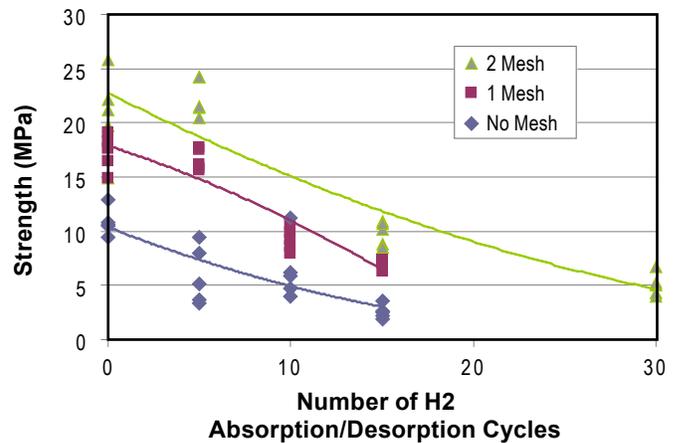

FIGURE 2. Effect of H₂ absorption and desorption cycles on the biaxial flexure strength of SAH pellets with and without internal mesh reinforcement.

cell module (Ford) and various representations of H₂ storage systems as formulated by General Motors (GM), UTRC, Jet Propulsion Laboratory, Savannah River National Laboratory, and the Pacific Northwest National Laboratory (PNNL), as shown in Figure 3. The framework is used within the HSECoE to compare all H₂ storage systems on a common basis. UTRC developed and implemented system models with SAH and LAMH in their powder or compacted form and 350 bar and 700 bar compressed H₂ gas benchmark systems in the Simulink framework. The LAMH system assumed similar heat transfer characteristics as the SAH system. Both systems operate at temperatures that are substantially higher than the temperature at which waste heat from the proton exchange membrane fuel cell can be made available and therefore require H₂ combustion in order to generate heat for hydrogen desorption during a drive cycle. H₂ combustion is also required to heat the storage systems to their operating temperature during a cold start. Such H₂ needs to be readily available and will hence need to be stored in the free volume of the tank or in a separate buffer volume. It was discovered from system simulations that the tank with compacted SAH pellets would no longer contain sufficient H₂ for a cold start and that therefore an additional buffer volume had to be made available to the system. This additional buffer volume reduces the benefits from powder compaction but the H₂ storage tank with the compacted material still occupies a smaller volume than a similar system with the material in its powder form. It is now being studied how the buffer volume can be reduced in order to improve the system volumetric capacity.

Balance of plant (BOP) components were selected by GM and PNNL and information about the weight of the carbon composite type IV pressure vessel were obtained from Lincoln Composites. This information was used to calculate the gravimetric and volumetric capacity of these two metal hydride H₂ storage systems and the results are shown in Figure 4, and also reported in Table 1. The

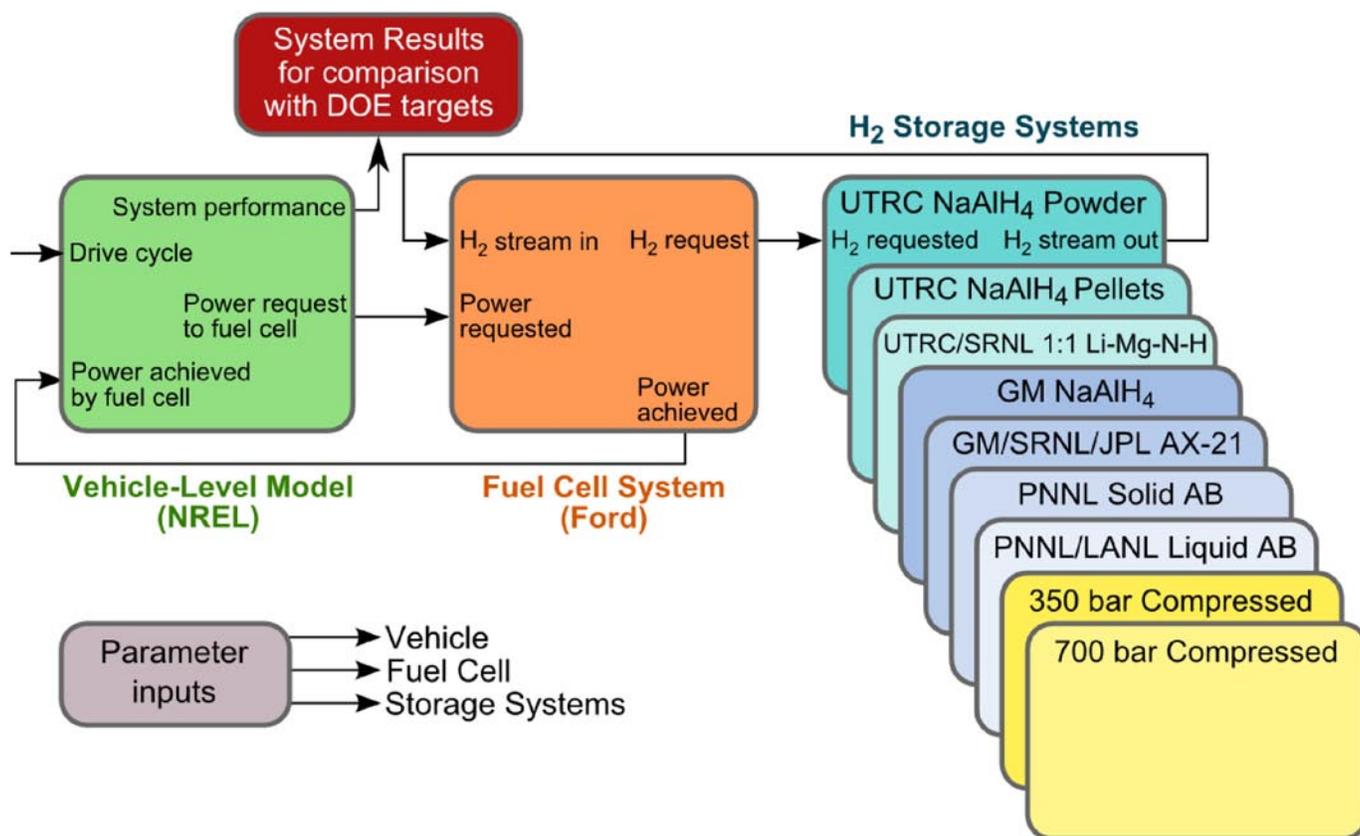

FIGURE 3. Simulink Framework for Comparing all H₂ Storage Systems on a Common Basis

gravimetric capacity of both systems is below the 2010 target and so is their volumetric capacity. It is therefore concluded that the on-board reversible metal hydride systems considered during Phase 1 of the HSECoE are heavy and occupy a much larger volume than the DOE targets allow. This is partly driven by the relative high weight and volume of the BOP components. This gets aggravated when using the heavy BOP components in combination with metal hydride materials like LAMH that have a higher materials gravimetric capacity. Reducing the BOP weight and volume is therefore critical when developing on-board reversible metal hydride H₂ storage systems that require supplementary heating by means of H₂ combustion.

All three H₂ storage systems in the HSECoE have issues related to H₂ quality [5] that need to be addressed. Particulate filters have been recommended by two suppliers in order to contain the cryo adsorbent and on-board reversible metal hydride materials within the pressure vessel while meeting the SAE J2719 APR2008 H₂ purity guideline (particulate size: <10 μm; particulate concentration: <1 μg/l). The standard test method ASTM D7650 standard was identified for assessing the presence of particulates in hydrogen released by the storage systems. UTRC characterized chemical and physical adsorbents for removing NH₃ from hydrogen that is released by the chemical hydride AB and the metal hydride LAMH. Most of the sorbents had

a NH₃ dynamic sorption capacity of about 2 wt%. It was shown that the physical adsorbent Selexsorb CD™ (BASF) has the advantage that it can be regenerated without loss of capacity. Cu-BTC metal organic framework was shown to have a very high NH₃ dynamic sorption capacity (12 wt%) but unfortunately it was very expensive and experiments showed that it could not be regenerated after NH₃ exposure.

UTRC performed qualitative risk assessments of all three H₂ storage systems with the objective to identify the critical risks, failure modes and other technical challenges. One critical risk for a sodium alanate H₂ storage system is dust explosion in air caused by an accidental rupture of the storage vessel upon collision. An example of a critical risk for an AB-based chemical hydride system is a runaway chemical reaction resulting from a loss of the exothermic heat removal capability in the system. Loss of vacuum insulation is a critical risk for the cryo-adsorbent system. It has been suggested to develop a framework for safety categorization of H₂ storage materials for on-board vehicular applications as the risks associated with the various materials vary widely.

Brainstorming resulted in several concepts that could be used to transport chemical hydrides like AB in their solid form on board a vehicle. The flexible screw feeder concept was selected for an experimental evaluation. The system was designed and constructed from off the shelf components

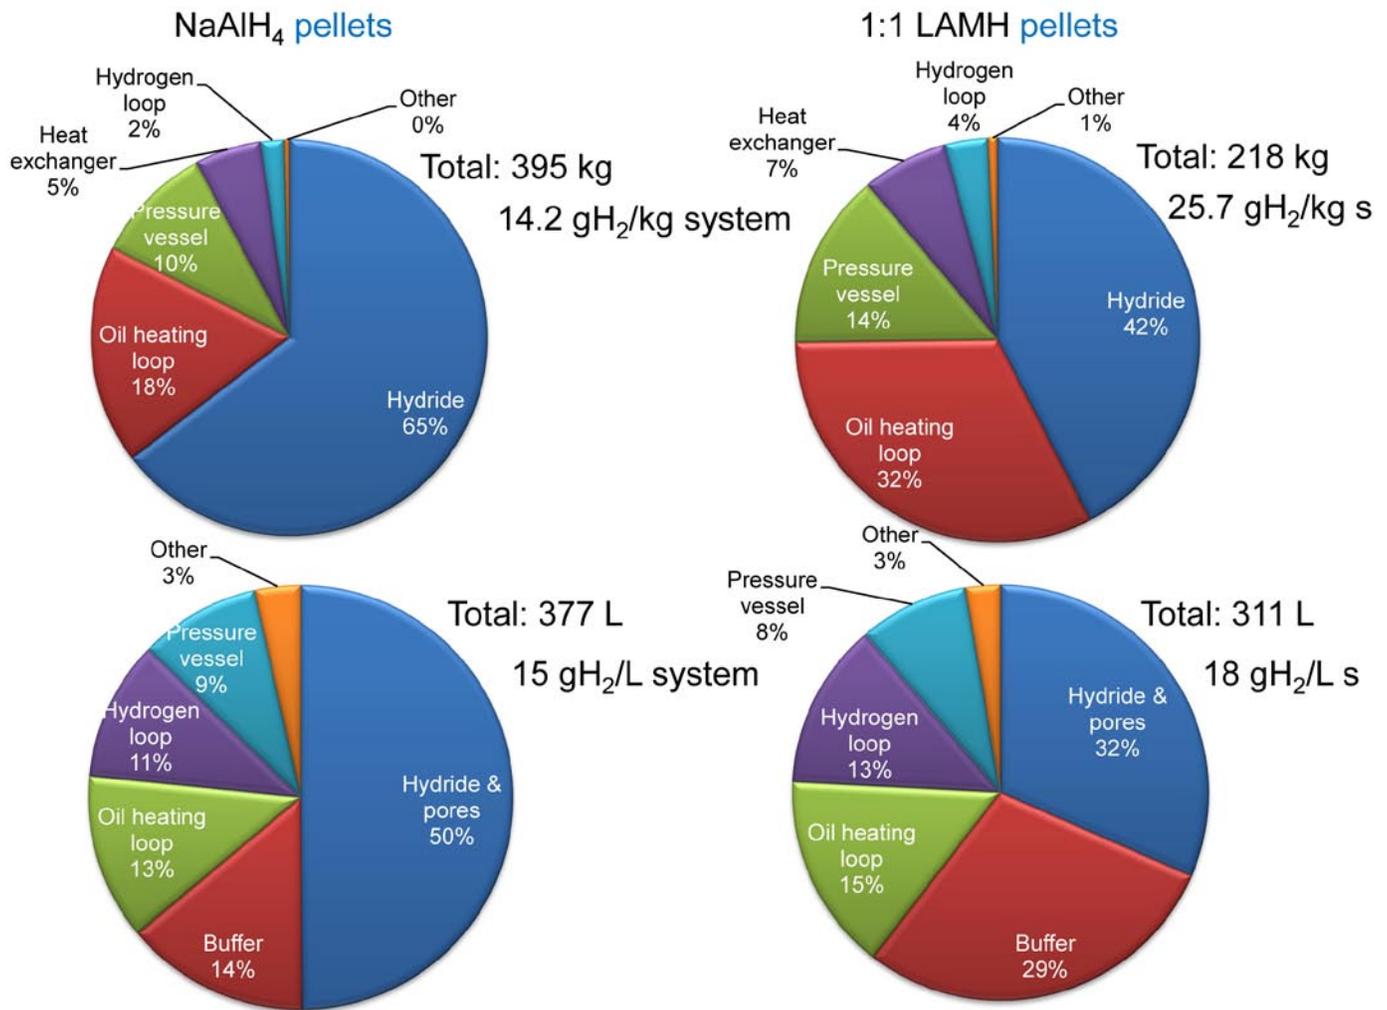

FIGURE 4. Effect of BOP Components on the Gravimetric and Volumetric Capacity of H₂ Storage Systems using SAH or LAMH

and is shown in Figure 5 with the flexible screw transporting an AB surrogate material in a powder form at high rate along a complex path with a 180 degrees bend. Tests were performed to quantify solid transport rate as a function of the flexible screw pitch, rotational speed and bend angle. Solid transport was rejected as a viable technology after PNNL experienced practical problems with transporting AB powder through a heated zone by means of an auger.

Conclusions and Future Directions

Conclusions derived from the work in FY 2011 are:

- ENG ‘worms’ are effective additives that increase the thermal conductivity of (complex) metal hydride materials and can serve as a binder for materials like LAMH mixtures.
- SAH pellets with and without internal mesh reinforcement show a rapid decline of their strength

upon H₂ absorption and desorption cycles due to volumetric expansion of the SAH phase.

- The current generation of BOP components is heavy and occupies a large volume, which negatively impacts the gravimetric and volumetric capacity that can be achieved with the complex metal hydrides considered during Phase 1 of the HSECoE.
- Complex metal hydrides that require supplemental heating need a substantial H₂ buffer volume in order to enable a cold start during which the system is heated to its operating temperature.
- Several sorbents have been identified that can capture NH₃ emissions from materials based H₂ storage systems based on AB and LAMH in order to improve H₂ quality.

Future work will comprise:

- Explore binderless compaction of AX21/MaxSorb.

FIGURE 5. Solid Transport of a Surrogate Material with a Flexible Screw along a Complex Path

- Identify ideal material properties of on-board reversible metal hydride material that will enable H₂ storage systems that meet all DOE targets.
- Sensitivity studies with Simulink framework in order to optimize system design.
- Improve understanding of repeated cold starts on system performance.
- Engineering of specialty components for H₂ storage systems and their experimental evaluation.
- Experimental evaluation of purification cartridge connected to H₂ generated from the thermolysis of liquid AB.
- Particulate mitigation strategy evaluation.
- Design failure modes and effects analysis of H₂ storage systems.
- Improve understanding of Department of Transportation requirements for materials-based H₂ storage systems.

Project Start Date: March 1, 2009
Project End Date: January 31, 2014

Fiscal Year (FY) 2011 Objectives

Main objectives of this project are:

- To develop system simulation models and detailed transport models for on-board hydrogen storage systems using metal hydride and adsorbent materials, and to determine system compliance with the DOE technical targets.
- To develop storage media structures with optimized engineering properties for use in storage systems.
- To design and build an experimental vessel for validation of cryoadsorption models.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development, and Demonstration Plan (MYPP):

- (A) System weight and volume
- (C) Efficiency
- (E) Charging/Discharging Rates
- (J) Thermal Management

Approach

As part of the Hydrogen Storage Engineering Center of Excellence (HSECoE) team, the GM team is building system models and detailed transport models for on-board hydrogen storage systems using metal hydrides and adsorbent materials. Detailed transport models have been developed for the metal hydride and adsorbent systems with a focus on optimization of heat exchanger design with the objective of minimizing the heat exchanger mass. We are also working on storage media structuring and enhancement studies for the metal hydride and adsorbent materials. Since the hydrogen storage materials are generally characterized by low density and low thermal conductivity, we are conducting experiments to form pellets and add thermal conductivity enhancers to the storage material, and to improve cycling stability and durability of the metal hydride and adsorbent materials. An additional area of focus has been on designing and building a cryoadsorption vessel for validation of cryoadsorption models.

FY 2011 Accomplishments

- Developed two system simulation models for sodium alanate employing different heat exchanger designs and integrated in the framework model.
- Developed and integrated a system simulation model for high-pressure metal hydrides ($Ti_{1.1}CrMn$).
- Optimized three different heat exchanger designs for the metal hydride systems, and identified the design for minimum heat exchanger weight.
- For adsorbent materials, determined optimum pellet size for fast refueling.
- Pelletization and thermal conductivity enhancement of metal hydride and adsorbent materials.

Results

System Models for Metal Hydride Systems: Three system simulation models have been integrated into a modeling framework developed by the Center for evaluation and comparison on a common basis. For sodium alanate, two system models were developed and integrated – one with a shell and tube heat exchanger with cooling tubes and fins, and second with a helical coil heat exchanger. The third system model is for a high-pressure metal hydride system that contains $Ti_{1.1}CrMn$ and is based on a shell and tube heat exchanger with cooling tubes and fins. The helical coil heat exchanger system for sodium alanate contains multiple beds that were sized to optimize heat

transfer between the alanate bed and the fluid flowing through the helical coil tube. Both systems were run within the framework to determine the sizing adjustments needed to deliver 5.6 kg of useable hydrogen to the fuel cell. Simulations were then run to test the performance of the storage systems for four drive cycles that feature various driving patterns and operating conditions: standard driving, aggressive driving, cold start, and hot start.

A hydrogen mass balance for a simulation of the standard driving cycle with the sodium alanate/helical coil system is presented in Table 1. For comparison, a mass balance for a dual bed sodium alanate system with parallel cooling tubes and fins for heat transfer is also included. Table 2 contains the mass balance for the aggressive driving cycle simulation. These results show that the helical coil heat exchanger design is a better design and is able

TABLE 1. Hydrogen Mass Balance for the Standard Driving Cycle

	H ₂ Delivered to the Fuel Cell	H ₂ to Heater	H ₂ in Bed
Helical Coil	78.4%	20.5%	1.1%
Dual Bed	73.2%	20.8%	6.0%

TABLE 2. Hydrogen Mass Balance for the Aggressive Driving Cycle

	H ₂ Delivered to the Fuel Cell	H ₂ to Heater	H ₂ in Bed
Helical Coil	75.4%	19.0%	5.6%
Dual Bed	58.2%	15.2%	26.0%

to use most of the hydrogen in the bed for both the normal and the aggressive driving cycles. In the Optimization Study detailed in the following, we present results showing that the helical coil design has much lower mass than the base design. For the Ti_{1.1}CrMn storage system, nearly all of the stored hydrogen is delivered to the fuel cell since it does not require a catalytic heater for desorption. While the Ti_{1.1}CrMn system has good cold start capability, it has the disadvantage of having a low H₂ absorption capacity of approximately 2%. Detailed results are presented in references [1,2].

Optimization of Heat Exchanger Designs: Refueling of metal hydride based hydrogen storage systems is a highly exothermic process. Because of the need for fast refueling rates, thermal management of the storage system is very important. Good heat exchanger design is crucial for a metal hydride-based hydrogen storage system in order to maximize gravimetric and volumetric storage densities of the bed and meet system performance requirements. We have analyzed various heat exchanger designs for sodium alanate-based hydrogen storage systems and systematically optimized the design configurations of these heat exchangers. Optimization is performed by employing an automated COMSOL-MATLAB interface tool to conduct

parametric sweeps of the geometry to optimize the heat exchanger design.

Three different heat exchanger designs are analyzed for sodium alanate-based hydrogen storage systems. The three designs are shown in Figure 1. COMSOL modeling is employed to optimize each design to yield maximum gravimetric capacity with the constraint that the local temperature of the bed should not rise above a pre-specified temperature. Optimized designs for each heat exchanger type have been compared. The helical coil heat exchanger is found to be the most compact and efficient heat exchanger design. The detailed results are presented in references [3,4].

Two-Dimensional (2-D) Analysis of Non-isothermal Adsorption in Cylindrical Pellets: For ease of handling and enhanced volumetric capacity, adsorbent powders are often

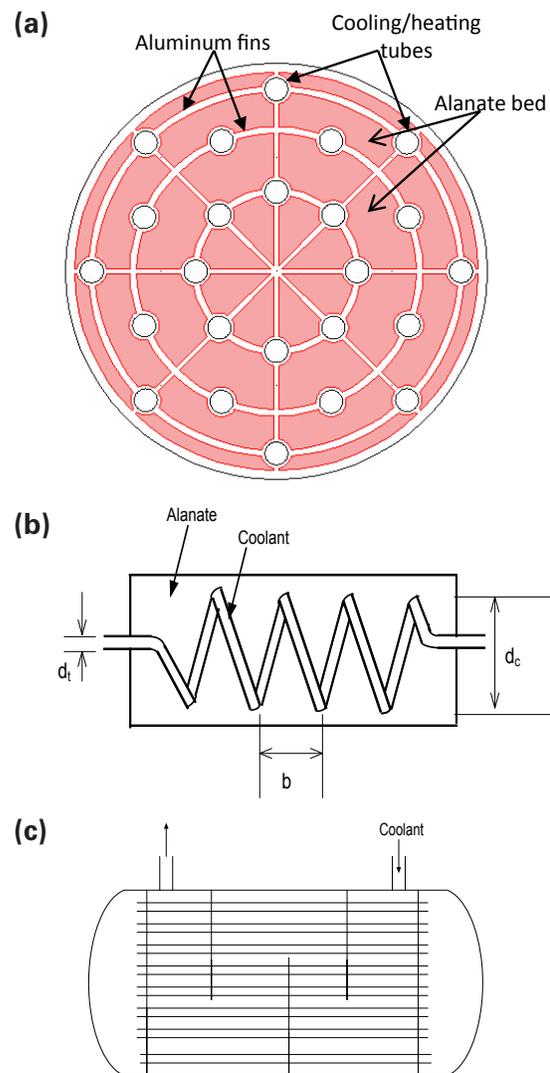

FIGURE 1. (a) Shell and Tube Heat Exchanger with Alanate in Shell; (b) Helical Coil Heat Exchanger; (c) Shell and Tube Heat Exchanger with Alanate in Tubes

compacted into pellets which can be packed in a random or structured fashion in a bed. In either case, one needs to study the intra pellet transport phenomena to arrive at a desired pellet size and aspect ratio. For a random packed bed, often short cylindrical pellets with height identical to diameter are used, since they pack uniformly like spheres.

In the first phase of this study we have analyzed the intra-pellet transport phenomena for short cylindrical pellets at three different sizes, 3 mm, 12 mm and 48 mm. Larger pellets have higher diffusional and thermal resistances, leading to slower adsorption of hydrogen. The aim of this part of the study is to ascertain a typical range of short cylindrical pellet diameters which could be considered for a random packed bed, wherein the intra-pellet transport gradients do not impede achieving short refueling times. A synopsis of these results is discussed below. We are continuing work on the analysis of hockey-puck shaped large pellets which have short heights but large diameters. Such pellets are used in structured packed beds for achieving higher volumetric capacities than a random packed bed.

Model equations were solved to determine the temperature, pressure, and adsorbate concentration fields in short cylindrical pellets. The pressure equilibration occurs quite rapidly, while temperature equilibration is relatively slower. Our analysis shows that simultaneous cooling and adsorption is the rate limiting process. By performing a volume integration of the 2-D total hydrogen content field within the pellet we computed the transient volumetric capacity of the pellet at three different pellet sizes: 3 mm, 12 mm and 48 mm. These results are shown in Figures 2 and 3. The 3 mm pellet reaches its saturation capacity by about 4 seconds, while the 12 mm and 48 mm pellets saturate by about 60 and 600 seconds, respectively. As pellet size increases, a pellet takes longer time to equilibrate with the bulk gas, due to higher diffusional and thermal resistances resulting in a reduced transient volumetric capacity of the pellet. Using very small size pellets increases the bed pressure drop while very large size pellets have poor transient utilization, leading to longer refueling times. This work on single pellet modeling and analysis will help us

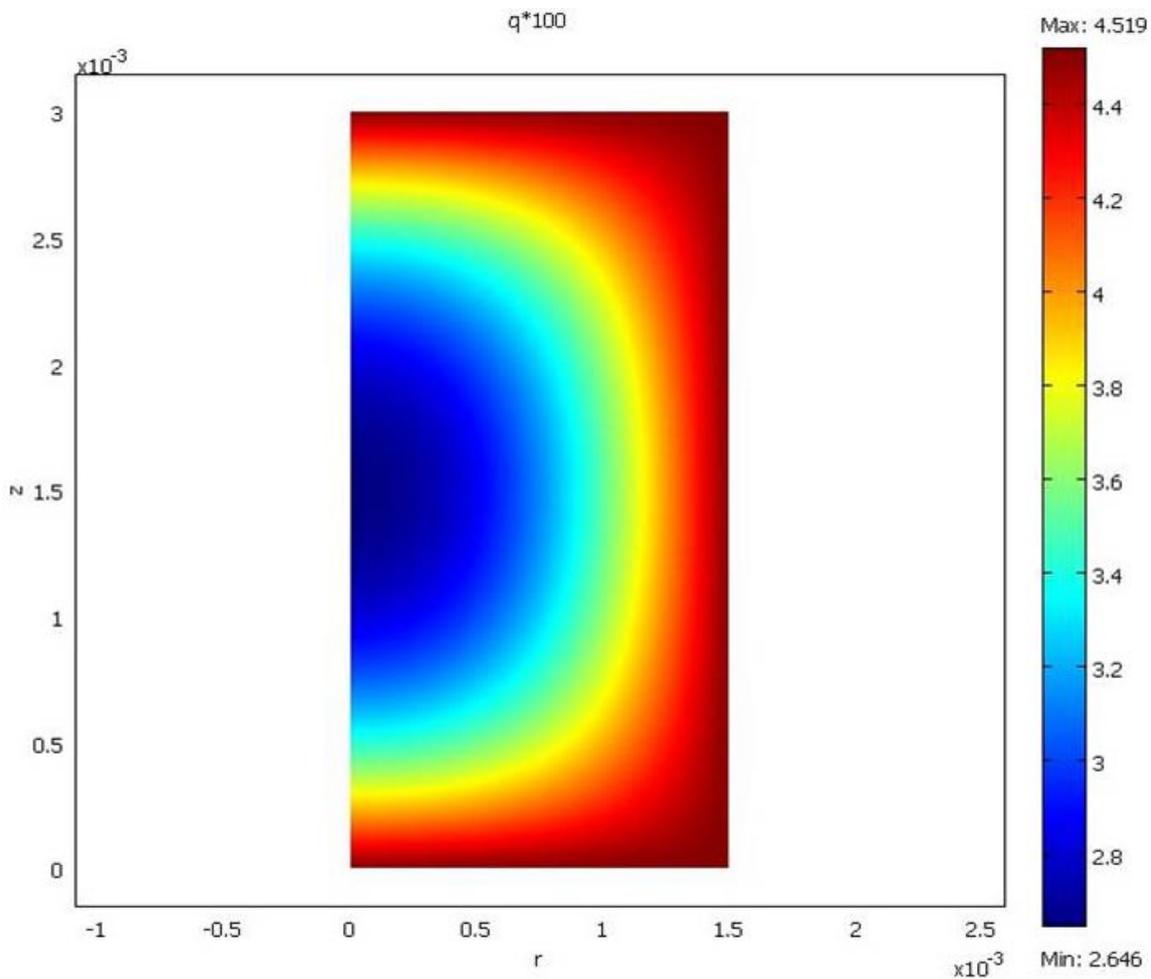

FIGURE 2. Adsorbate Concentration Field in a 3 mm Short Cylindrical Pellet at $t = 1$ s

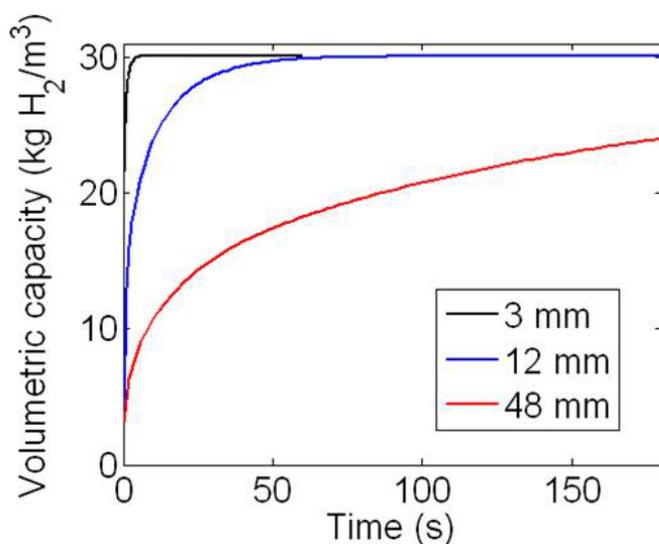

FIGURE 3. Transient Volumetric Capacity for Three Different Pellet Sizes

identify an appropriate range of pellet sizes for conventional packed bed design.

Pelletization of Sodium Alanate and AX-21 Powder:

Both the metal hydrides and adsorbent materials for hydrogen storage have low densities and low thermal conductivities. Therefore, it is necessary to find ways to pelletize these materials to increase both the density and thermal conductivity without adversely affecting the hydrogen uptake capacity and kinetics. Experiments conducted in our laboratory show that the high thermal conductivity of pelletized titanium doped sodium alanate ($\text{NaH} + \text{Al} + \text{TiCl}_3$) dramatically degrades (up to 80%) within the first 10 cycles due to extensive pellet expansion. Upon further hydrogen cycling, pellets continue to expand leading to complete failure of structural integrity. To counter thermal conductivity degradation two approaches were explored; incorporation of high thermal conductivity additives (expanded natural graphite and graphite flakes) into the alanate before pelletization and mechanical confinement of pellets during cycling. Both forms of graphite additive exhibited similar loss in thermal conductivity over the first 10 cycles. While pellets with graphite additives have a slightly higher thermal conductivity at each cycle compared to pellets without additives, the overall degradation effect of cycling is similar and not favorable.

While the addition of graphite to sodium alanate pellets lessens the decrease in thermal conductivity over 10 cycles compared to pellets without graphite, pellet expansion (previously reported) is not mitigated and has an overwhelming adverse effect on thermal conductivity. Confinement of sodium alanate pellets by mechanical means showed slowed degradation of thermal conductivity over first 10 cycles, compared to unconfined pellets run in parallel, confined pellets had twice the thermal conductivity after 10 cycles (2.57 and 4.80 W/mK, respectively). After

50 cycles, confined pellets had a thermal conductivity of 3.72 W/mK. Unconfined pellets could not be measured after 10 cycles due to expansion. Various methods of confinement have been explored, all showing similar degradation control. Sodium alanate pellets were also observed to fuse to one another during cycling. Fusion of a pellet stack can minimize surface area contact resistance and allow for improved heat transfer between neighboring pellet bodies. The confined fused pellets show a degradation of thermal conductivity.

The increased volumetric capacity of activated carbon through pelletization requires the addition of a binder. Current procedures employ extensive elevated temperature work-up resulting in lengthy processing time per pellet. To expedite pelletization, we are focusing on room temperature binders. The binder is combined with AX-21 resulting in a fibrous network which holds the activated carbon together. The fiber network cold flows under high pressures allowing the AX-21 mixture to be pelletized rapidly under room temperature conditions. The pellet density is improved by a factor of 1.5-1.8 ($0.45\text{-}0.55 \text{ g/cm}^3$, powder = 0.3 g/cm^3) but the surface area decreases by 20% compared to the powder alone (2,400 and 3,000 m^2/g , respectively). These pellets show gravimetric capacity similar to that of the powder at 77 K but the volumetric capacity is substantially improved through pelletization compared to the powder. Work on identifying the best room temperature binder and pellet properties is continuing.

Future Direction

- Extend the modeling work to short cylindrical pellets that can be used for structured packing of the bed for high volumetric capacity to determine optimum pellet size.
- Optimize binders for pelletizing activated carbon with respect to engineering properties of interest for hydrogen storage.
- Design and build a cryoadsorption vessel for validating the flow-through cooling concept for recharging.
- Conduct experiments to validate the cryoadsorption models for charging and discharging of adsorption based storage beds.
- With the HSECoE team, determine the material properties for metal hydrides that are necessary to meet DOE 2015 hydrogen storage system goals.

Technical Targets

The outcomes of this project affect vehicle and system level models, cost analysis, and materials property assessment/optimization. Insights gained from these studies are applied towards the engineering of hydrogen storage systems that meet the following DOE 2010 and ultimately 2015 hydrogen storage targets shown in Table 1.

TABLE. DOE Hydrogen Storage Targets

Storage Parameter	Units	2010	2015
System Gravimetric Capacity	kg-H ₂ /kg	0.045	0.055
System Volumetric Capacity	kg-H ₂ /L	0.028	0.040
Storage System Cost	\$/kWh _{net}	To Be Determined	To Be Determined
System Fill Time (for 5 kg H ₂)	min	4.2	3.3
Minimum Full Flow Rate	(g/s)/kW	0.02	0.02
Min/Max Delivery Temperature	°C	-40/85	-40/85
Min. Delivery Pressure (Fuel cell)	atm	4	3

Fiscal Year (FY) 2011 Objectives

This project addresses three of the key technical obstacles associated with the development of a viable hydrogen storage system for automotive applications:

- (Task 1) Create accurate system models that account for realistic interactions between the fuel system and the vehicle powerplant.
- (Task 2) Develop robust cost projections for various hydrogen storage system configurations.
- (Task 3) Assess and optimize the effective engineering properties of framework-based hydrogen storage media (such as metal-organic frameworks, MOFs).

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume

FY 2011 Accomplishments

Below is a list of accomplishments by task:

- Task 1. System Modeling
 - Evaluated and constructed baseline fuel cell model to support the interaction with the vehicle and hydrogen storage system model.
 - Completed classification of the 2010 and 2015 DOE hydrogen storage targets for optimization and tradeoff analysis amongst the storage system concepts.
 - Developed a common set of drive-cycles for vehicle simulation performance evaluations.

- Task 2. Cost Analysis
 - Supported the manufacturing and cost analysis technology team in the evaluation of the initial cost assessments for the hydrogen storage systems.
 - Established initial phase of cost analysis through the development of a component cost matrix.
 - Assisted in the approach of using the component library to decompose the key system elements to evaluate the cost drivers and establishing cost sensitivity items for future trade-offs.
- Task 3. Assessment/Optimization of Framework-Based Storage Media
 - Prepared a set of variable-density *neat* MOF-5 compacts ranging from 0.3 to 0.8 g/cm³ which have the potential to realize significant volumetric capacity improvement as compared to the powder ($\rho=0.13$ g/cm³).
 - Characterized key physical and mechanical properties of MOF-5 compacts including crush strength, Brunauer-Emmett-Teller (BET) surface area, and total pore volume for comparison with known sorbent data (e.g. for AX-21, polyether ether ether ketone [PEEK], MOF-177).
 - Determined excess and estimated total gravimetric and volumetric capacities for MOF-5 compacts and realized a 4× improvement in excess volumetric capacity for 0.5 g/cm³ compact with only a small decrease (~15%) in excess gravimetric capacity (as compared to powder MOF-5).
 - Evaluated principle thermal property data (i.e. thermal diffusivity, heat capacity, and thermal conductivity) for *neat* MOF-5 compacts (e.g. k at 25°C for 0.35 g/cm³ is 0.072 W/mK).
 - Prepared a series of variable-density MOF-5 compacts containing expanded natural graphite (ENG; 1, 5, and 10 wt% additions) as a thermal conductivity aid.
 - Evaluated preliminary thermal conductivity and surface area characteristics for ENG-containing MOF-5 compacts, revealing a 5× improvement in thermal conductivity (e.g. 0.56 W/mK for 0.5 g/cm³ MOF-5 compact w/ 10 wt% ENG as compared to <0.1 W/mK for neat compact).
 - Designed, fabricated hardware, and completed experiment of first-time in situ characterization (via neutron imaging) of hydrogen dynamics in a cryogenic storage vessel on MOF-5 pellets.

Introduction

Widespread adoption of hydrogen as a vehicular fuel depends critically on the development of low-cost, on-board hydrogen storage technologies capable of achieving

high energy densities and fast kinetics for hydrogen uptake and release. As present-day technologies -- which rely on physical storage methods such as pressurization or liquefaction -- are unlikely to attain established DOE targets, interest in materials-based approaches for storing hydrogen have garnered increasing attention. To hasten development of these 'hydride' materials, the DOE has established three Centers of Excellence for materials-based hydrogen storage research as part of a "Grand Challenge" to the scientific community. While the Centers of Excellence have made substantial progress in developing new storage materials, significant challenges associated with the engineering of the storage system around a candidate storage material remain largely unresolved.

Approach

As a partner in the Hydrogen Storage Engineering Center of Excellence, Ford-UM-BASF is conducting a multi-faceted research project that addresses three of the key engineering challenges associated with the development of materials-based hydrogen storage systems.

Systems Modeling (Task 1): Drawing on our extensive expertise in the engineering of fuel cell (FC) and H₂ internal combustion engine (H₂-ICE) vehicles, we are evaluating and developing system engineering technical elements with a focus on hydrogen storage system operating parameters. This effort will result in a set of dynamic operating parameters and a high-level system model describing the interaction of the fuel storage system with the FC (or H₂-ICE) power plant.

Cost Analysis (Task 2): We are leveraging the unique capabilities of the "Ford/Massachusetts Institute of Technology cost model" to develop and perform hydrogen storage manufacturing cost analyses for various candidate system configurations and operating strategies. This analysis facilitates a technology roadmap for potential cost reductions and manufacturing optimization, while providing important feedback to Go/No-Go decisions on prototype design and construction.

Sorbent Media Assessment and Optimization (Task 3): We are evaluating and optimizing the "effective engineering properties" of an important class of sorbent materials (MOFs) and other framework-like materials in order to devise improved packing and processing strategies for their use in a systems context. Various mechanical processing routes are being examined (ranging from powders to pelletization to extrusion) in an effort to simultaneously maximize packing density, heat and mass transfer, and hydrogen uptake characteristics.

This work is expected to impact the broader goals for the DOE and FreedomCAR, leading to a significant advance in the engineering of materials-based hydrogen storage systems, refinement in our understanding of the performance targets of hydride materials, and ultimately, the development of commercially viable hydrogen storage systems.

Results

Following is a description of our technical results for each task and how these results relate to achieving the DOE targets.

Task 1. System Modeling

The Integrated Power Plant/Storage System Modeling Technology Area during the past year focused on the framework elements that were needed to establish simulation modeling parameters for a consistent assessment of the storage systems in support of the phase 1 milestone review. Within this year, the modeling framework was established and fully utilized to assess the multiple storage systems in a consistent manner. Further details in the powerplant models were refined such as the fuel cell stack efficiency and the associated parasitics. The fuel cell stack was sized for 80 kW net operating power at 80°C temperature. In the refinement of the model, the fuel cell system efficiency was evaluated and adjusted to be consistent with the DOE fuel cell system targets for efficiency at rated power (50%) and quarter power (60%) as shown in Figure 1.

The fuel cell model includes the essential elements to interface between the vehicle and the hydrogen storage model blocks. These elements include: the polarization curve to translate requested vehicle power to current and hydrogen flow request, parasitic power from the compressor, and stack temperature to provide the waste heat stream. Each of these elements were integrated and evaluated during this year. The polarization curve transfer functions were compared against the latest results from the general computational (GC) tool. The assessment concluded that an additional effect for temperature would be added to the Hydrogen Storage Engineering Center of Excellence (HSECoE) modeling framework while the GC tool effects to

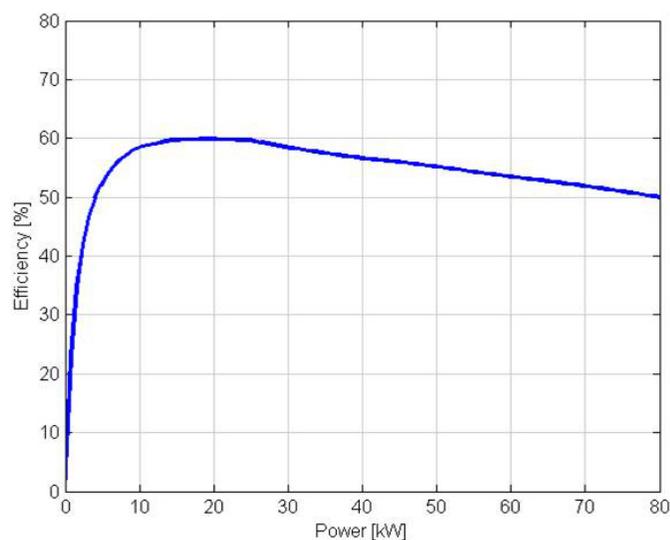

FIGURE 1. Fuel Cell System Efficiency in the HSECoE Universal Framework Model

temperature appeared higher due to sensitivity of the future catalyst assumptions. The other activities in the modeling area included confirmation of the maximum flow condition and definition of success criteria for following the flow demand trace within the modeling simulation.

In this year, a key accomplishment was the establishment of the modeling structure for the baseline vehicle assumptions and drive cycle test cases. In the evaluation of useable hydrogen and other performance attributes, the system architects and storage system modelers had various simulation approaches and assumptions. In order to have a consistent approach, a baseline vehicle and test matrix was developed to establish the storage capacity assessment along with the functional confirmation at the boundary conditions such as high flow, cold cycle, and hot cycle. The initial vehicle proposal was based on the compact vehicle based on a global view of vehicle platforms but was revised to mid-size assumptions to maintain consistency with prior analysis such as those assumed in the Argonne National Laboratory Powertrain Systems Analysis Toolkit model. The emphasis in developing these simulation assumptions was to have consistency and references for the rationale inside of developing unique baseline parameters for the center. The simulation test cases were formulated based on specific needs expected usages to demonstrate a certain performance target. The test case 1 was developed for the basic fuel economy evaluation and confirmation of the usable capacity of the storage systems, which was standardized at 5.6 kg (for consistency with previous studies). The test case 1 utilizes the Environmental Protection Agency (EPA) fuel economy (FE) Urban Dynamometer Driving Schedule (UDDS) and Highway Fuel Economy Test (HWFET) drive cycles and then adjusts them to the post-2008 five-cycle EPA fuel economies from a prior regression correlation in the simulated vehicle fuel economy estimation. The test case 2 consisted of the US06 that simulates aggressive driving and includes the high flow conditions for evaluating the minimum full flow target. The test case 3 is a cold test case with a lower temperature than the EPA cold test to align with the -20°C start-up criteria within the target requirements. The Federal Test Procedure (FTP)-75 was selected for the cold test case since the cycle has low power demand and has idle periods within the drive cycle which would be worst case for systems depending on waste heat or other usage parameters to increase their operating temperatures. The test case 4 is a hot test case based on the drive cycle and consistent with the temperature utilized in the EPA hot condition testing. The final test case 5 was established for the dormancy test case and was based on a month static storage time period at the high EPA temperature. The resulting test cycle matrix is shown in Table 1.

In addition, the HSECoE requested the original equipment manufacturers (OEMs) to assist in the classification of the DOE hydrogen storage targets. The classification of DOE targets was needed for guiding the upcoming phase 1 milestone (i.e. 4 at 100% and remaining at

TABLE 1. HSECoE Simulation and Evaluation Drive Cycle Matrix

Case	Test Schedule	Cycles	Description	Test Temp (°F)	Distance per cycle (miles)	Duration per cycle (minutes)	Top Speed (mph)	Average Speed (mph)	Max. Acc. (mph /sec)	Stops	Idle	Avg. H2 Flow (g/s)*	Peak H2 Flow (g/s)*	Expected Usage

*Based on NREL simulation with mid-size vehicle, 5.6 kg usable H2, 80 kW fuel cell with a 20 kW battery

40% criteria) and for providing trade-off recommendations to the system architects. The Ford team took the leadership role to brainstorm methods and organize the classification approach. After consideration, the decision was to use a quality function deployment (QFD) method since this tool provides an organized structure to assessing the targets using OEM system engineering disciplines. The system engineering approach uses a cascade from the customer musts/wants to the system requirements/targets. The QFD identifies the priorities of the customer attributes and then ranks the relationships of the system targets to the customer attributes. The cause-effect relationships used a 1 (low effect) to 9 (high effect) scale by evaluating the change in the vehicle attribute based on a 40% reduced target. The priority of the customer attributes utilized the analytic hierarchy process which a series of pairwise comparison judgments to express the relative strength or impact of the element compared to another.

The results of this classification process produced the ranking of the 2010 targets as shown in Figure 2. As indicated by the color codes, the OEM team classified the targets as safety, performance musts (required for basic function), environmental factors (not actual targets), and design choices. The targets classified as design choices were viewed as the attributes that should be utilized by the system architects to emphasize the development of the higher ranked items. The lower ranked design choice targets

are still important but could be deemphasized in the system design (at a 40% lower limit). It is important to recognize the analysis was conducted based on the DOE phase 1 milestone criteria that allowed a hydrogen storage system to meet a 40% target level. Therefore, this ranking approach is only valid to a 40% lower limit of the existing DOE target. When considering this assumption, certain targets were relatively immune to a 40% setting of the value. The process was repeated for the 2015 targets at a 50% lower limit and the top five target priorities remained the same with only minor changes in the absolute classification levels.

Task 2. Cost Analysis

The Manufacturing and Cost Analysis Technology Team during the past year established the HSECoE component library foundation to provide the cost evaluation and initial assessment of overall system weight and volume attributes. The HSECoE component library was populated to provide the system architects with the elements needed for the system assessments to support phase 1 milestone review. The system architects utilized the library for the system references for the milestone to ensure the common assumptions are being used throughout the HSECoE. Alignment of the library and the structure of cost evaluation analysis were completed during this year. The component library progressed through various reviews and industry

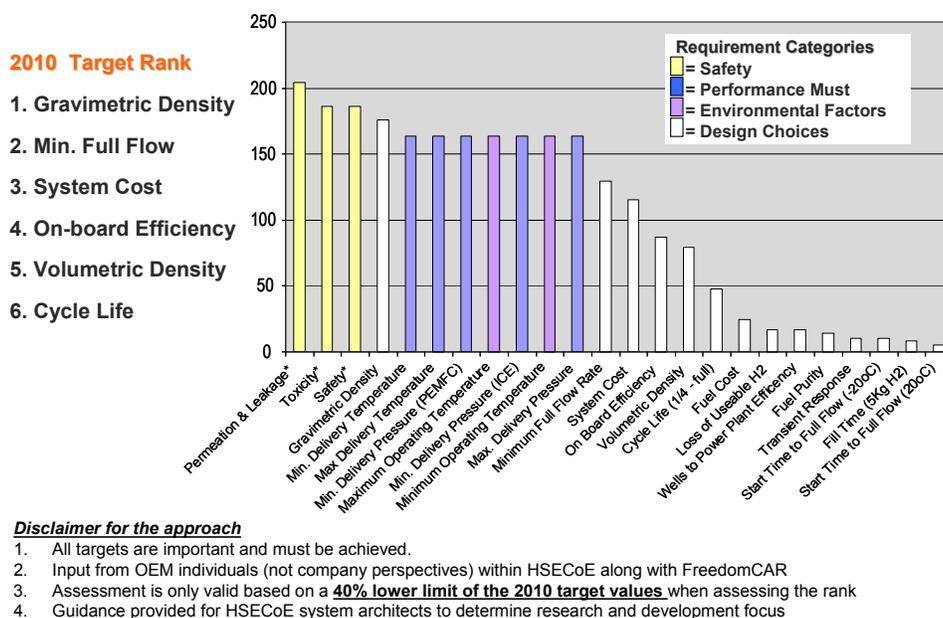

FIGURE 2. HSECoE Hydrogen Storage Target Classification Pareto Assessment

sources. The effort in developing the library was led by the Pacific Northwest National Laboratory along with input from Ford and other HSECoE partners to ensure the required data for the phase 1 milestone was available. The benchmarking and comparison of other cost models were conducted during this year and will continue as the cost approach advances from catalog components to enhanced manufacturing assessments of key components.

Task 3. Sorbent Media Assessment and Optimization

During the previous year (FY 2010), the HSECoE collaboratively selected MOF-5 as the initial framework material of interest. Therefore during last year a complete set of its fundamental and engineering materials properties were assessed and the primary properties for *powder* MOF-5 deduced including thermal properties (e.g., thermal conductivity, heat capacity), bulk properties (e.g., density, surface area, particle size, pore volume), and isotherm properties. These engineering properties were submitted and distributed to the HSECoE to aid in the creation of preliminary system models for *powder* MOF-5.

Based on preliminary performance modeling data, two principle materials property deficiencies were identified for the *powder* MOF-5 system: 1) low volumetric capacity and 2) poor thermal conductivity. This year's focus aimed at addressing these gaps through both materials compaction and the incorporation of thermal conductivity additives. A series of six *neat* MOF-5 pellets were initially prepared with varying densities from 0.31 to 0.79 g/cm³. For reference, the loose powder and single crystal densities for MOF-5 are 0.13 and 0.61 g/cm³, respectively. The goal of MOF-5 compaction is to sufficiently compress the powder

to eliminate interparticle voids without compressing the internal (micropores) pores of the MOF structure (i.e. not going beyond the single crystal density). Unlike many other sorbents (e.g. AX-21 or PEEK), addition of a binder is not necessary to form stable MOF-5 compacts, as cohesion within the pellet is high. MOF-5 compacts were fabricated using a manual arbor press with pressing pressures ranging from approximately 30 MPa up to 100 MPa to construct pellets with densities of 0.31 to 0.79 g/cm³, respectively.

Select physical properties, in particular, phase characterization, BET surface area, and total pore volume of variable density MOF-5 pellets were determined. The phase characterization of each compact was analyzed by powder X-ray diffraction (XRD) to investigate to what extent the original crystal structure of MOF-5 was maintained (i.e. qualitatively evaluate any increase in amorphous content). Based on the XRD data, it was evident that as the pellet density is increases, the intensity of MOF-5 diffraction peaks decreases along with a concomitant increase in the amorphous content (i.e. low angle diffuse scattering). This behavior becomes more pronounced as density is increased from 0.51 g/cm³ to 0.65 g/cm³ (i.e. beyond the single crystal density). Thus this data confirms that to simultaneously improve the volumetric efficiency while preserving the MOF-5 structure, it is necessary to use densities slightly below the MOF-5 single crystal density of 0.61 g/cm³.

Mechanical strength is also an important consideration in determining optimum compact density. To evaluate the mechanical properties of pelletized MOF-5, radial crush strengths of several sets of MOF-5 pellets were determined. These data reveal that compacts with a density of 0.31 g/cm³ show almost no resistance to compressive loads applied along their radius. However, tablets with larger densities

have greatly improved crush strength. For 0.41 g/cm³ pellets, the average crush strength was 24 N. This increases to 71 N and 106 N for pellets having densities of 0.51 g/cm³ and 0.60 g/cm³, respectively.

The BET surface areas and total pore volumes of the variable density MOF-5 compacts were also determined (Figure 3). These data indicate that as one initially begins to compress MOF-5 from a loose powder density of 0.13 g/cm³ to 0.3 g/cm³, the BET surface area and total pore volume remain roughly constant at approximately 2,700 m²/g and 1.4 cm³/g, respectively. Beyond 0.3 g/cm³, the BET surface area and total pore volume decrease linearly with increasing density. The linear decrease in surface area with increasing density is an effect also observed for activated carbon (AX-21). Since the storage of hydrogen in sorbents such as MOFs and activated carbons relies on physisorption of hydrogen onto the surfaces of the host sorbent (i.e. MOF), the hydrogen capacity typically scales with surface area. Based on Figure 3, going to a MOF-5 density of 0.51 g/cm³ results in a 20% decrease in BET surface area (and total pore volume). One must evaluate the hydrogen storage uptake to determine if the reduction in surface area results in a corresponding 20% reduction in hydrogen capacity.

The excess hydrogen adsorption isotherms for MOF-5 powder and compacts are shown in Figure 4 along with fits to the empirical data (Figure 4, symbols) using the modified D-A model (Figure 4, lines). Similar to the surface area results above, the maximum gravimetric uptake is unchanged in the 0.31 g/cm³ pellet relative to the powder. However, a 15% or 41% decrease in gravimetric uptake is observed for the 0.51 g/cm³ or 0.79 g/cm³ samples; these reductions are comparable to the respective 20% and 50% loss in surface area. This suggests that some of the surface area lost upon compression was not active in uptake of hydrogen. The maximum volumetric excess adsorption is increased by a

factor of 2.5 for the 0.31 g/cm³ sample relative to the powder. The increase is a factor of 3.7 for the 0.79 g/cm³ sample.

The total amount of hydrogen storage at 77 K by MOF-5 compacts is defined as the excess adsorption plus the gas phase H₂ within the void space of the pellets. Relative to the MOF-5 powder, total storage at 80 bar is increased by 26% in the 0.31 g/cm³ sample and by 40% in the 0.51 g/cm³ sample. On the other hand, if desorption occurs isothermally at 77 K by a pressure decrease from 80 bar to 3 bar, then the total hydrogen delivery is increased by 13% in the 0.31 g/cm³ sample, versus 17% for the 0.51 g/cm³ sample. The total *materials-based* volumetric capacity for the 0.51 g/cm³ MOF-5 compact at 80 bar and 77 K is 40 g/L, a 150% improvement as compared to powder (0.13 g/cm³). (For reference the 2015 DOE *system-based* volumetric capacity target is 40 g/L.[1].)

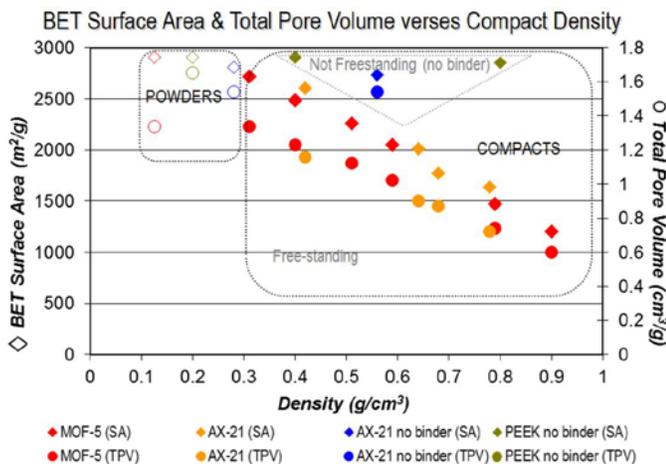

FIGURE 3. BET surface area (\diamond , primary y-axis) and total pore volume (\circ , secondary y-axis) versus compact density for powders (open symbols) of MOF-5 (red), AX-21 with binder (orange), AX-21 without binder (blue) and PEEK without binder (green).

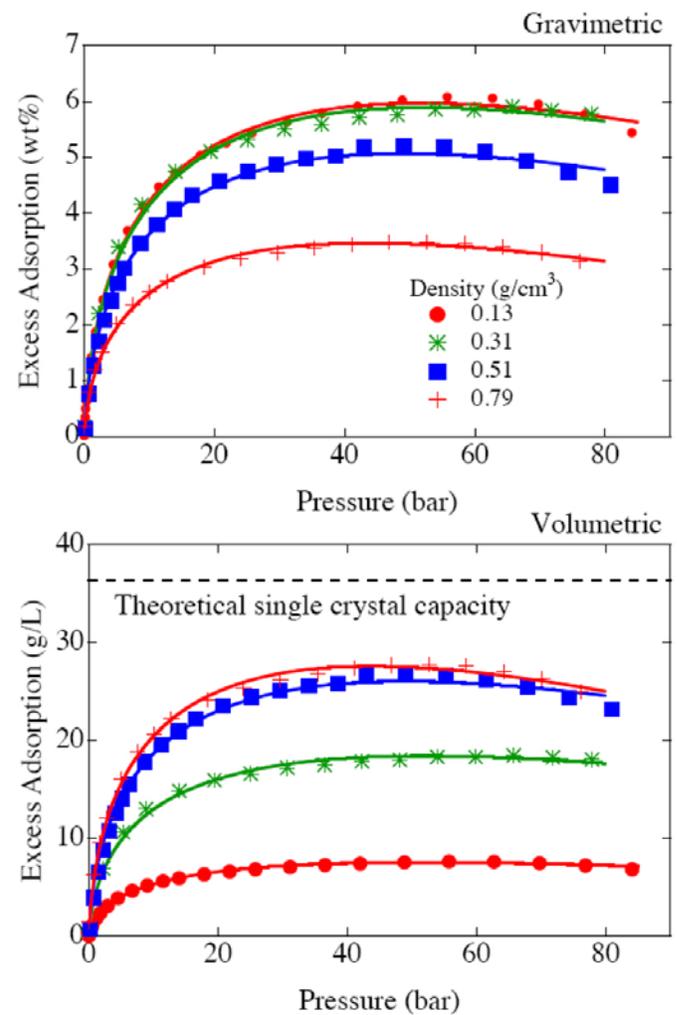

FIGURE 4. Excess hydrogen adsorption at 77 K from 0 to 80 bar by MOF-5 powder ($\rho=0.13$ g/cm³) and MOF-5 compacts with $\rho=0.31$ – 0.79 g/cm³. Excess gravimetric adsorption (top) and excess volumetric adsorption (bottom) expressed as a mass fraction (i.e. $m_H/m_{sample} \times 100$). Fits of empirical data (symbols) to the modified D-A model (lines) are shown.

The thermal conductivity of most microporous materials (e.g. MOFs) is expected to be low due to their large pore size ($>20 \text{ \AA}$ in diameter) and high free volume ($>90\%$). For example, the measured thermal conductivity of a single crystal of MOF-5 was previously determined to be 0.3 W/mK between 70 and 300 K [2]. The thermal conductivity (k) for neat MOF-5 compacts with densities from 0.35 to 0.69 g/cm^3 were determined over the temperature range of 25 to 65°C from the measured thermal diffusivity (α), heat capacity (c_p), and density (ρ) using the equation, $k = \alpha \times c_p \times \rho$. Thermal conductivity verses temperature data are shown in Figure 5. Increasing pellet density from 0.35 g/cm^3 to 0.52 g/cm^3 (33% increase) results in only a modest increase in thermal conductivity, from 0.072 to 0.095 W/mK (at 25°C). We speculate that this small improvement in k arises from a decrease in the amount of inter-particle void space within the pellet volume. Despite this improvement, the neat MOF-5 compact conductivities are all uniformly low and well below the single crystal value of 0.3 W/mK at room temperature. Since hydrogen uptake in sorbents is an exothermic process, low thermal conductivity could restrict the design of efficient MOF-5 based storage systems. In order to achieve targeted refueling times (2015 DOE target is 3.3 min for 5 kg H_2 [1]), and maximize the amount of hydrogen stored, this heat of adsorption must be removed from the storage bed in order to quickly reach the desired operation temperature (e.g. 77 K). Therefore, the identification of methods to augment the thermal conductivity of MOF-5 is desirable; moreover such techniques could be generally applicable to other MOFs as well as the broader class of framework materials (e.g. zeolitic imidizolate frameworks and covalent organic frameworks).

To achieve greater improvements in thermal conductivity, we prepared a series of MOF-5 compacts containing ENG as thermal conductivity enhancer. Analogous to the neat MOF-5 compacts, the MOF-5/ENG composites explored also had densities between 0.35 g/cm^3 and 0.69 g/cm^3 with the ENG mixed at varying mass ratios of 1%, 5% and 10%

(by weight). Thermal conductivity verses temperature data are also given in Figure 5. Over the examined temperature range of 25 to 65°C , there is no systematic temperature dependence, consistent with previous data for MOF-5 [2]. Adding 1 wt% ENG to MOF-5 with compaction up to 0.69 g/cm^3 , does not significantly enhance thermal conductivity. However, increasing the ENG content to 5 wt% reveals a 300% enhancement relative to the neat MOF-5 compact of comparable density. For example, at a density of approximately 0.5 g/cm^3 , the 5 wt% ENG MOF-5 compact has thermal conductivity of 0.3 W/mK at 25°C as compared to the neat MOF-5 compact which has a value of 0.1 W/mK . Similarly, for a 10 wt% ENG addition, a 600% enhancement is observed. In particular, for the 0.5 g/cm^3 density at 25°C , a thermal conductivity of almost 0.6 W/mK is observed. Therefore, ENG additions do appear to be effective at increasing the thermal conductivity of MOF-5. Future work (described below) will focus on understanding the impact (tradeoffs) of ENG on other properties such as hydrogen uptake, permeability, crush strength, surface area, etc.

Conclusions and Future Directions

- Task 1. System Modeling
 - Benchmark the system modeling results in comparison to other hydrogen vehicle and storage analysis (i.e. Argonne National Laboratory) and identify the areas of differing assumptions or modeling approaches.
 - Enhance the framework and validate the elements of the universal HSECoE Simulink model with the objective of stabilizing the vehicle and fuel cell model blocks within the universal model for the storage optimization analysis.
 - Further refine the fuel cell model to ensure the waste heat and temperature polarization effects are representative of future integration with the hydrogen storage systems and evaluate additional

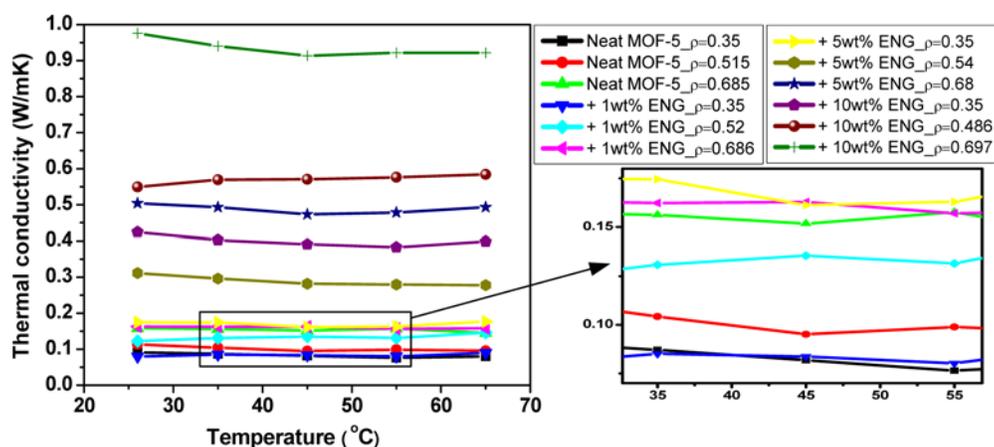

FIGURE 5. Thermal conductivity of pellets of neat MOF-5 and MOF-5/ENG composites with varying densities (from 0.35 to 0.69 g/cm^3) and ENG content (1, 5, or 10 wt%) as a function of temperature ($T = 26$ to 65°C).

opportunities of vehicle and storage system integration.

- Assess any needed revisions in the test matrix and modeling assumptions based on the feedback from the phase 1 milestone review.
- Task 2. Cost Analysis
 - Enhance the component library information through the development of the manufacturing model structure of the key components.
 - Evolve the cost and weight estimates in the component from available industry catalog items to projected attributes that are representative of automotive designed systems.
 - Decompose the components for the purpose of detailed system design trade-offs and component optimization in addition to the pursuit of equivalent data sources and sensitivity cost assessments.
 - Develop cost estimating resource tools to be utilized for the manufacturing models with additional cost estimation capability based on an agreed set of manufacturing assumptions of the key cost drivers.
- Task 3. Sorbent Media Assessment and Optimization
 - Validate powder MOF-5 isotherm model parameters at higher pressure (i.e. up to 200 bar), and at temperatures within the anticipated operating window.
 - Continue to assess impact of thermal conductivity aids on other principle hydrogen storage engineering properties (e.g., gravimetric capacity, gas permeability, crush strength, etc.); identify correlation between densification conditions, microstructure, and conductivity.
 - Collaboratively with HSECoE modeling efforts, determine required materials property values which are necessary to yield desired system performance.
 - Establish relationship between density and gas transport; collaboratively with HSECoE modeling teams, determine required value to optimize compact dimensions and shape.
 - Continue to support the experimental validation of sorbent bed and system models through neutron imaging and/or other experimental characterization efforts.

Special Recognitions & Awards

Mike Veenstra received a Special Recognition Award from USCAR for his proactive leadership role as a liaison between the Hydrogen Storage Tech Team and the Hydrogen Storage Engineering Center of Excellence.

Contract Number: DE-FC36-08GO19005

Project Start Date: February 1, 2009

Project End Date: January 31, 2014

- Complete identification of the highest value applications of microchannel-based technology.
- Complete experimental investigations and modeling to collect data that will support the Go/No-Go decision to proceed to Phase II.

The Phase I Go/No-Go Criteria associated with these technical goals are:

- Identify and demonstrate, through experiment and simulation, one or more high-priority applications where the application of microchannel technology can make a significant contribution to meeting DOE 2015 performance goals.
- Develop specific performance, weight, and size goals for each application included in the OSU Phase II scope of work.

FY 2011 Accomplishments

Key developments and technical accomplishments for the reporting period are summarized in the following.

- Completed system design of a modular adsorption tank insert that facilitates the use of densified storage media while providing cooling for charging, heating for discharging, and hydrogen distribution (Barriers A and E).
- Initiated experimental investigations to validate key design assumptions used in the design of the modular adsorption tank insert (Barriers A and E).
- Completed system design and production cost estimate for a microchannel combustor/heat exchanger to heat oil using catalytic combustion of discharge hydrogen from storage (Barrier H).
- Completed experimental validation of performance and size estimates used in developing the microchannel combustor/heat exchanger (Barrier H).

Introduction

Hydrogen storage involves coupled heat and mass transfer processes that are significantly impacted by size, weight, cost, and performance of system components. Micro-technology devices that contain channels of 10-500 microns in characteristic length offer substantial heat and mass transfer enhancements by greatly increasing the surface to volume ratio and by reducing the distance that heat or molecules must traverse. These enhancements

Fiscal Year (FY) 2011 Objectives

Use microchannel processing techniques to:

- Demonstrate reduction in size and weight.
- Improvement of charge/and discharge rates.
- Reduce size and weight and increase performance of thermal balance-of-plant components.

Technical Barriers

This project addresses the following technical barriers from the Storage section (3.3.4) of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

(A) System Weight and Volume

(E) Charging/Discharging Rates

(H) Balance of Plant (BOP) Components

Technical Targets

The Phase I technical targets for the Microscale Enhancement of Heat and Mass Transfer for Hydrogen Energy Storage project are:

often result in a reduction in the size of energy and chemical systems by a factor of 5-10 over conventional designs, while attaining substantially higher heat and mass transfer efficiency. In cooperation with the OSU Microproducts Breakthrough Institute and groups at the Pacific Northwest National Laboratory, Savannah River National Laboratory, and Los Alamos National Laboratory, we are developing: 1) advanced tank inserts for enhanced and mass transfer during charge and discharge of metal hydride and adsorbent hydrogen storage systems; and 2) microchannel-based thermal balance of plant components such as combustors, heat exchangers, and chemical reactors.

Approach

Our technical approach to meet the Phase I goals involves: 1) OSU will focus on simulation and experimental investigations to identify and prioritize opportunities for applying microscale heat and mass transfer enhancement techniques; and 2) working with other team members, OSU will identify the highest value applications and conduct experimental investigations and modeling to collect data necessary to support the Go/No-Go decision to proceed to Phase II.

For each high-priority component, we plan to use microchannel technology to reduce the relevant barriers to heat and mass transfer. Our approach involves: 1) the optimization of the performance of a single unit cell (i.e., an individual microchannel) and then “number up” using appropriate simulation tools that we then validate by experimental investigation; and 2) develop microlamination methods as a path to “numbering up” by low-cost high-volume manufacturing.

Results

With respect to our Phase I technical targets, we identified two high-value applications of microchannel technology. The first is the development of a modular microchannel tank insert for cooling during charging, heating during discharging, and hydrogen distribution. The tank insert can be used with either metal hydride or cryogenic adsorbing material; however, we have focused on applying the modular tank insert to cryogenic adsorption hydrogen storage. The second application is the development of an integrated microchannel combustor and heat exchanger that can be used for on-board oil heating during discharge of a metal hydride hydrogen storage system. Results relative to these two applications are summarized below.

Microchannel-Based Tank Insert – A tank insert that integrates storage media, microchannel heat exchangers, and microchannel hydrogen distribution plates may provide improved charging of the storage system, rapid startup, and quicker response to changing driving conditions. Progress-to-date on the development of the microchannel-based tank insert includes:

- **Cooling Plate Fabrication and Performance Validation** – During the reporting period, we completed the assembly and testing of a 5-cm diameter cooling plate that includes two sets of microchannel cooling channels and microchannels for the distribution of hydrogen. The resulting cooling plate is on the order of 1-mm thick. The overall conclusion from these experiments is that the pressure drop through the microchannel heat exchanger and hydrogen distributor plates is reasonably small (15 kPa at a flow rate of 0.15 l/min). Furthermore, the above experiments indicate that the major pressure drop in the cooling subsystem will be located in the coolant feed and in exit lines. These components can be redesigned to further reduce pressure drop.
- **Insert Design Development** – Figure 1 shows the design of a multi-module tank insert including the headers to distribute cooling fluid. Figure 2 shows

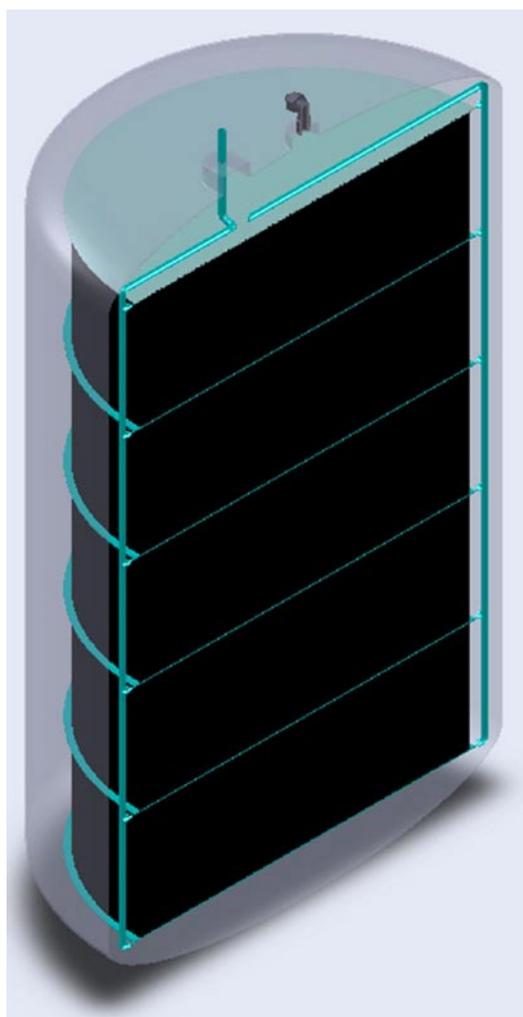

FIGURE 1. Schematic Diagram of Modular Adsorption System including Five Modules and Cooling Fluid Headers

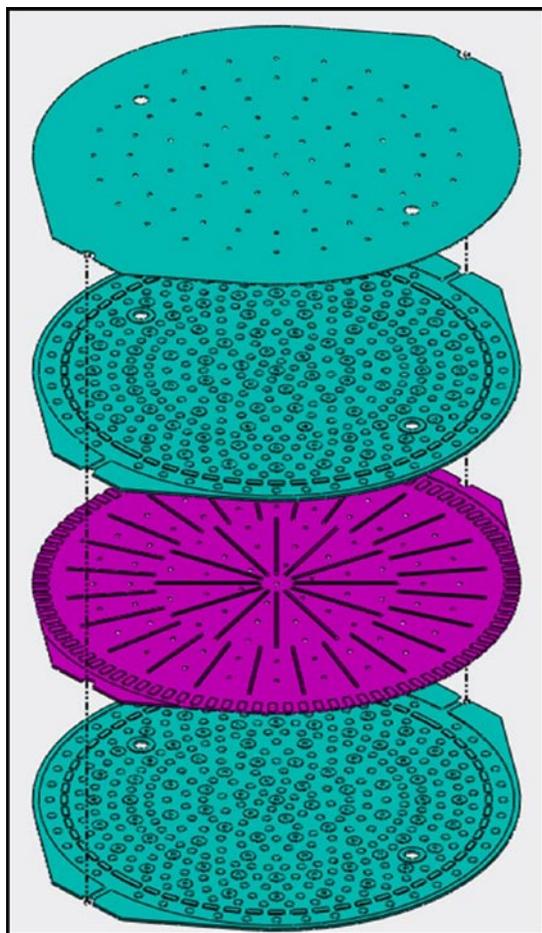

FIGURE 2. Schematic Diagram of Cooling plate including One Hydrogen Distribution Lamina (Purple) and Two Cooling Fluid Lamina (Teal)

the design of one cooling plate with one lamina used for hydrogen distribution and two laminae used for cooling. An individual module will consist of two cooling plates with media located between the cooling plates. Computational fluid dynamics (CFD) modeling was used to predict cooling fluid pressure drop and flow distribution both across one cooling plate as well as for a multi-module system. Overall pressure drop from the cooling fluid system inlet to outlet was predicted to be on the order of 1 bar. CFD modeling showed that flow maldistribution between plates in a single cooling plate was not a problem.

- Insert Fabrication and Weight Analysis – The system design described above was used as the basis for developing a fabrication approach and an estimated system weight. The fabrication strategy is amenable to high-volume production. The weight analysis for a cryo-adsorption hydrogen storage system capable of storing 5.6 kg of hydrogen and being filled in 4 minutes was on the order of 9 kg. This is based on a cooling plate spacing of 5 cm and assumes that the insert if fabricated from aluminum.

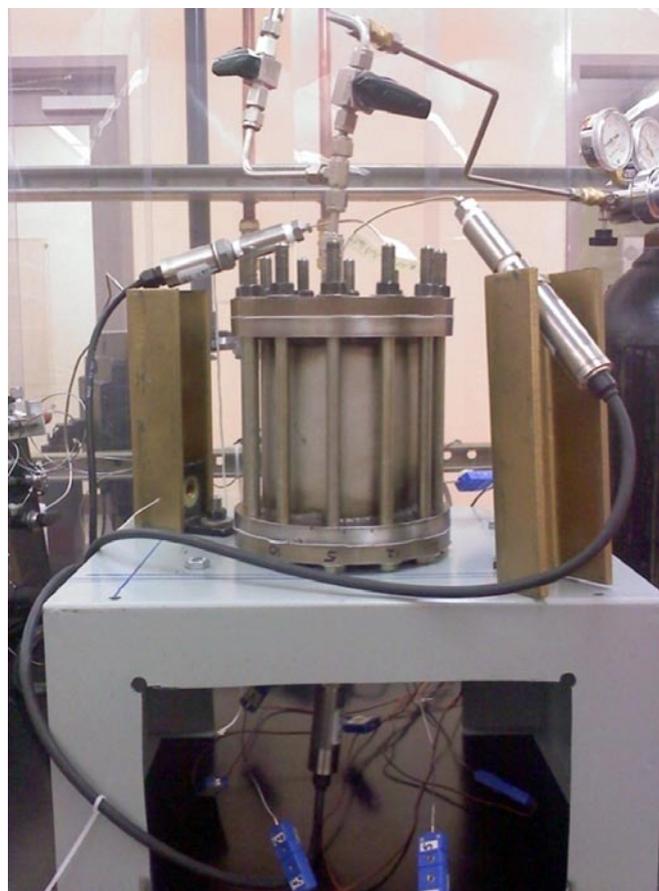

FIGURE 3. Modular Adsorption System Test Apparatus

- Experimental Investigations – We are currently starting up our test apparatus, shown in Figure 3, which will allow the testing of a cooling plate and media. The system is being converted to be able to operate at cryogenic temperatures so that we can test a 5-cm diameter module with liquid nitrogen cooling and hydrogen adsorption. The existing pressure vessel is limited to hydrogen pressures of 50 bars.

Integrated Microscale Combustor/Heat Exchanger (μ CHX) – The microscale combustor/heat exchanger (μ CHX, Figure 4) will be used to safely and efficiently produce heated oil, which is used to discharge hydrogen from the storage bed. Combining the combustion and heat exchanger systems and the use of microchannels for enhanced heat and mass transfer can drastically reduce the size and weight required for this function, while simultaneously increasing efficiency. A substantial safety benefit of a microscale combustor is that flames cannot be sustained in the sub-millimeter microchannels. Progress-to-date on the development of the μ CHX includes:

- μ CHX System Design, Weight and Cost Estimate – Previously we used simulation to predict the size, weight, and performance of a single unit cell of the

FIGURE 4. Schematic Diagram of μ CHX

μ CHX. During the reporting period, we used these results to develop the design of a full-sized μ CHX (12 kW to 30 kW heating capacity) including the headers needed to distribute the feed (a mixture of hydrogen and air), combustion products, and oil between a large number of unit cells. The overall system dimensions of a 12 kW μ CHX was estimated to be 15.1 cm by 15.6 cm by 4.3 cm with an overall volume of approximately 1 liter. The predicted volume of the μ CHX is approximately 10% of the best alternative design. The predicted mass of the μ CHX was estimated to be between 1.3 and 3.8 kg with an overall system efficiency of 92% (thermal energy transferred to the oil/chemical energy in the feed stream). Using this design as the basis for a bottom-up cost estimate we predicted a cost for this component of \$120 to \$200 at an annual production rate of 500,000 units. The production cost assumed that microlamination was used to fabricate the device with chemical etching used for patterning and laser welding used for bonding. Both stainless steel and aluminum were considered for fabrication materials. Simulation suggested that aluminum was a suitable material because material temperatures in the device were well below the temperature limits for aluminum.

- Unit Cell Experimental Validation of μ CHX Performance and Weight Estimates – During the reporting period we completed preliminary testing of a single unit cell. The results showed an efficiency of 92%. Our results also showed that 130 to 140 W of thermal energy was being transferred to the oil, which is consistent with our size and weight estimates reported above.

Conclusions and Future Directions

Key conclusions resulting from our research include:

- As shown by the μ CHX, when addressing a component that is limited by diffusion (heat or mass transfer), the application of microchannel technology can result in significant reductions in the size and weight of the device. Results also show that the cost of μ CHX can be attractive.
- The use of the modular adsorption tank insert allows convenient use of densified adsorption media and is amenable to high volume production.

The future direction of our research on the application of microchannel technology to hydrogen storage includes:

- Complete the demonstration of a 1 kW μ CHX demonstrating hindering and overall system performance.
- Complete demonstration of a multi-module 5-cm diameter modular tank insert including heat removal rates, hydrogen distribution, durability, and complete a production cost estimate for the system.

Introduction

Lincoln Composites is conducting research to meet DOE 2010 and 2015 Hydrogen Storage Goals for a storage system by identifying appropriate materials and design approaches for the composite container. At the same time, continue to maintain durability, operability and safety characteristics that already meet DOE guidelines for 2010 and 2015. There is a continuation of work with Hydrogen Storage Engineering Center of Excellence (HSECoE) partners to identify pressure vessel characteristics and opportunities for performance improvement. Lincoln Composites is working to develop high pressure vessels as are required to enable hybrid tank approaches to meet weight and volume goals and to allow metal hydrides with slow charging kinetics to meet charging goals.

Approach

Lincoln Composites is establishing and documenting a baseline design as a means to compare and evaluate potential improvements in design, materials and process to achieve cylinder performance improvements for weight, volume and cost. Lincoln Composites will then down-select the most promising engineering concepts which will then be evaluated to meet Go/No-Go requirements for moving forward.

The following areas will be researched and documented:

- Evaluation of alternate fiber reinforcement
- Evaluation of boss materials and designs
- Evaluation of resin toughening agents
- Evaluation of alternate liner materials
- Evaluation of damage vs. impact
- Evaluation of stress rupture characteristics
- Evaluation of in situ non-destructive examination (NDE) methods to detect damage

Fiscal Year (FY) 2011 Objectives

- To improve the performance characteristics, including weight, volumetric efficiency, and cost, of composite pressure vessels used to contain hydrogen in media such as metal hydrides, chemical hydrides, or adsorbents.
- To evaluate design, materials, or manufacturing process improvements necessary for containing metal hydrides, chemical hydrides, or adsorbents.
- To demonstrate these improvements in prototype systems through fabrication, testing, and evaluation.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (B) System Cost
- (G) Materials of Construction

Technical Targets

This project is conducting fundamental studies for the development of improved composite pressure vessels for hydrogen storage. Insights gained from these studies will be applied toward the design and manufacturing of hydrogen

Results

Lincoln Composites has completed the documentation of a baseline design as a means to compare and evaluate potential improvements in design, materials and process to achieve cylinder performance improvements for weight, volume and cost. Baseline characteristics, service conditions and nominal properties, are listed in Table 2.

Lincoln Composites has completed testing on alternate fibers relative to fiber strength and impact tolerance. Baseline fiber was selected as Toray T700. Five alternative carbon fibers were tested as part of the study. Vessels were constructed with each of the five fibers using same parameters on each: mandrel, wind patterns, tooling and processing. Tow count was adjusted, per fiber, to maintain consistent band cross sectional area. Testing was completed on all vessels including burst testing and drop/cycling. (See Table 3 showing a comparison of results of initial testing.) Two of the fibers indicated higher strength than baseline. Four fibers showed a potential lower cost per pound. The testing showed that these new fibers as received and tested

did not meet expectations and strength versus cost showed no improvement compared with the baseline. Lincoln Composites worked directly with two of the fiber suppliers, Toho and Grafil, to obtain improved fiber strength. After making improvements to their fibers, additional vessels were fabricated and their fibers were found to match existing baseline fiber in strength during burst testing. A benefit is the fact that having alternate fibers could potentially reduce costs by 10-15% from suppliers. Three fibers now could be used interchangeably in the construction of composite pressure vessels.

Lincoln Composites has completed the testing of an alternative boss material as part of the project. Baseline material is 6061-T6 aluminum. Investigations have been completed to create bosses constructed with aluminum 7075-T73. Properties, of which, are difficult to acquire through entire thickness. Higher strength would allow reduction in boss size and allow aluminum use at high pressures. Proper heat treat is a challenge to get correct strength properties and to avoid embrittlement. Near net shaped bosses were machined from 7075-T6 aluminum with the following

TABLE 2. Service Conditions and Nominal Cylinder Properties

Service Pressure	5,000 psi (344.7 bar)
Gas Settling Temperature	59 °F (15 °C)
Maximum Fill Pressure	6,500 psi (448 bar)
Service Life	20 years
Gas Fill Temperature Limits	-40 to 149 °F (-40 to 65 °C)
Operating Temperature Limits	-40 to 180 °F (-40 to 82 °C)
Proof Test Pressure	7500 psi (517 bar)
Minimum Rupture Pressure	11,700 psi (807 bar)
Cylinder Diameter	21.4 inches (543.4 mm)
Cylinder Length (unpressurized)	63.0 inches (1600 mm)
Cylinder Length at Maximum Fill Pressure	63.34 inches (1609 mm)
Cylinder Empty Weight (excluding hardware)	231 lbs (105 kg)
Cylinder Volume	15,865 in ³ (260 L)
Cylinder Volume at Service Pressure	16,132 in ³ (264.4 L)
Cylinder interior diameter	19.2 inches (488 mm)

TABLE 3. Initial Results of Alternate Fiber Testing

Fiber	Performance			Construction	
	Virgin Burst (psi)	Burst after Drop/ Cycle (psi)	% Reduction	Tows of Carbon Fiber	Band Carbon Cross Section (in ²)
Toray T700 24K (Baseline)	13,415	-		3	0.00429
Toray T800 24K	16,009	14,599	-9%	5	0.00444
Toho J30743HP 24K	12,249	10,543	-14%	3	0.00433
Grafil TRH50 18K	13,542	12,837	-5%	5	0.00433
Grafil TRH50 60K	12,152	10,193	-16%	2	0.00548
Hexcel AS7 12K	11,721	9,841	-16%	6	0.00414

surface finishes: smooth machining, rough machining, sand blasted and chemical etching. These bosses were then heat treated to a T73 condition. Bosses were sectioned and tensile testing on the specimens has been completed. Testing has confirmed the proper heat treat on the aluminum. Yield strength is 2 times that of 6061-T6 aluminum or 316 SS. Cost of bosses could be same to 1.5 times that of 6061-T6 and 1/5 that of 316 SS. Next step is to incorporate 7075 aluminum into new designs.

Investigations into alternate resin compilation are underway to determine effects on the toughening properties of a full-scale vessel, and would support the reduction in safety factors required for the vessel. First phase was to research and perform testing on alternate hardeners that could be used with our current baseline resin. Several experiments were run with alternate hardeners with an end result that our current hardener performs best. Next step is to use this hardener to begin looking at different resin formulations. One task is to down-select based on screening of viscosity and T_g results. Further testing is planned to determine mechanical and environmental/chemical properties. Upon completion, a down-select activity will determine what resin formulations will be used to produce coupons for impact testing. The last activity will then be to build full-scale vessels with the alternate resin formulations and to perform further testing such as impact. Initial candidates for toughening agents have been selected. This task will be continued as composite coupons and full-scale vessels are built for further testing.

Studies are ongoing with respect to alternate materials to minimize the permeability of gas through the high-density polyethylene (HDPE) liners that Lincoln Composites currently uses. The evaluations of coatings and surface treatments have shown blistering following a hydrogen soak and blow down. Surface treatments have not shown to be effective. The first investigation into Nanoclay additives gave unsuccessful results. The molecular properties of HDPE did not promote dispersion. However, new material found from alternate vendor has shown some improvements, with a reduction of about 40% in permeation. HDPE with titanium dioxide has resulted in a 25% reduction in permeation. Lincoln Composites has also worked with the addition of ethylene vinyl alcohol (EVOH). We encountered problems with layered materials including the ability to weld. We looked at adding as an outside layer to keep the material away from the weld joint, however, have had issues with adhesion of the EVOH to the HDPE. Lincoln Composites is in the process of looking at EVOH that has been modified to increase ductility. The evaluation of nylon as a filler has also been targeted. The cost of nylon, when compared with HDPE, would generate a large cost increase. Liners have been built with the following conditions: HDPE (baseline), HDPE/standard nanoclay, HDPE/development nanoclay, and HDPE/titanium dioxide. These have been wound into short tanks and testing will then move forward on full-scale models. A permeation rate versus cost relative to HDPE is shown in Figure 1. HDPE is the baseline at

1:1. HDPE fillers show a 40% reduction with limited cost increase. Alternate materials show promise of significant permeation reduction while others are prohibitively expensive. Reduction of the liner thickness will increase internal volume, allowing storage of more hydrogen, and will reduce weight. This task will be continued as further means to reduce permeation are investigated.

Lincoln Composites is looking into an improved data base for stress rupture of carbon fiber that may allow for reduced safety factors. This will in turn maintain projected reliability and reduce cost, weight and increase volumetric efficiency with thinner walls. A stress rupture project presented at industry workshop to gain feedback and support was conducted. The project is currently being refined with some collaborators and funding identified. Additional collaboration and funding is being sought, however, this additional funding has not been committed. Stress rupture, fatigue and damage tolerance are all being considered in the study. Fiber stress rupture and cyclic fatigue are directly related to stress ratio and damage tolerance is affected. The reduction in safety factor from 2.25 to 2.00 is planned and studies indicate that high reliability is maintained. Field experience indicates safe operation as long as damage tolerance is addressed. It can be addressed by other designs and testing. The evaluation of damage vs. impact is being considered to characterize safety and ability to remain in service after damage. NDE as a means of monitoring the structural integrity is being considered which will allow for thinner laminates and removal from service before rupture. The benefits of a reduced safety factor include: carbon fiber cost reduction of 10%, potential for increased cylinder volume, and the potential for weight reduction. All factors must be balanced against cost, envelope, and weight of other means of damage

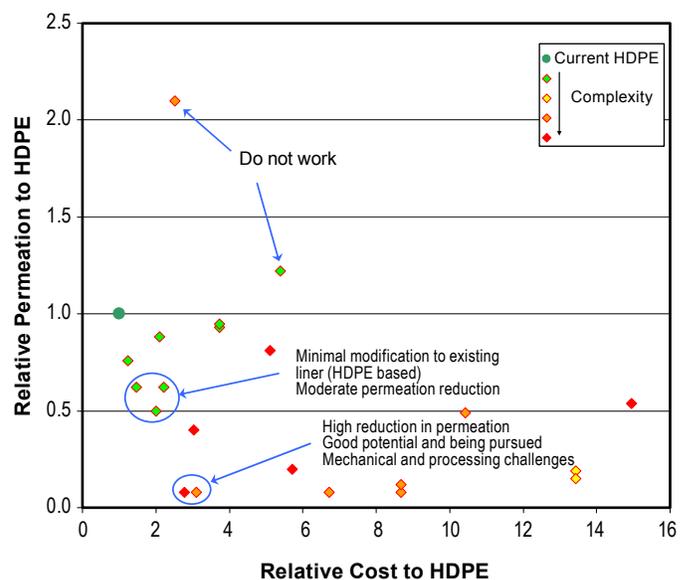

FIGURE 1. Permeation Rate versus Cost Relative to HDPE Liner Material

protection, if necessary. This task is on hold pending location of additional partners and funding.

Conclusions and Future Directions

The studies above have provided progress to meeting DOE goals for hydrogen storage. The full effectiveness of these improvements must be evaluated as part of a full system. However, improvements for the composite vessel itself are as follows:

- Reduced cost and weight from improved boss material.
- Reduced fiber cost by developing alternate fibers of equal strength.
- Reduced cost, potential reduced weight and increase volume, by reducing carbon fiber factor of safety.
- Reduced weight, increased volume, by reducing liner thickness.

For the cylinder itself, these improvements indicate the potential for:

- 11% lower weight
- 4% larger internal volume
- 10% lower cost

Future work for this project will be to continue progress on evaluating potential improvements, particularly as noted above for projects not yet completed. After completion of Phase 1, Lincoln Composites will down-select the most promising engineering concepts and evaluate against DOE 2010 and 2015 Hydrogen Storage Go/No-Go criteria.

Plans are being solidified for the evaluation of liner materials that can withstand high and low temperatures. Current materials in use have an operating temperature range of -40° to $+85^{\circ}\text{C}$. We plan to look into materials at -200°C on the low end and up to 375°C on the high end. Testing has begun to cycle tanks cold to ambient and hot to ambient followed by a burst test to evaluate our current materials. This was not part of the original scope of the project, but is being requested by team members of the HSECoE. Initial results show cold temperature exposure, to liquid nitrogen and soaking, does not affect the strength. Additional testing will be conducted.

Phase 2 is continuation of container development in support of system requirements. Specific attention will be directed to input from partners in support of concepts selected to go forward with Phase 3 and the fabrication of subscale vessels to support assembly of prototype systems for evaluation.

Subcontractor:

Kidde-Fenwal, Combustion Research Center,
Holliston, MA

Project Start Date: June 1, 2007

Project End Date: September 30, 2011

Fiscal Year (FY) 2011 Objectives

Provide improved definition of the DOE Environmental Health and Safety (EH&S) target and its link to material reactivity to guide research of storage materials. Detailed objectives include:

- Develop qualitative and quantitative analysis methods and tools to evaluate risks for materials-based hydrogen storage systems before and after risk mitigation methods.
- Perform dust characterization tests for metal hydride, chemical hydride and adsorbent materials.
- Characterize chemical reactions for material exposures associated with both risk events and mitigation approaches using time resolved X-ray diffraction (XRD), liquid reactivity and other specialized testing.
- Assess the trade-offs between residual risk after mitigation and the system weight and volume as well as reaction rates.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan [1]:

- (A) System Weight and Volume
- (F) Codes and Standards

Technical Targets

The key technical target of this project is EH&S, having a focus on the safety sub-target with some consideration for toxicity. The technical target for safety is specified generally as "Meets or exceeds applicable standards." For metal hydride, chemical hydride and adsorbent materials and systems, however, no such standards exist today. Furthermore, standards currently under development will be high-level in scope, primarily focused on systems and will not provide adequate guidance for evaluating and selecting viable candidate materials. As part of this effort, trade-offs will be evaluated between residual risks after mitigation and the two technical barriers:

- (A) System Weight and Volume
- (E) Charging/Discharging Rates

FY 2011 Accomplishments

- Quantitative risk analysis (QRA): developed and quantified fault tree (FT) models for:
 - On-board reversible hydrogen storage system.
 - Solid ammonia borane (AB) off-board regenerable storage system.
 - On-board solid AB thermolysis reactor.
 - Hydrogen permeation/leakage from Type-III and Type-IV storage vessels.
 - Finally, developed a risk reduction worth (RRW) methodology for quantifying the importance of each basic event (BE) in a fault tree system model.
- Qualitative risk analysis (QLRA):
 - Identified critical risks and failure mechanisms of a baseline design of an off-board regenerable alane-based (AlH_3) storage system.
- Risk mitigation:
 - Theoretical studies - performed atomic and thermodynamic modeling of sodium alanate (NaAlH_4) oxidation and hydration reactions.
 - Experimental studies - performed the following tests for NaAlH_4 , $3\text{Mg}(\text{NH}_2)_2 \cdot 8\text{LiH}$, and NH_3BH_3 :
 - Material reactivity in different fluids (water, windshield washing fluid, brine, antifreeze, and engine oil).
 - Fast blowdown (depressurization) which mimics accidental storage vessel breach.

- Dust cloud combustion characterization. Tests also included Maxsorb (AX-21).
- Mechanical impact sensitivity.
- Hot surface contact tests.
- XRD tests for material characterization.

Introduction

Safety is one of the most significant issues affecting consumer acceptance and adoption of hydrogen-fueled vehicles. Through DOE efforts to understand general public opinions, people have indicated that when selecting a fuel supply, safety is the most important factor. The current project, in close coordination with efforts at Savannah River National Laboratory (SRNL) and Sandia National Laboratories (SNL), will provide quantitative insights to the DOE safety target and support the development of future risk-informed hydrogen safety codes and standards (C&S).

The results from these collaborative efforts will also have nearer term impact in guiding storage materials research and the development of materials/systems risk mitigation methods.

Approach

The current project has five distinct elements as follows: 1) risk analysis framework (QLRA and QRA), 2) materials reactivity testing, 3) chemical reaction kinetics testing and modeling, 4) risk mitigation methods, and 5) limited scope prototype testing.

Results

QRA

Developed and quantified FT models for: a) on-board reversible hydrogen storage system, b) solid AB off-board regenerable alane-based storage system, c) on-board solid AB thermolysis reactor, and d) hydrogen permeation/

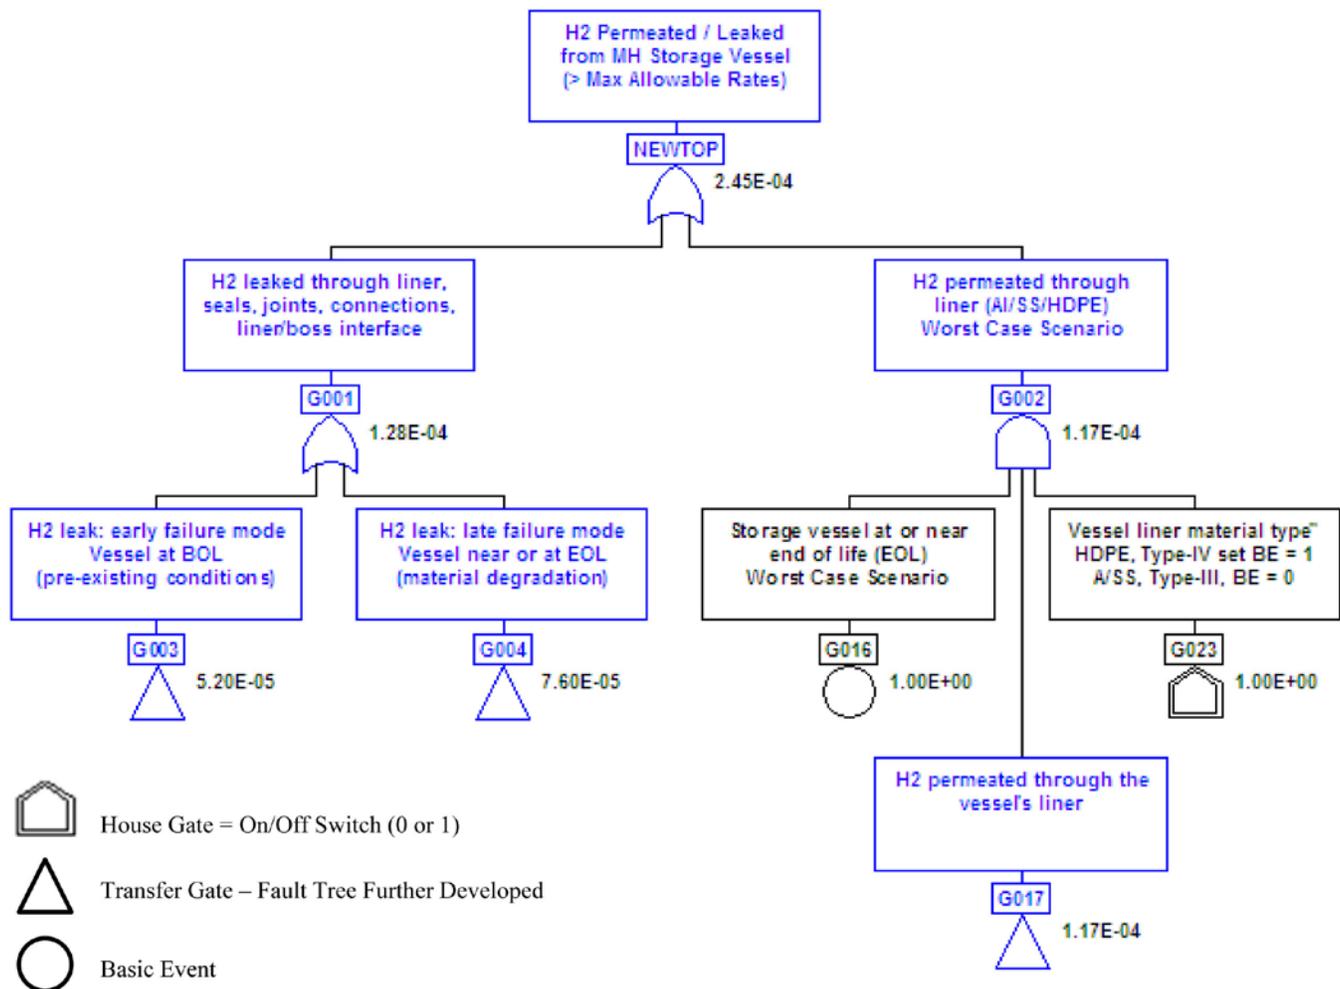

FIGURE 1. Fault Tree Model for Gaseous Hydrogen Permeation/Leakage through Type-III and Type-IV Liners

leakage from Type-III and Type-IV storage vessels. Figure 1 shows the top portion of the FT model for the hydrogen permeation/leakage from the storage vessel. The complete FT model, quantification results, minimal cutsets (i.e., sequences leading to hydrogen permeation or leakage from the storage vessel), and potential failure mechanisms are discussed in detail in reference [2]. The two failure modes for hydrogen leakage through the vessel's seals, joints, connections, liner/boss interfaces include: i) an early failure mode due to pre-existing conditions (Gate G003) in Figure 1 and ii) a late failure mode caused by time-dependent failure mechanisms with the vessel at or near end of life (EOL), Gate G004 in Figure 1. The time-dependent failure mechanisms include cyclic fatigue stresses leading to crack growth and propagation and material aging. Hydrogen permeation through the vessel liner is more likely to be a dominant failure mechanism when the vessel is at or near EOL. As part of the FT modeling and quantification, a RRW methodology has been developed for quantifying the safety importance of each BE in the fault tree model [2].

QLRA

- Developed a baseline design of an off-board regenerable hydrogen storage system using alane (AlH_3) as the solid-state storage medium (Figure 2).
- Performed failure mode and effects analysis (FMEA) for the proposed baseline design.
- Identified the following safety-significant failure mechanisms for this alane-based system:
 - Failure to transport the fresh alane powder through the on-board system.
 - Failure to transport the spent fuel (discharged alane) to the on-board collection tank.
 - Failure of thermal management subsystem of the on-board alane thermolysis reactor.
 - One of the critical hazards of the alane-based off-board regenerable system is related to the accidental exposure of discharged alane powder (spent fuel) to air. Under such postulated condition, the resulting

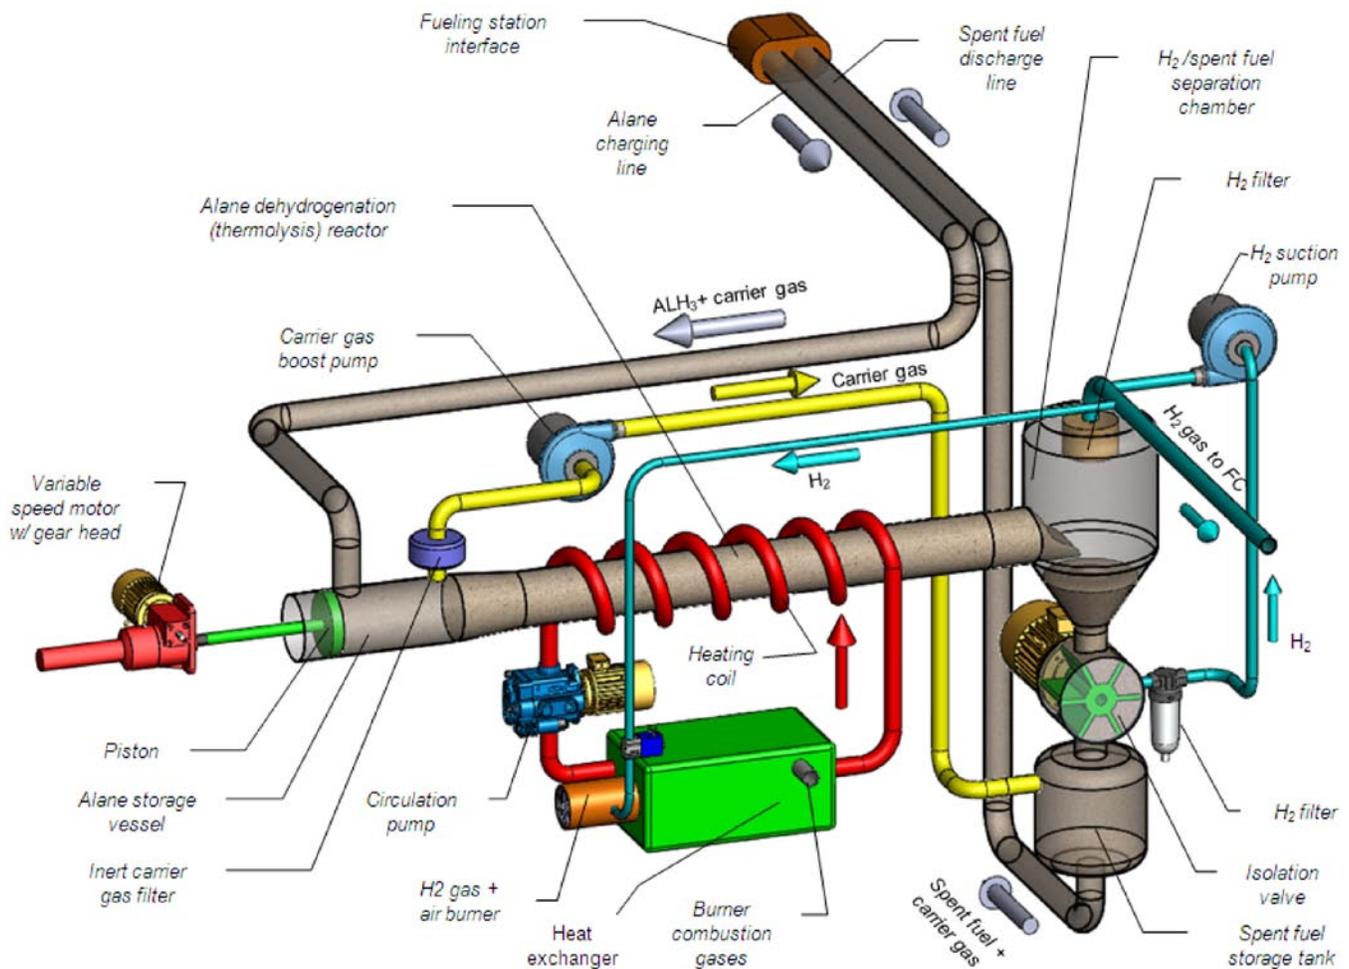

FIGURE 2. UTRC Baseline Design of an Off-Board Regenerable Alane-Based System

dust cloud explosion would be more severe compared to an accidental exposure of charged alane dust to air (Table 1).

Risk Mitigation – Experimental Studies

- Performed a series of scoping tests to evaluate the reactivity of selected complex metal hydrides, NaAlH_4 and $3\text{Mg}(\text{NH}_2)_2 \cdot 8\text{LiH}$, and chemical hydride, NH_3BH_3 , under environmental conditions that may exist during a postulated vehicular accident.
 - In immersion tests, loose powder as well as powder compacts (wafers) were immersed in different liquids at room temperature. The liquids selected were water, windshield washing fluid, thermo-oil, engine coolant (antifreeze), engine oil and NaCl solution (brine), respectively. These tests were repeated using powder compacts.
 - In the droplet tests, each of these liquids was dropped on the hydride loose powder and powder compacts (wafers).

The results of these tests demonstrated that powder compaction has a potential for reducing reactivity risks by suppressing the hydride/liquid reaction and, thus, preventing consequential ignition of the evolved reaction gases.

- Performed mechanical impact sensitivity tests (Figure 3) for complex metal hydrides (partially-charged NaAlH_4 and charged $3\text{Mg}(\text{NH}_2)_2 \cdot 8\text{LiH}$) and an as-received chemical hydride (NH_3BH_3). The results of the tests

n/a - not applicable; MIE - minimum ignition energy; MEC - minimum explosive concentration

showed that NaAlH_4 and $3\text{Mg}(\text{NH}_2)_2 \cdot 8\text{LiH}$ powder compacts were sensitive to mechanical impact where the test samples ignited on the first impact. The NH_3BH_3 powder compact, however, did not ignite during the impact tests.

- Conducted risk mitigation tests to prevent the observed mechanical impact sensitivity of NaAlH_4 . In these tests, the hydride powder was ball milled for 15 minutes, before compaction, with different flame retardant additives (10 wt% and 20 wt%, respectively) including aluminum oxide (Al_2O_3), aluminum hydroxide ($\text{Al}(\text{OH})_3$), magnesium hydroxide ($\text{Mg}(\text{OH})_2$), and melamine, respectively. None of these chemical additives was successful in preventing the sensitivity of sodium alanate to mechanical impact. More testing with other chemical additives is in progress.

Risk Mitigation – Atomic and Thermodynamics modeling

The thermodynamic modeling showed that $\text{NaAl}(\text{OH})_4$ is the most favorable product to form when 1 mole NaAlH_4 reacts with ≥ 2 moles O_2 or ≥ 4 moles H_2O in an inert atmosphere. The atomic modeling showed the $\text{NaAl}(\text{OH})_4$ product can favorably form a coherent, non-passivating layer on the NaAlH_4 surface (Figure 4).

Dust Cloud Combustion Characterization Tests

Table 1 summarizes the results of dust cloud combustion characterization tests for complex metal hydride (charged

NaAlH_4), chemical hydrides (as received NH_3BH_3 , charged/discharged AlH_3), and Maxsorb (AX-21).

Conclusions and Future Work

Conclusions - the work performed this period covered QRA, QLRA, risk mitigation tests, dust cloud characterization tests, and atomic and thermodynamics modeling. The QLRA identified safety significant failure mechanisms of the alane-based off-board regenerable system. The QRA covered FT modeling and quantification of on-board reversible, off-board regenerable systems, and hydrogen permeation/leakage from the storage vessels. The risk mitigation tests evaluated the reactivity of selected complex metal hydrides [NaAlH_4 and $3\text{Mg}(\text{NH}_2)_2 \cdot 8\text{LiH}$] and chemical hydride [NH_3BH_3] (loose powder and powder compacts) under different environmental conditions and postulated scenarios. Finally, performed atomic and thermodynamic modeling of sodium alanate (NaAlH_4) oxidation and hydration reactions.

Future work will focus on:

- Risk Analysis:** 1) complete risk analysis framework (both QLRA and QRA) incorporating results from dust cloud characterization tests, experimental and modeling activities at SNL and SRNL and 2) develop an economic consequence analysis framework for the identified most probable and worst-case scenarios to assess the safety benefits of selected risk mitigation methods.

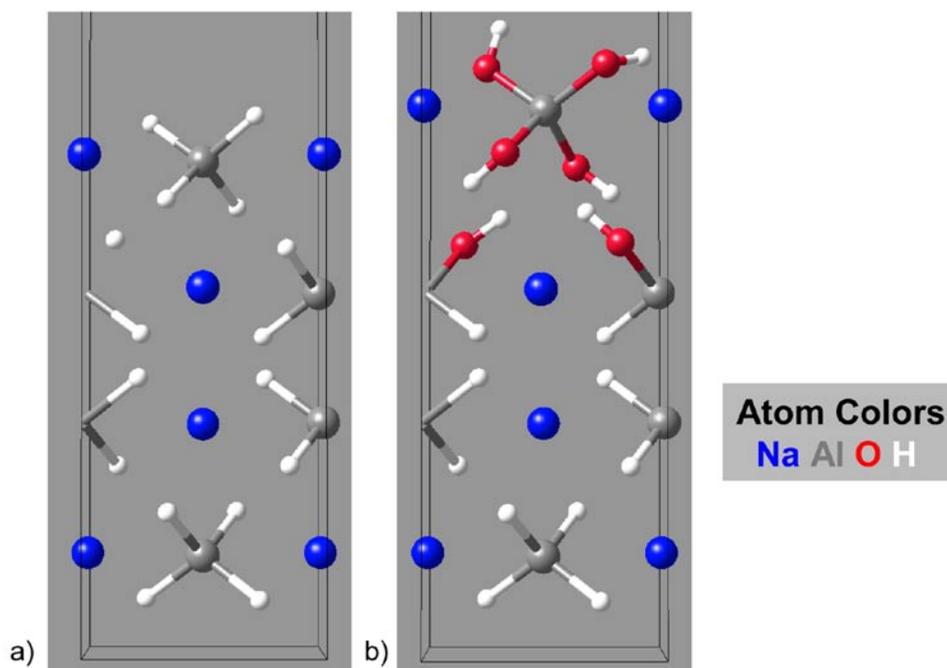

FIGURE 4. Atomic and Thermodynamics Modeling of NaAlH_4 Reactions with Air and Water

- **Atomic and Thermodynamic Modeling:** Additional atomic modeling and thermodynamic modeling are underway to identify the mechanisms for $\text{NaAl}(\text{OH})_4$ decomposition to the elemental oxide and hydroxide phases under inert and ambient conditions.
- **Risk Mitigation Experimental Studies (including those planned and coordinated with SNL material reactivity project:** 1) evaluate the effectiveness of fire-retardant chemical additives to eliminate the mechanical impact sensitivity of NaAlH_4 powder compact and 2) perform the localized flame impingement (external fire) test using UTRC Prototype-2 Type-III storage vessel. Currently, this task is being coordinated with SNL [3].

Special Recognitions & Awards

1. The International Energy Agency, Hydrogen Implementation Agreement (IEA/HIA), Task-31 (Hydrogen Safety) selected Dr. Y. (John) Khalil to lead its Subtask-B on Hydrogen Storage Materials Reactivity, Safety, and Materials Compatibility.

Start Date: October 1, 2004
Projected End Date: September 30, 2014

- System gravimetric capacity: 1.8 kWh/kg
- System volumetric capacity: 1.3 kWh/L
- Minimum H₂ delivery pressure: 5 bar
- Refueling rate: 1.5 kg/min
- Minimum full flow rate of H₂: 0.02 g/s/kW

FY 2011 Accomplishments

- Analyzed the gravimetric and volumetric capacities of Type-3 and Type-4 two-tank compressed hydrogen (cH₂) physical storage systems.
- Updated the on-board and off-board analyses of the activated carbon (AX-21) system with adiabatic liquid hydrogen (LH₂) refueling and cryogenic liner fatigue considerations.
- Conducted the on-board and off-board analyses of the metal-organic framework (MOF-5) system (powder and pellets) with adiabatic LH₂ refueling. Determined the intrinsic capacities, thermodynamics, dormancy, H₂ refueling dynamics, and discharge dynamics.
- Updated system analysis of on-board hydrogen storage systems that use ammonia borane (AB) in ionic liquids (IL) as the hydrogen storage medium.
- Performed off-board analysis of AB regeneration using hydrazine. Identified processes that consume significant amounts of energy in regeneration and provided feedback to stakeholders.
- Revised off-board analysis of alane regeneration using the three-step organometallic approach. Identified processes that consume significant amounts of energy in regeneration and provided feedback to stakeholders.

Fiscal Year (FY) 2011 Objectives

The overall objective of this effort is to support DOE with independent system level analyses of various H₂ storage approaches, to help to assess and down-select options, and to determine the feasibility of meeting DOE targets. Specific objectives in FY 2011 included:

- Model various developmental hydrogen storage systems.
- Provide results to Hydrogen Storage Engineering Center of Excellence (HSECoE) for assessment of performance targets and goals.
- Develop models to “reverse-engineer” particular approaches.
- Identify interface issues, opportunities, and data needs for technology development.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- (A) System Weight and Volume
- (B) System Cost
- (C) Efficiency
- (E) Charging/Discharging Rates
- (J) Thermal Management
- (K) System Life Cycle Assessments

Technical Targets

This project is conducting system level analyses to address the DOE 2015 technical targets for on-board hydrogen storage systems:

Introduction

Several different approaches are being pursued to develop on-board hydrogen storage systems with the goal of meeting the DOE targets for light-duty vehicle applications. Each approach has unique characteristics, such as the thermal energy and temperature of charge and discharge, kinetics of the physical and chemical process steps involved, and requirements for the materials and energy interfaces between the storage system and the fuel supply system on the one hand, and the fuel user on the other. Other storage system design and operating parameters influence the projected system costs as well. We are developing models to understand the characteristics of storage systems based on the various approaches, and to evaluate their potential to meet the DOE targets for on-board applications including the off-board targets for energy efficiency.

Approach

Our approach is to develop thermodynamic, kinetic, and engineering models of the various hydrogen storage systems being developed under DOE sponsorship. We then use these models to identify significant component and performance issues, and to assist DOE and its contractors in evaluating alternative system configurations and design and operating parameters. We establish performance criteria that may be used, for example, in developing storage system cost models. We refine and validate the models as data become available from the various developers. We work with the Hydrogen Storage Systems Analysis Working Group to coordinate our research activities with other analysis projects to assure consistency and to avoid duplication. An important aspect of our work is to develop overall systems models that include the interfaces between hydrogen production and delivery, hydrogen storage, and the fuel cell or internal combustion engine hydrogen user.

Results

Physical Storage

We expanded our analysis of cH_2 physical storage to include systems that may use two smaller, equal tanks that are in close communication (equalized pressures) and do not require duplicate controls. There is only a small weight (5-10%) and volume (<3%) increase in going from single-tank to two-tank systems; the penalty would be larger if the two tanks are not in close communication and require duplicate balance-of-plant components.

Hydrogen Storage in Metal-Organic Frameworks (MOF-5)

We conducted an analysis of on-board hydrogen storage in MOF-5 (Basolite Z 100-H) powder (130 kg.m^{-3}) and pellets ($310\text{-}790 \text{ kg.m}^{-3}$). Figure 1 shows the principal components of the reference on-board hydrogen storage system with adiabatic refueling, in which the MOF tank is evaporatively cooled during refueling with LH_2 . During discharge, the heat of desorption and any temperature swing in the sorbent bed is provided by recirculating the hydrogen through a small ex-tank heat exchanger. The composite pressure vessel consists of T700S carbon fiber (2,550 MPa tensile strength) wound on an Al 6061-T6 alloy liner, and it is thermally insulated with multi-layer vacuum super insulation in a 3-mm-thick Al 6061-T6 alloy vacuum shell. We conducted fatigue analyses to estimate the required liner thickness to meet the target life of 5,500 pressure cycles (Society of Engineers [SAE] J2579 requirement). The thickness of the insulation was determined so as to limit the heat transfer rate from the ambient to 5 W. A geodesic winding algorithm was employed to determine the optimal dome shape for the composite vessel and the carbon fiber thickness required for a 2.35 safety factor (SAE requirement) at the peak storage pressure.

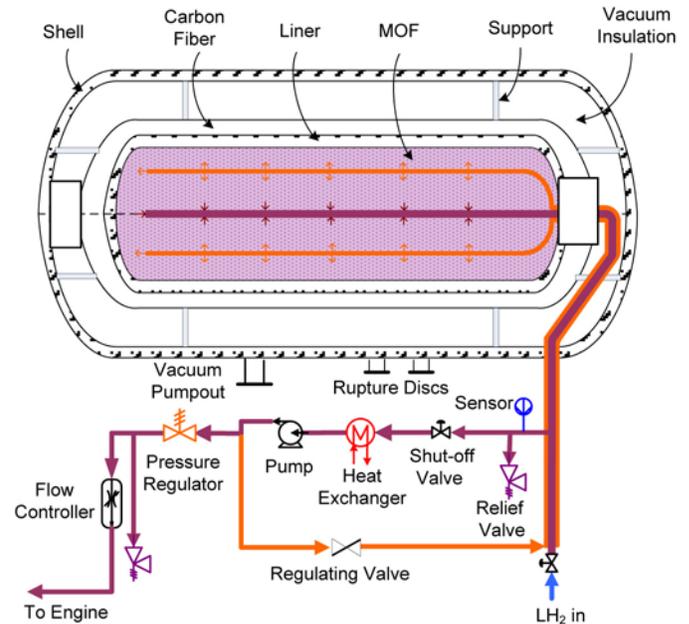

FIGURE 1. On-Board MOF-5 Storage System with LH_2 Refueling

We modeled the MOF-5 powder (130 kg.m^{-3}) hydrogen adsorption isotherms by fitting the low-temperature data of Zhou et al. [1] and Sudik et al. [2] to the Dubinin-Astakhov (D-A) equation. We used solution thermodynamics to evaluate the integral enthalpy of adsorption. We modeled the MOF-5 pellets ($310\text{-}790 \text{ kg.m}^{-3}$) hydrogen adsorption isotherms by fitting the data of Sudik et al. [2] to the D-A model. We incorporated the fitted isotherms in our system model to estimate the gravimetric and volumetric capacity for 5.6 kg recoverable H_2 at 5-bar minimum delivery pressure and 1.5-kg.min^{-1} refueling rate. Figure 2 shows the calculated system capacities for powder and pellets. The optimal pressure and temperature for maximum gravimetric capacity are 100-120 bar and $\sim 60 \text{ K}$ for powder and 310 kg.m^{-3} pellet bulk density, and $\sim 100 \text{ K}$ for 510 kg.m^{-3} pellet bulk density. The gravimetric capacity peaks at 6.6 wt% for powder, 4.8 wt% for 310 kg.m^{-3} pellets, and 3.3 wt% for 510 kg.m^{-3} pellets. The optimal temperature for maximum gravimetric capacity is lower than the temperature at which recoverable excess uptake is at a maximum. The system volumetric capacity increases with pressure for $130\text{-}310 \text{ kg.m}^{-3}$ bulk density, but does not reach the 40 g.L^{-1} 2015 target. The maximum volumetric capacity for powder is achieved at 150-250 atm, but at those pressures, a higher volumetric capacity can be achieved without using the sorbent. The volumetric capacity for the 510 kg.m^{-3} pellet bulk density decreases with increasing pressures above 100 atm as a result of the lower recoverable excess adsorption. For hydrogen storage in MOF-5 powder (150 atm, 60 K), the containment (liner, carbon fiber, and shell), the storage medium, and the balance-of-plant components account for 44%, 24% and 31%, respectively. The system has a volumetric efficiency of 69%, and 20% of

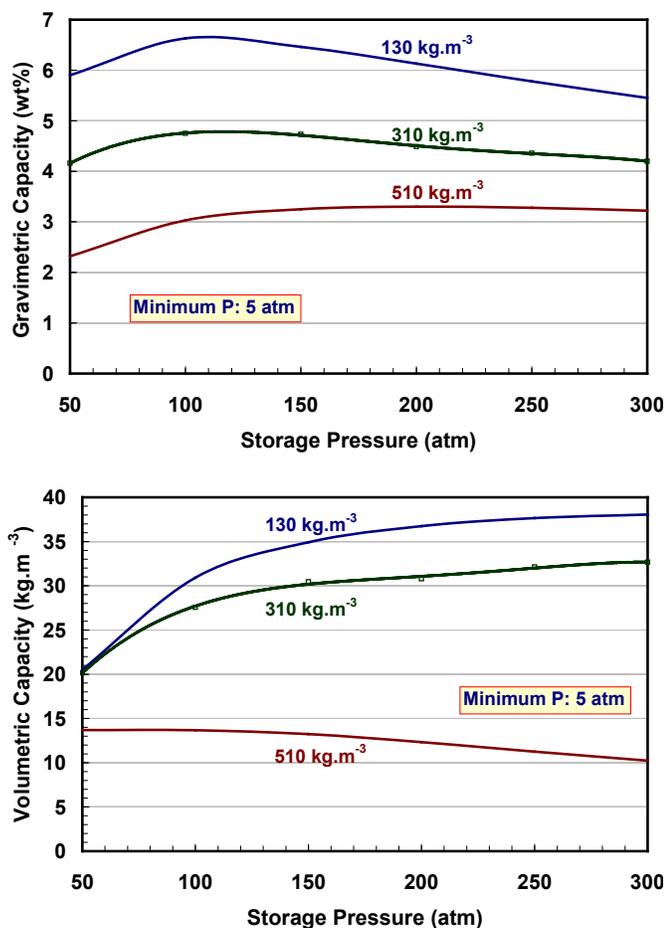

FIGURE 2. Usable Gravimetric and Volumetric Capacities of MOF-5 Powder and Pellets

the system volume is due to the vacuum insulation and the balance-of-plant components.

Analysis of the refueling dynamics showed that the total cooling load is 2, 2.1, and 3.9 MJ (maximum, from completely empty to completely full) for 130, 310 and 510 kg.m⁻³ bulk density, respectively. The heat of hydrogen adsorption accounts for 41-53% of the total cooling load; the thermal mass and the pressure-volume work of compressing the hydrogen in the tank account for the balance of the cooling load. Recoverable adsorption accounts for less than 10% of the 5.6-kg usable H₂ in the system with MOF-5 powder or 310 kg.m⁻³ pellets. For discharge, we estimated that the required bed permeability is 10⁻¹⁴ to 10⁻¹³ m² for 1 psi in-bed pressure drop and 20 charge and discharge tubes. The initial measurement [3] is 5.4 x 10⁻¹³ m² for the 360 kg.m⁻³ density pellet. We estimated that the required bed thermal conductivity for 10 U tubes is 0.04–0.05 W.m⁻¹.K⁻¹. The measured conductivity for powder and pellets is 0.088 W.m⁻¹.K⁻¹ and ~0.6 W.m⁻¹.K⁻¹ for 500 kg.m⁻³ pellets with 10 wt% graphite flakes added to MOF-5.

We determined the dormancy capability of the MOF-5 system as a function of temperature, pressure, and the

amount of hydrogen stored at the start of the dormancy period. We estimated the minimum dormancy by analyzing the worst-case scenario, in which a MOF tank is fully charged with H₂ at 150 atm at 60 K, and it is then parked for an extended time. Assuming that the relief valve is set at 25% above the design pressure, H₂ would begin to vent after 6 W.d of cumulative heat transfer (1.2 days at 5 W heat in-leakage rate). In this scenario, the calculated peak H₂ loss rate is 1.9 g.h⁻¹.kg⁻¹ for 5 W in-leakage rate. This rate decreases as H₂ vents from the tank. Also, the peak H₂ loss rate decreases to 0.3 g.h⁻¹.kg⁻¹ if the tank is initially 25% full, and there is no loss of H₂ if the tank is less than 15% full, or with minimal daily driving.

Chemical Storage

We conducted an on-board analysis for hydrogen storage in a 50:50 (by weight) liquid mixture of AB and an IL, bmimCl (1-butyl-3-methylimidazolium chloride, C₈H₁₅ClN₂). This AB solution is a stirrable, viscous liquid at room temperature, with a freezing point below -10°C. However, the solution foams once H₂ is released from the AB in the exothermic process; the foam begins to convert to a white solid after releasing 1 H₂-equiv, with the entire mixture becoming solid after releasing 2 H₂-equiv [4]. Assuming that an alternative IL (or a mixture of ILs) is found such that the solution does not foam or solidify, we developed a conceptual on-board dehydrogenation reactor model using the kinetic data for the AB-bmimCl mixture. The main challenge is to control the peak temperature in this exothermic process, as too high a temperature may lead to undesirable side reactions, as well as issues of solvent stability and AB conversion (complete AB conversion would impede regenerability). The reactor temperatures can be controlled by using a heat transfer coolant, product recycle, or a combination of the two. The reactor model was set up to yield 1.6 g/s of H₂ at 100% conversion (2.35 H₂-equiv) using ethylene glycol as the coolant with a 10°C temperature rise through the reactor. The peak reactor temperature is a function of the solution inlet temperature and the recycle ratio. For a specified conversion, it may not be possible to control the peak temperature adequately by just reducing the inlet temperature.

In our simulations, we varied the coolant flow rate (100°C coolant inlet temperature) to control the reactor outlet temperature. For a fixed reactor outlet temperature (200°C), Figure 3a presents the reactor inlet and peak temperatures as functions of the recycle ratio for 100% conversion, and 100 h⁻¹ (square symbols) and 200 h⁻¹ (triangle symbols) space velocities (liquid hourly space velocity, LHSV). Figure 3a shows that the reactor inlet temperature decreases with decreasing recycle ratio (R), and drops below 130°C at R = 0.62, at which inlet temperature 100% conversion cannot be achieved. The results in Figure 3a also indicate that the reactor temperatures are insensitive to space velocities over the range of LHSV considered. The reactor outlet temperature has only a

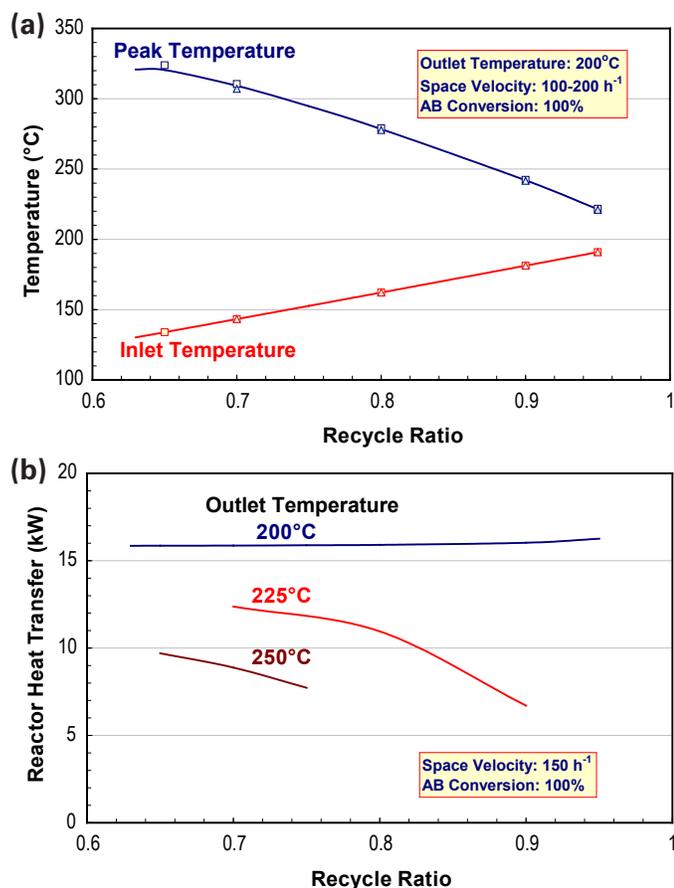

FIGURE 3. Performance of On-Board AB reactor

small effect on the reactor peak and inlet temperatures; the heat transfer, however, is affected by the reactor outlet temperature and the recycle ratio. The reactor heat transfer decreases as the outlet temperature is allowed to rise (see Figure 3b). Finally, we note that whereas high recycle ratios help in limiting the operating temperatures, the inlet flow rate and, therefore, the pumping power increases non-linearly with increasing R.

Our modeling results indicate that the peak rate of H₂ loss from the exothermic decomposition of AB/IL in the storage tank depends on the heat transfer coefficient (assumed 15 W.m⁻².K⁻¹ for natural convection) in addition to the Avrami kinetics and the ambient temperature. Based on the 75-110°C kinetics data, we estimate that H₂ loss rate from a full tank significantly exceeds the DOE target (0.05 g.h⁻¹.kg⁻¹) at >50°C ambient temperature, but is lower than the target at <30°C ambient temperature. The loss rates are proportionally lower with partially full tank. Also, the maximum cumulative loss is limited to 1 H₂-equiv since the kinetics of the second decomposition step that releases H₂ beyond 1 H₂-equiv is slow at low temperatures.

We calculated that the AB/IL system has a gravimetric capacity of 4.9 wt%, which is below the 2015 target, and a volumetric capacity of 49.5 g.L⁻¹, which exceeds the 2015

target. The AB/IL solution accounts for 63% of the system weight and 79% of the system volume.

Off-Board Regeneration of Alane

We updated and analyzed two engineering flowsheets for converting spent Al to alane by a three-step method, using information available in the literature as well as recent unpublished experimental data obtained at Brookhaven National Laboratory [5,6]. Figure 4 shows one of the two flowsheets. In the first step, dimethylethylamine reacts with pressurized hydrogen gas and Ti-catalyzed Al in diethyl ether to form dimethylethylamine alane adduct. The second step involves transamination of the adduct by triethylamine to form triethylamine alane adduct which is less stable and can be thermally decomposed in a final step to yield alane. All reagents, except aluminum and hydrogen, are recovered and recycled. In the second flowsheet, trimethylamine replaces dimethylethylamine in the first step to form trimethylamine alane adduct. Most of the process steps in this flowsheet are similar to those in the first flowsheet, with a few exceptions.

We estimated that the well-to-tank (WTT) efficiency of the first flowsheet is 24%, which increases to 42% if low-temperature waste heat is freely available from an external source. The corresponding efficiencies in the second flowsheet are 23 and 37%, respectively. The estimated greenhouse gas emissions in both flowsheet are ~32 kg CO₂-equiv/kg-H₂, which reduce to ~22 kg CO₂-equiv/kg-H₂ if free waste heat is available.

Off-Board Regeneration of AB using Hydrazine

We analyzed the off-board regeneration process for ammonia borane in a single-pot scheme, in which the spent AB is reacted with hydrazine (N₂H₄, limiting reagent) in liquid ammonia [7].

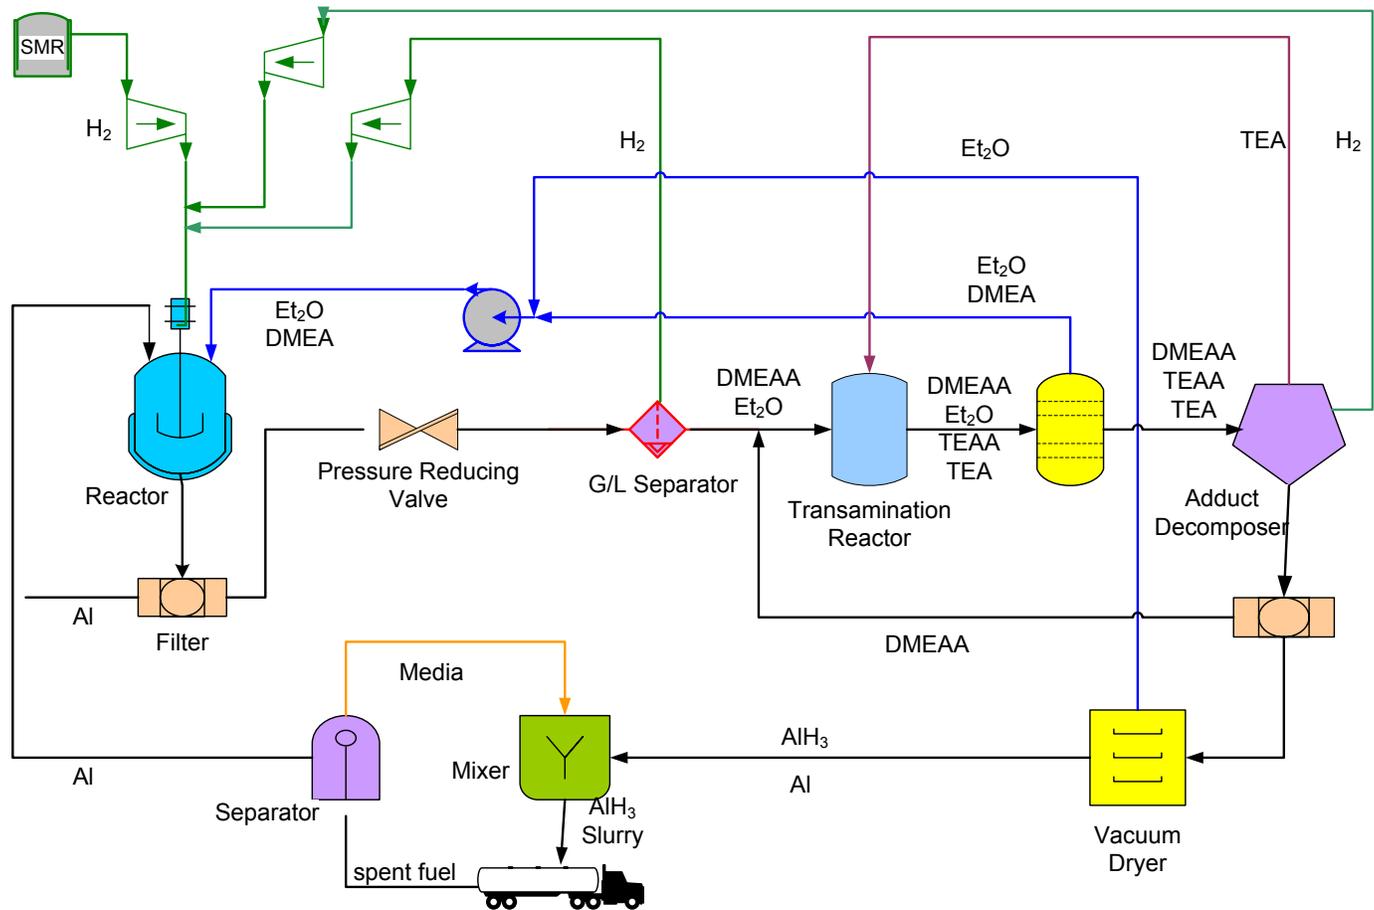

Two flow sheets were constructed to close the cycles by considering the commercial processes (Bayer Ketazine and PCUK) for producing hydrazine. The Bayer Ketazine process requires large amounts of electricity to produce NaOH and Cl₂, which are the feed materials for hydrazine production.

The PCUK process consumes a large amount of steam in making hydrogen peroxide.

We estimated that the WTT efficiency for AB regeneration is 12% via the PCUK pathway and 8% via the Bayer Ketazine pathway. We also estimated that the total greenhouse gas emissions are 63 and 101 kg CO₂-equiv/kg-H₂ for the PCUK and Bayer Ketazine pathways, respectively.

DMEAA - dimethylethylamine alane; DMEA - dimethylethylamine; TEAA - triethylethylamine alane adduct; TEA - triethylamine; SMR - steam methane reformer

FIGURE 4. Process Flowsheet for Regeneration of Alane using Dimethylethylamine

Conclusions and Future Directions

- We project that an on-board MOF-5 system with adiabatic LH₂ refueling and 5.6 kg recoverable H₂ can achieve 6.5 wt% gravimetric capacity and 34.9 g.L⁻¹ volumetric capacity at 150 atm. The loss-free time and hydrogen loss rate are functions of the amount of hydrogen stored and the pressure and temperature at the start of the dormancy event.
- Assuming that an alternative IL (or a mixture of ionic liquids) is found such that the AB/IL solution does not foam or solidify upon releasing hydrogen, we calculate that the AB/IL system has a gravimetric capacity of 4.9 wt% and a volumetric capacity of 49.5 g.L⁻¹. We estimate that the H₂ loss rate from a full tank significantly exceeds the DOE target (0.05 g.h⁻¹.kg⁻¹) at >50°C ambient temperature, but it would meet the target at <30°C ambient temperature.
- We estimate WTT efficiencies of 8-12% for regenerating AB using hydrazine in liquid ammonia in the single pot scheme developed at Los Alamos National Laboratory. We estimate WTT efficiencies of 24-42% for regenerating alane by a three-step organometallic

approach using dimethylethylamine or trimethylamine as the primary amine to form an amine alane adduct.

- In FY 2012, we will update our analysis of alane slurry storage with new kinetics data from Brookhaven National Laboratory for micrometer-sized alane.
- In FY 2012, we will analyze hydrogen storage in a generic sorbent system with an arbitrary heat of adsorption, and for the LiNH₂:MgH₂ on-board reversible metal hydride system.
- Also in FY 2012, we will further extend our systems analysis work on physical, sorbent, and metal-hydride storage methods.

Contract Number: DE-FC36-04GO14283

Start Date: June 2004

Projected End Date: March 2012

Technical Targets

This project evaluates the various on-board hydrogen storage technologies being developed by the DOE Hydrogen Storage Centers of Excellence and independent projects. Insights gained from these evaluations will help guide DOE and developers toward promising hydrogen storage materials and system-level designs and approaches that could meet the DOE targets for storage system cost, specific energy, energy density, fuel cost, and efficiency.

FY 2011 Accomplishments

We have performed preliminary and/or updated assessments for several hydrogen storage systems. For each system assessment, we projected on-board system performance and high-volume (~500,000 units/year) manufactured cost, as well as determined the critical cost drivers and conducted single- and multi-variable sensitivity analyses to bound cost results. We have also completed a preliminary analysis of low-volume compressed single-tank systems. We also reviewed key assumptions and results with developers, DOE, and stakeholders (e.g., material suppliers, national labs, FreedomCAR and Fuel Partnership Tech Teams) and incorporated their feedback into the final results. Finally we compared performance and cost results to other baseline technologies and DOE targets for the on-board storage system. Specific accomplishments include:

- Completed preliminary low-volume (10,000, 30,000, 80,000, 130,000, and 500,000 units/year) on-board system factory cost assessments for 350 and 700 bar compressed single-tank systems. The projected costs for the 350 bar system are \$29, \$26, \$20, \$18, and \$15/kWh for 10,000, 30,000, 80,000, 130,000, and 500,000 units per year, respectively. The projected costs for the 700 bar system are \$36, \$33, \$25, \$22, and \$19/kWh for 10,000, 30,000, 80,000, 130,000, and 500,000 units per year, respectively.
- Completed a review of Dow Chemical's ammonia borane (AB) off-board first fill and fuel regeneration cost projections and submitted a final memo to DOE summarizing these results.
- Finalized the liquid carrier hydrogen (LCH₂) storage system cost analysis, submitted a final report to DOE for review, and submitted an executive summary to Argonne National Laboratory (ANL) for inclusion in the combined ANL/TIAX final report. Compared to TIAX's prior analysis, the updated LCH₂ storage system uses an updated catalyst replacement rate, adjusted material and balance-of-plant (BOP) costs, and several additional minor changes. These changes reduced the cost of hydrogen fuel by over 30% from \$4.75 to \$3.27 and increased the cost of onboard storage by less than 5%, from \$15.4 to \$15.7/kWh.

Fiscal Year (FY) 2011 Objectives

The overall objective for this project is provide independent analysis to help guide the DOE and developers toward promising research and development (R&D) and commercialization pathways by evaluating the various on-board hydrogen storage technologies on a consistent basis. Specific objectives include:

- Compare different on-board hydrogen storage approaches in terms of lifecycle costs, energy efficiency and environmental impact;
- Identify and compare other performance aspects that could result in barriers to successful commercialization (e.g., on-board system weight and volume);
- Examine the effects of system-level cost and performance trade-offs for different storage approaches; and
- Project performance and cost relative to DOE targets.

Technical Barriers

This project addresses the following technical barriers from the Hydrogen Storage section of the Hydrogen, Fuel Cells and Infrastructure Technologies Program Multi-Year Research, Development, and Demonstration Plan:

- (A) System Weight and Volume
- (B) System Cost
- (K) System Life-Cycle Assessments

- Reviewed and completed analysis for metal organic framework (MOF)-177 and AX-21. We developed a bottom-up cost estimate for MOF-177 and continued to use an older estimate for AX-21. Reviewers felt the approach used for MOF was generally sound, though characterized by high uncertainty. The AX-21 cost estimate is based on information from the literature, and may be high. Rather than revisit the AX-21 cost, we expanded our sensitivity analysis to capture this uncertainty.
- Revised and completed high-volume on-board system factory cost assessments of cryo-compressed and 350 bar and 700 bar compressed tank systems. For the compressed systems, the analysis was extended to include Type 3 and Type 4 tanks and single and dual tank systems. We submitted a revised final report to DOE for review and submitted a revised executive summary to ANL for inclusion in the combined ANL/TIAX final report.
- Supported the Storage Systems Analysis Working Group (SSAWG) evaluation of the well-to-tank (WTT) energy use and greenhouse gas emissions for MOF-177 tanks, cryo-compressed tanks, 350 and 700 bar tanks, and cold gas tanks.

Introduction

DOE is funding the development of a number of hydrogen storage technologies as part of its “Grand Challenge” applied R&D program. This independent analysis project helps guide the DOE and Grand Challenge participants toward promising R&D and commercialization pathways by evaluating the various hydrogen storage technologies on a consistent basis. Using this consistent and complete comparison of various technology options, R&D can be focused and accelerated. Without such an approach, erroneous investment and commercialization decisions could be made, resulting in wasted effort and risk to the development of hydrogen vehicles and a hydrogen infrastructure.

TIAX is conducting system-level evaluations of the on-board storage systems cost and performance for four broad categories of on-board hydrogen storage. The four categories are: reversible on-board (e.g., metal hydrides and alanates), regenerable off-board (e.g., chemical hydrides); and high surface area sorbents (e.g., carbon-based materials), and advanced physical storage (e.g., cryo-compressed hydrogen, liquid hydrogen). Evaluations are based on developers’ on-going research, input from DOE and key stakeholders, and in-house expertise.

Approach

This project utilizes an approach that is designed to minimize the risks associated with achieving the project

objectives. In coordination with ANL, system-level conceptual designs are developed for each on-board storage system and required fueling infrastructure. We work closely with ANL to develop a bill of materials consistent with their performance assessment. Next, system models and cost models are used to develop preliminary performance and cost results. We utilize in-house activities and product-based cost models to determine high-volume manufactured cost projections for the on-board storage system, and H₂A-based discounted cash flow models to estimate hydrogen selling prices based on the required off-board hydrogen infrastructure. Subsequently, these results are vetted with developers and key stakeholders and refined based on their feedback. Coordination with DOE’s Hydrogen SSAWG avoids duplication and ensures consistency. This is an on-going and iterative process so that DOE and its contractors can increasingly focus their efforts on the most promising storage technology options.

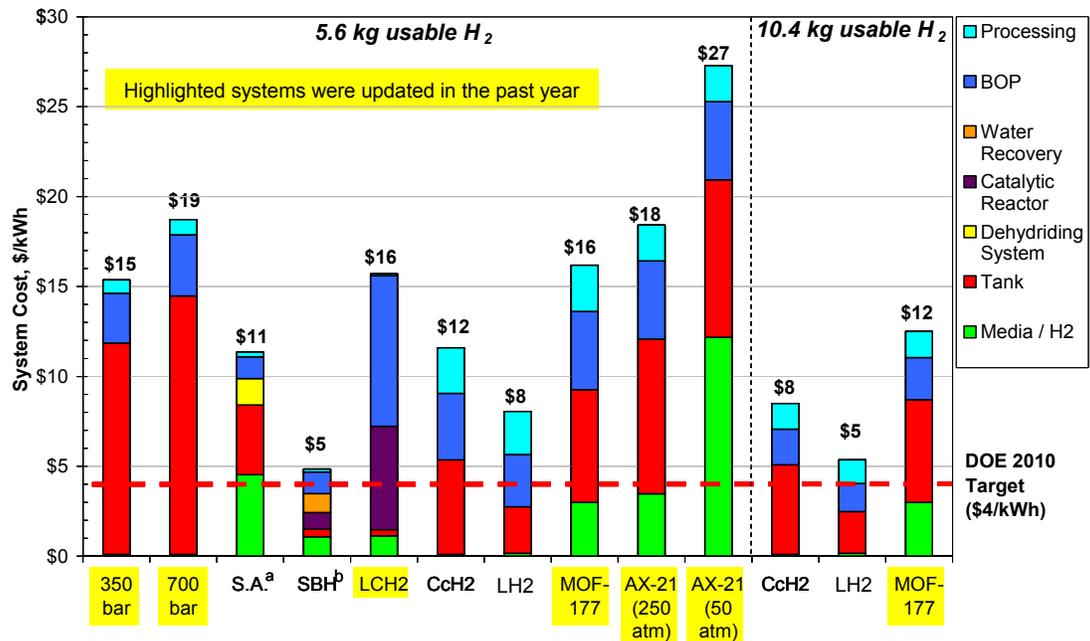

Results

TIAX developed preliminary cost estimates for low-volume manufacturing of 350 and 700 bar compressed storage systems, and updated and completed previous cost estimates for compressed (high-volume one and two tank), cryo-compressed, MOF-177, AX-21, ammonium borane, and LCH₂ storage systems. Each of the storage system cost projections are estimated based on on-board system designs developed by ANL [1]. Figure 1 shows the updated costs for the systems completed in FY 2011. The remaining portion this section discusses the preliminary low-volume manufacturing cost analysis for compressed systems.

Low-volume manufacturing costs were estimated for 10,000, 30,000, 80,000, 130,000, and 500,000 units per year for both 350 and 700 bar systems. The preliminary cost estimate focused mainly on the cost of carbon fiber, differences in manufacturing costs, and BOP costs. The systems modeled are identical to those used for the cost estimate for the 500,000 units per year shown in Figure 1. Figure 2 shows the preliminary costing results for low-volume manufacturing of compressed systems.

The carbon fiber cost for low- and high-volume manufacturing, based on conversations with carbon fiber manufacturers, will stay relatively the same with potentially a small price decrease of \$1.5/lb around 80,000 units per year. The projections of carbon fiber cost may go up, independent of volume, due to increases in the costs of carbon fiber precursors. Figure 2 shows that tank material costs, which do not include manufacturing and are primarily carbon fiber costs, remain relatively constant, due to carbon fiber costs remaining relatively constant.

Manufacturing costs were projected assuming a high level of automation, similar to that of high-volume manufacturing. This assumption was made based on the significant amount of manufacturing still required for 10,000 units per year. After recent discussions with tank manufacturers, this assumption will be the main revision for

^a The sodium alanate system requires high temp. waste heat for hydrogen desorption, otherwise the usable hydrogen capacity would be reduced.
^b SBH = Sodium borohydride, "A NO-GO decision was made on the hydrolysis of SBH for on-board application"

FIGURE 1. Updated Hydrogen Storage System Costs

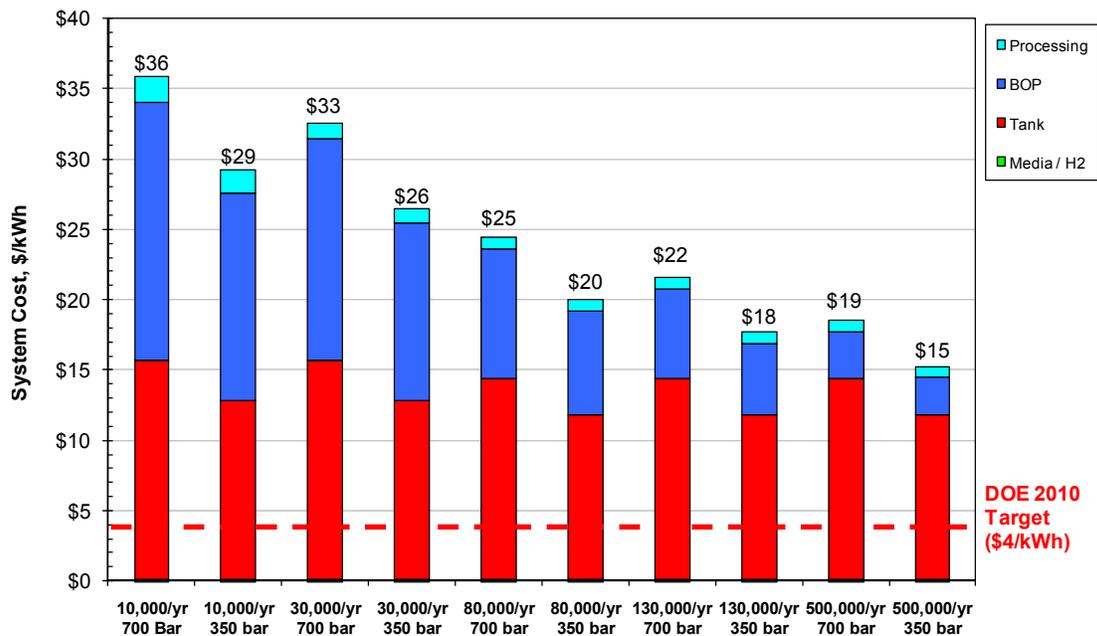

FIGURE 2. Preliminary Low-Volume Manufacturing Results for One-Tank 350 and 700 Bar Compressed Systems

the finalized of cost estimates for low-volume manufacturing. Figure 2 shows that with the assumption of a high level of automation, processing costs are very small compared to tank and BOP costs.

The cost that is most affected by manufacturing volume is the BOP cost. This is a result of components, especially

valves, regulators, and sensors, being made at low volumes at the specifications required for high pressure hydrogen. Many of these components need to be individually machined, which is more costly than being forged. The basis of the cost curve for the BOP components is data supplied by a sensor manufacturer and their projected costs for 10,000, 100,000, and 500,000 units per year.

The projected costs for the 350 bar system are \$29, \$26, \$20, \$18, and \$15/kWh for 10,000, 30,000, 80,000, 130,000, and 500,000 units per year, respectively. The projected costs for the 700 bar system are \$36, \$33, \$25, \$22, and \$19/kWh for 10,000, 30,000, 80,000, 130,000, and 500,000 units per year, respectively. The BOP components decreased from 50% of the total cost at 10,000 units per year to 17% at 500,000 units per year. The tank increased from 44% of the total cost at 10,000 units per year to 78% at 500,000 units per year.

Conclusions and Future Directions

The cost assessments conducted this year allow direct comparison with prior cost assessments and DOE targets. Our models allow us to identify critical cost components, which enables focused discussion with tank developers and manufacturers.

- None of the systems assessed meet DOE's 2010 cost target of \$4/Wh. The cost of the 5.6 kg 350 bar, 700 bar, cryo-compressed, liquid, and MOF-177 storage systems range from 2 to 5 times the cost of the DOE target. Key factors influencing system costs are the carbon fiber material cost, the cost of aluminum, and in the case of the MOF system, the storage media.
- The low-volume compressed systems are 7 and 9 times the 2010 DOE target of \$4/kWh, with the cost of BOP components showing the greatest potential for cost reduction.
- The MOF-177 system cost is 3 and 4 times the 2010 DOE target of \$4/kWh for the 10.4 and 5.6 kg systems, respectively. Achieving the DOE cost targets will require large reductions in the cost of the storage media and the tank materials (aluminum and carbon fiber).
- The onboard liquid hydrogen system cost is 1.3 and 2 times the 2010 DOE target for the 10.4 and 5.6 kg systems, respectively. While the liquid system has amongst the lowest onboard storage system cost, it has low volumetric efficiency, WTT efficiency, and high fuel costs. These shortcomings are a function of fuel boil off and the high energy requirement associated with liquefaction.
- The cryo-compressed system is 2 and 3 times the 2010 DOE target for the 10.4 and 5.6 kg systems, but meets the 2010 volumetric and gravimetric targets. The base case 350 bar and 700 bar systems are 4 and 5 times higher than the 2010 DOE targets for the 350 bar Type 4 and 700 bar Type 4 systems, respectively, and both systems fall short of the 2010 volumetric capacity targets. Additional analysis of 350 and 700 bar dual tank systems showed minor cost increases of less than 5%; 350 and 700 bar Type 3 systems showed moderate cost increases on the order of 10%. The major cost driver for the compressed system is carbon fiber, while the cryo-compressed system cost is driven by carbon fiber, aluminum liner, and BOP component costs.

The rest of this fiscal year, we plan to continue to work with developers and stakeholders to improve the accuracy of the analyzed on-board and off-board system models and finalize our analysis of storage technology options. Specifically, we plan to:

- Refine the modeling and analysis and complete the report for the low-volume manufacturing of 350 and 700 compressed systems.
- Perform the preliminary and final costing analysis of the MOF-5 system.
- Continue to work with DOE, SSAWG, Centers of Excellence, other analysis projects, developers, Tech Teams and other stakeholders (as necessary) to revise and improve system models.

E-mail: Ned.Stetson@ee.doe.gov

Project Start Date: September 30, 2010
Project End Date: September 30, 2011

FY 2011 Accomplishments

- Identified highest priority pieces of non-motive equipment in portable power, aviation GSE, construction equipment, cell phone backup power and portable electronics industries.
- Identified how that high priority equipment uses energy, the associated energy densities (gravimetric, volumetric), and what the environmental requirements are (temperature, etc.) for their use.
- Conducted extensive questionnaire surveys of end users and new technology experts about the use of current equipment and therefore the requirements for a new clean technology replacement.
- Held workshop at Sandia-CA, attended by end users of non-motive equipment in the construction industry, telecommunications, entertainment, portable power and aviation industries, as well as the Air Force.

Fiscal Year (FY) 2011 Objectives

- Engage end users in the airport ground support equipment (GSE), portable power, construction equipment, telecom power, and “man-portable” electronics industries to understand what pieces of their non-motive equipment would be good early market introduction points for fuel cells.
- From the engagements above, and with the highest priority equipment identified, determine how the equipment is used and their current requirements for power, duration, gravimetric and volumetric energy densities, as well as the required operating conditions (temperature, etc.).

Technical Barriers

This project addresses the following technical barriers assigned to this project:

- (A) System Weight and Volume
- (B) Cost
- (C) Efficiency

Technical Targets

Data from early markets will allow DOE to determine the technical targets and research and development (R&D) needs for hydrogen storage that would enable the use of fuel cells for early market non-motive applications.

Introduction

Historically the DOE has funded a great deal of work on hydrogen storage. Most of this hydrogen storage R&D has focused on hydrogen storage for light-duty vehicle applications. However, recently DOE has expanded the scope of its fuel cell technology interests to include non-motive early market applications of fuel cells. By non-motive equipment, we mean equipment that is not driven directly by a human being (i.e. does not possess a steering wheel). The equipment is either stationary, or, if portable, it is carried or towed by a person or vehicle. Examples of non-motive equipment included portable power generators, air compressors, airport luggage belt loaders (an example of aviation GSE) and backup power systems for cell phone towers. Additionally, the DOE is interested in how fuel cells might be used as power sources in “man portable” electronic systems, and what the implications are for the hydrogen storage required for using fuel cells for man-portable electronics.

It is highly likely that the hydrogen storage needs for non-motive uses of fuel cells are different than the well-known hydrogen storage needs for light-duty vehicle applications. In order for the DOE to understand the eventual hydrogen storage needs for non-motive fuel cell use, it's important to understand what the highest priority pieces of equipment are in the non-motive equipment realm that would best be suited for conversion to fuel cell power. Additionally, it is vital to fully understand how this non-motive equipment is actually used and what the demands

are on the energy system. Toward that end, the goals of this project are to engage end-users, technical experts and manufacturing experts in various non-motive equipment realms, identify the highest priority pieces of equipment in each one of those realms, and understand in detail how that equipment is used. By understanding how that equipment is used currently, the DOE can better understand where the hydrogen storage performance gaps truly are if hydrogen-fueled fuel cell-based non-motive equipment were to meet or exceed the capabilities of the current equipment.

Approach

To gather this information, we approached end-users, technical experts and mass manufacturers in the following areas: construction equipment, portable power, telecommunications, aviation, and portable electronics. A database of representatives in these markets was generated. Our initial step was to host a workshop at Sandia National Laboratories, Livermore, California on February 8, 2011. The workshop was attended by representatives from the construction equipment, portable power, telecommunications and aviation markets. In aviation, Department of Defense representatives from Travis Air Force Base were also present. During this workshop, the attendees were surveyed with multiple questionnaires to help identify how equipment is used in their respective realms. Also at this workshop, break-out sessions were held to extract the highest priority pieces of equipment in each one of these non-motive early markets, so that specific non-motive pieces of equipment were identified. After the workshop, the results of the surveys were quantified using a Kano-type analysis. In addition, selected representatives of the four areas were contacted again to gain a quantitative understanding, for the highest priority equipment items, of how this non-motive equipment is actually used and what the demands are on the energy system. Furthermore, a quantitative understanding of the operational requirements was gathered.

The portable electronics realm was not covered at the workshop. However this market was engaged after the

workshop, using existing contacts in this market provided by the DOE, and also our own research in this area. Similarly, the highest priority portable electronic uses were identified by engaging the man-portable power industry (both end users and manufacturers), and gaining a quantitative understanding of what the needs are for power, duration, frequency of use, and environmental durability if fuel cells were to meet or exceed the capabilities of the current (typically battery-based) portable electronics power systems.

Results

A picture of the attendees for the Sandia-CA workshop held on 2/8/2011 is shown in Figure 1. In all, 22 “end-users” and nine “technology experts” attended the workshop. There were a total of 40 attendees. In the morning the attendees heard fuel cell technology presentations from DOE (Scott McWhorter) and Sandia (Lennie Klebanoff). For the remainder of the morning, the group heard presentations on uses of equipment in construction (Torsten Erbel, Multiquip), entertainment (Russ Saunders, Saunders Electric), telecommunications (Kevin Kenny, Sprint) and in aviation ground support (Roger Hooson, San Francisco International Airport). In the afternoon, break-out sessions were held in the areas of construction equipment, portable power, aviation GSE, and telecom backup power. For each breakout session, we sought to identify the top three highest-priority pieces of equipment to target in each category, and for each one solicit information on the following questions: Who is using it?, How is it being used?, What are the environmental and worksite conditions?, What are the performance requirements?, What is the cost sensitivity?, What works well now, what doesn’t, what could be improved?

From the breakout sessions, the highest priority pieces of equipment were found to be:

Aviation GSE

1. 5–10 kW power generators, the power basis for light towers, light crosses, light ropes, and hand tools. These

FIGURE 1. Workshop Attendees Visiting Sandia-CA on February 8, 2011

were identified as high priority because there are so many of them. These are typically Honda gasoline generators.

2. 90–120 kW portable power based on diesel generators and turbine systems for aircraft electrical support and engine start.
3. Heater carts, run on diesel, 400,000 Btu, 160 hp, used to heat the interiors of aircraft during maintenance. It is important to heat the aircraft during maintenance periods because one cannot allow condensation on the avionics during maintenance.

Some key pieces of learning from the Aviation GSE breakout session were that such equipment is very cost sensitive, the end-users have little desire to pay extra for fuel cell versions. This group also stated that although the fuel cell life cycle savings over diesel equipment carries weight, that argument has a time horizon of only five years or less.

Portable Power

This breakout session identified the following high-priority pieces of equipment:

1. 2–6.5 kW: gasoline generator replacement
2. 60–100 kW: diesel generator replacement
3. 3–5 kW: office trailer generator

Some key learning from this group are that only 2,500 hours of operational life are expected for current small units (~5 kW). In addition, while the capital expense for small generator sets is currently \$400-\$600/kW, the yearly operating expense can be \$700/kW. So the current diesel equipment is very expensive to maintain and operate.

Telecom Backup Power

In this realm, the highest priority item is a 5–30 kW backup power system. Some key learning from this area are that cell phone towers are often placed in very high density areas, making the footprint of a fuel cell-based backup power system very critical.

Construction Equipment

This breakout session identified the following high-priority pieces of equipment:

1. Lighting: Light towers, portable message boards, remote message boards, arrow signs. These are ubiquitous items, currently diesel-powered.
2. Air Compressors: Noisy, much room for improvement of this technology.
3. Scissor Lifts: Want quiet, non-polluting equipment, and more reliable than battery-based.

Some key learning from this breakout session are that construction equipment is very cost sensitive. Lifecycle costs, even project-cycle costs are considered. Furthermore, construction equipment must be very durable. The attendees indicated that because fuel cells “load follow”, and only generate power to meet the load demanded, this “smart technology” aspect may be a way for a fuel cell system to gain acceptance faster.

The questionnaires were analyzed using the Kano methodology. An example of how the Kano methodology was used is shown in Figure 2. The question being asked is: “How would you feel if this equipment could be refueled quickly?” In this example, the collection of data points in

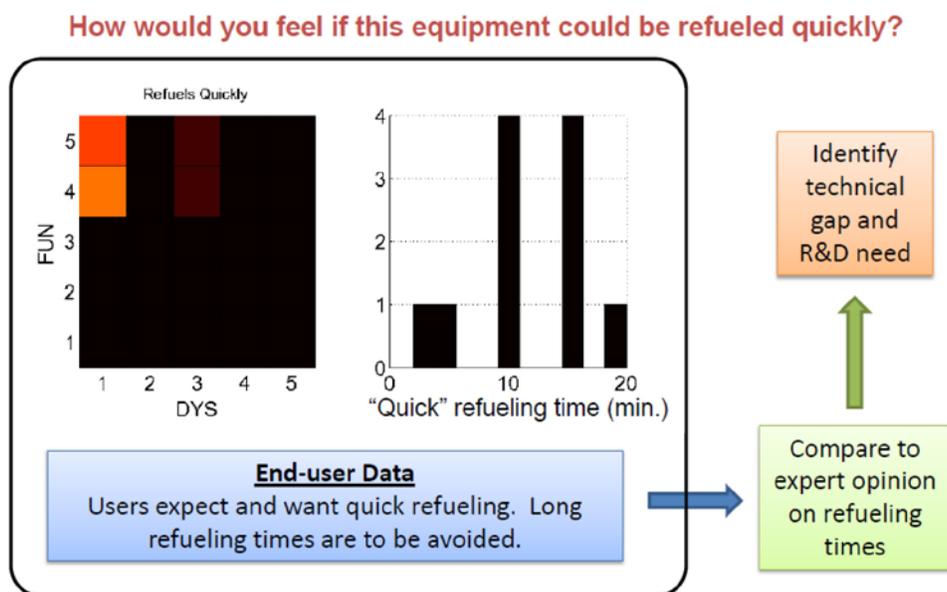

FIGURE 2. Figure Describing an Example Use of Kano Methodology in Extracting Information from Surveys

the upper-left corner of the left-hand figure reveals that end-users not only want quick refueling times, but expect it. That means if refueling times are long, they will be dissatisfied with the equipment. The right-hand figure shows how the end-users define “quick” in terms of number of minutes needed to refuel a tank. Overall, the conclusion is that a hydrogen fuel tank needs to be able to be refueled in about 10–15 minutes or less to gain user acceptance. This data can then be compared to the capability of current hydrogen storage technology to see if improvements in actual refueling times are needed.

Work is ongoing collecting similar market feedback from the portable electronics community.

Conclusions and Future Directions

We have engaged end-users, manufacturers and technology experts in the non-motive equipment realms of construction equipment, portable power, aviation GSE and portable electronics. We have identified high-priority early market non-motive pieces of equipment that would benefit by conversion to fuel cell operation. We have gained a quantitative understanding of the energy requirements for these items, how they are used, and what the environmental requirements are. With this information, the DOE will be able to identify the performance gaps in current hydrogen storage technology that would allow fuel cells to be used in these early market non-motive applications.

Sandia National Laboratories is a multi-program laboratory managed and operated by Sandia Corporation, a wholly owned subsidiary of Lockheed Martin Corporation, for the U.S. Department of Energy’s National Nuclear Security Administration under contract DE-AC04-94AL85000.

Subcontractor:

Energetics Inc., Columbia, MD

Project Start Date: October, 2010

Project End Date: September, 2011

- Participated in “Utilizing Hydrogen Power as an Alternative Energy Source” and non-motive stakeholder workshop.
- Implemented Kano Method into questionnaire development and analysis to classify solution-independent customer needs.
- Completed and transmitted electronic questionnaire to key stakeholders and end-users in key early motive markets.
- Collaborated with Sandia National Laboratories (lead for similar activity with non-motive applications) and Pacific Northwest National Laboratory (lead for technology readiness assessment of hydrogen storage technologies).

Introduction

The market adoption of non-motive fuel cell systems can be accelerated by improving storage system technologies. Effective improvements in hydrogen storage systems will result in extended product run times, increased productivity, decreased installation and operating costs, improved delivery methods, improved volumetric capacity, and facilitation of siting and permitting processes. These improvements can be achieved through focused R&D efforts based upon an in-depth understanding of storage requirements in key early markets. As fuel cell systems penetrate these early markets, increased manufacturing volumes, learning-by-doing, and technology advancements will result in cost reductions and performance improvements. Additional market opportunities will open up for fuel cell systems as they become established in key early markets. Early motive fuel cell markets with hydrogen storage can be categorized in three segments:

- **Material Handling and Ground Equipment.** This market includes traditional forklifts and pallet jacks for material handling in warehouses and manufacturing facilities, as well as other ground equipment used in airports, mining operations, and grounds keeping/maintenance operations.
- **Public Transit.** This market includes transit services (urban routes, commuter and para-transit) and shuttle services (airport, campus and large events).
- **Niche Motive Markets.** These markets include applications for unmanned air vehicles, heavy-duty trucks, and other military motive applications.

Approach

NREL is identifying storage R&D needs for fuel cell systems for these early markets by obtaining information

Fiscal Year (FY) 2011 Objectives

- Identify needs for onboard energy storage in key early motive markets.
- Target early motive markets such as material handling equipment (MHE), ground support equipment (GSE), public transit, and unmanned vehicles.
- Identify gaps of current hydrogen storage technologies to the onboard energy storage needs.

Technical Barriers

This project addresses the technical barrier of a lack of knowledge of energy storage performance needs for early fuel cell motive markets.

Technical Targets

This project is investigating gaps of current hydrogen storage technologies against the needs of onboard energy storage in early motive markets. Insights gained from this investigation will be used to focus research and development (R&D) efforts in hydrogen storage technologies that can accelerate market adoption.

FY 2011 Accomplishments

- Organized and completed two workshops held in conjunction with the Fuel Cells and Hydrogen Energy Association conference and ProMat2011 expo.
- Summarized top needs for MHE and public transit onboard energy storage based on workshop breakout groups.

from the broad set of contacts. NREL is leveraging: 1) understanding of early motive market applications through data analysis in NREL's Hydrogen Secure Data Center, 2) expertise in hydrogen storage, and 3) existing industry contacts.

NREL used workshops for gathering and prioritizing hydrogen storage needs, dialog within and across applications, along with conducting interviews with individual companies. NREL is also using an electronic questionnaire designed to categorize the user's needs for onboard energy storage. The questionnaire is based on the Kano Method and identifies important performance metrics and the corresponding quantitative performance levels without specifying a storage technology. Response from the workshops and questionnaires are the basis for the analysis to detail performance gaps of existing hydrogen storage technologies.

Results

The majority of work completed to date has been focused on the information gathering and analysis

preparation. Figure 1 is a snap shot of the first two pages of the electronic questionnaire. The questions are asked in positive and negative pairs along with a third question to gather the quantitative data. Topics covered in the questionnaire include run time, refueling, weight, volume, operation lifetime, operation conditions (e.g. temperature, shock and vibration, and environment), safety (procedural controls), cost (e.g. operation, fuel, maintenance, and end of life), preventative maintenance, availability, emissions, reliability, time for maintenance, operator training and expertise, and warranty. To date, 34 people have submitted their responses.

NREL also used workshops held in conjunction with market relevant conference(s) and expo(s) to capitalize on end user attendance. The workshops focused on breakout sessions with two questions:

1. What are the key performance needs for your application?
2. How could advanced onboard energy storage technology improve the performance of your vehicles or operation?

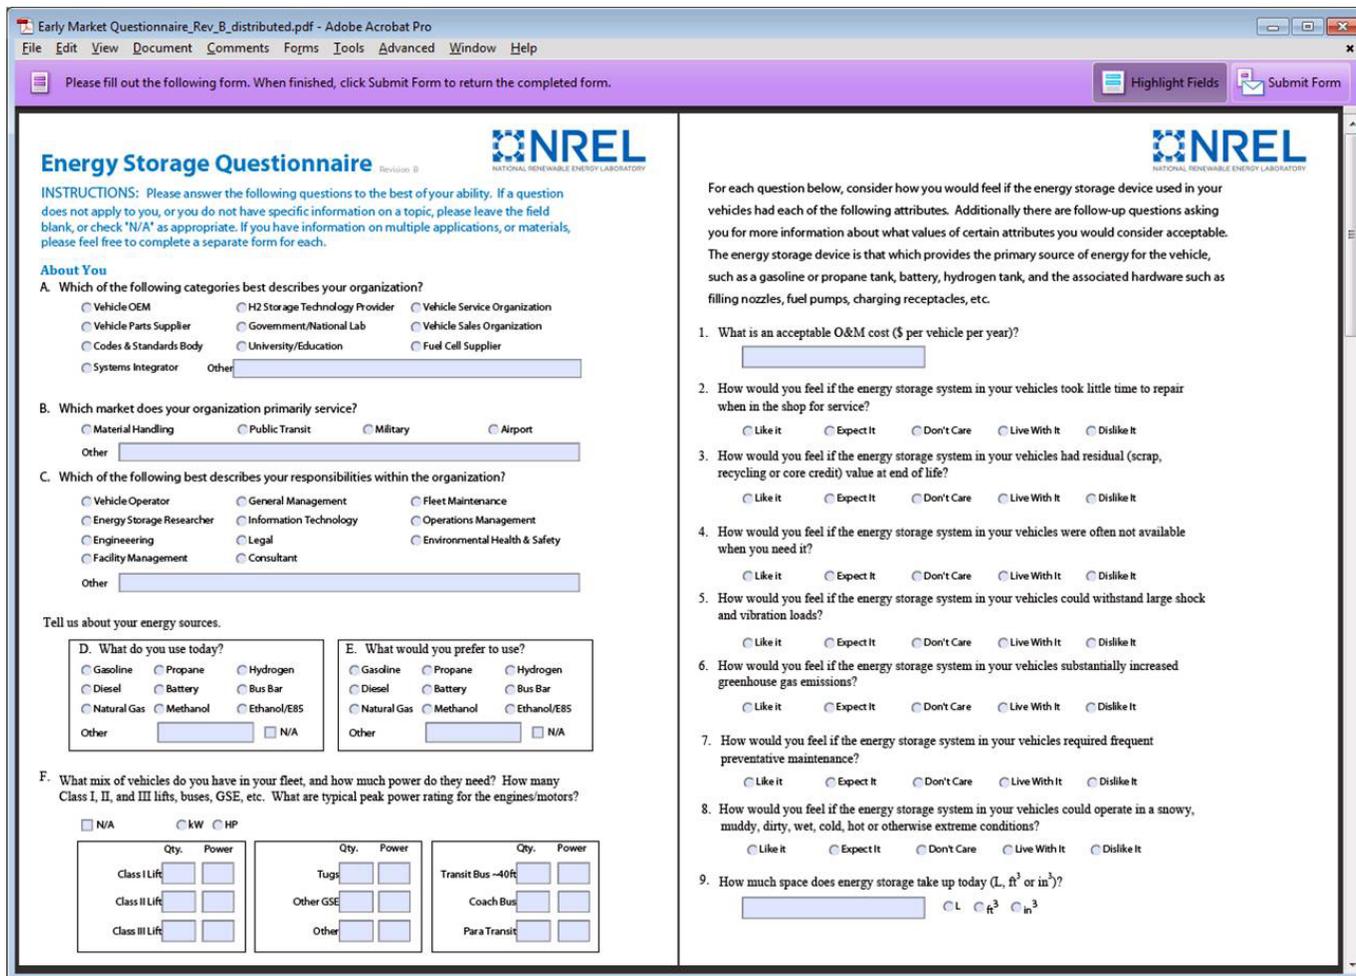

FIGURE 1. Pages 1 and 2 of Electronic Questionnaire

A summary of the top performance needs in MHE as discussed in the workshops are:

- Robust tanks capable of high cycling (fill frequency) over 10 years.
- Certified field support with low maintenance requirements (e.g. 2-3 maintenance hours per 500 operation hours) and cost.
- Onboard storage capacity limits should be about one shift (5 to 8 hours).
- Onboard energy storage should be easy to use with fast and convenient filling.
- Flexible storage designs to fit within existing or custom products.
- Simple, low-cost options to compete with incumbent technologies.

A summary of the top performance needs in public transit as discussed in the workshop are:

- Low cost of storage through consistent tank system designed for low weight.
- Low storage system weight.
- Operation period should match that of the bus (e.g., 12 years/500,000 miles or ~5,000 tank cycles) with a daily operation range of between 200 and 250 miles.

We completed an early set of draft results. Figure 2 includes results for storage capacity, fill rate, operation lifetime, and preventative maintenance. At the time of this figure creation, most of the responses were from the MHE application. (The response analysis in the final report will be broken down by application and the other performance categories.) The four metrics in Figure 2 are all important to the responders and the corresponding bar charts breakdown the expected performance level. For instance, storage capacity is an important metric and most of the responders say that 8-10 hours is the necessary capacity level.

Conclusions and Future Direction

The analysis preparation and workshops have created a foundation for identifying the onboard energy storage needs and the following gap analysis task. So far, the performance needs are application specific and focus around robustness, simplicity, runtime, weight, and cost.

Planned future work includes:

- Continue questionnaire response and information gathering.
- Continue analyzing response and workshop data and summarizing important performance metrics and the corresponding performance levels.

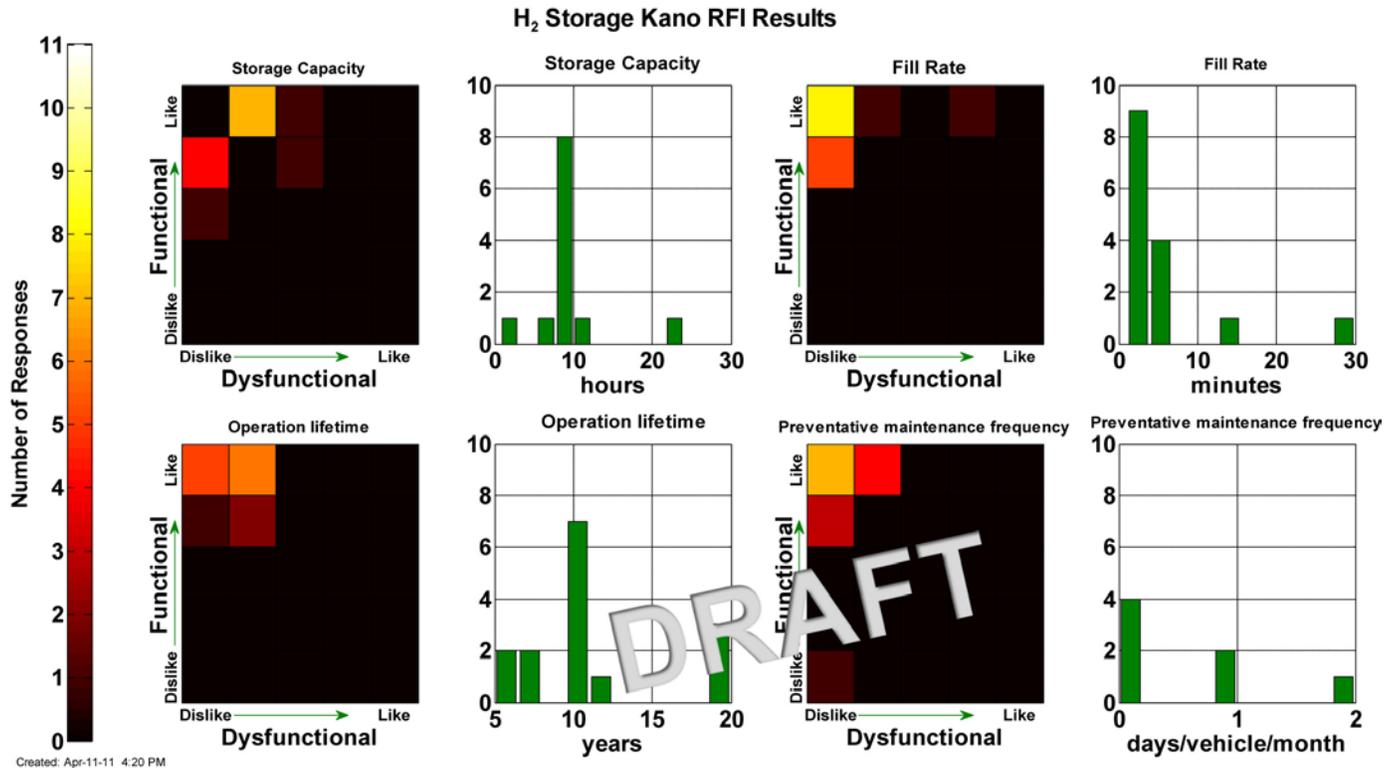

FIGURE 2. Draft Results of Important Performance Metrics using Kano Method

- Summarize capabilities of current hydrogen storage technologies.
- Gap analysis of current hydrogen storage technologies to the early motive fuel cell markets' onboard energy storage needs.
- Complete final report.

Contract Number: DEFC3602AL67619

Subcontractor:
Ovonic Hydrogen Systems LLC, Rochester Hills, MI

Start Date: October 1, 2006
Projected End Date: March 30, 2012

Fiscal Year (FY) 2011 Objectives

Overall

- Support DOE's Hydrogen Storage sub-program by operating an independent, national-level reference laboratory aimed at assessing and validating the performance of novel and emerging solid-state hydrogen storage materials and full-scale systems.
- Conduct measurements using established protocols to derive performance metrics: capacity, kinetics, thermodynamics, and cycle life.
- Support parallel efforts underway within the international community, in Europe and Japan, to assess and validate the performance of related solid-state materials for hydrogen storage.
- Validate the technologies required to achieve the 2015 DOE on-board vehicle hydrogen storage goals.
- Continue new hydrogen storage materials discovery research and development for advanced storage systems.

Current

Analyze hydrogen sorption properties at 77 and 298 K of:

- Polyether ether ether ketone (PEEK)-derived carbon (material provided by the State University of New York, SUNY).
- Microporous carbon (material provided by the National Renewable Energy Laboratory, NREL).
- Porous polymer network (PPN) (material provided by Texas A&M University, TAMU).

Technical Barriers

The technical barriers associated with the operational objectives of the laboratory are:

- Standardization of methods suitable to a wide variety of compositions of matter.
- Development and implementation of "Gold Standard" measurement techniques.

Moreover, this project addresses the following technical barriers from section 3.3.4.2 of the Fuel Cell Technologies Program Multi-Year Research, Development and Demonstration Plan:

- Verification of Material Performance
 - (P) Lack of Understanding of Hydrogen Physisorption and Chemisorption
 - (A) Reproducibility of Performance
- Verification of System Performance
 - (K) System Life-Cycle Assessment
 - (Q) Reproducibility of Performance
- (F) Codes and Standards

Technical Targets

This project addresses the fundamental need for establishing a national-level laboratory whose core mission is to study and independently verify the intrinsic sorption characteristics of novel and emerging materials for hydrogen storage, including such activities as they pertain to their use in full-scale storage systems. As a fully qualified laboratory under the purview of the DOE, the laboratory plays a central role in down-selecting materials and systems that emerge from the centers of excellence and outside entities by:

- Providing in-depth analysis and understanding of hydrogen physisorption and chemisorption mechanistic behavior.

- Determining and validating material and system storage capacities.
- Determining material and system kinetics (charging/discharging rates), thermodynamics, and cycle-life durability.
- Contributing to the testing requirements for codes and standards of full-scale systems.
- Providing listing and labeling services for full-scale systems such as fire safety performance.

FY 2011 Accomplishments

- Validated the hydrogen sorption capacity in PEEK-derived carbon at 77 and 298 K using material provided by SUNY. Experimental measurements showed:
 - Maximum excess concentration of 5.5 wt% at 77 K and 49 bar.
 - Absolute volumetric capacity approaching 38 g/L at 77 K and 71 bar.
- Evaluated the hydrogen sorption capacity in microporous carbon at 77 K using material provided by NREL, which showed 4.8 wt% gravimetric excess adsorption at 45 bar and a volumetric capacity of 28.2 g/L at 70 bar.
- Validated the hydrogen sorption capacity in PPN at 77 and 298 K using material provided by TAMU.

Introduction

Promising classes of materials being developed for reversible on-board hydrogen storage have emerged, thus compelling a rigorous and independent evaluation of their storage capacity, thermodynamics, and kinetics. Occasionally, entirely new chemistries or structural motifs are discovered that yield unexpected properties which must be further studied or validated. Notably, metal organic frameworks (MOFs) [1], destabilized nitrogen-based metal borohydrides [2], and spillover compounds of MOFs and nanoporous carbon materials [3,4] have captured the interest of researchers over the past five years. These examples have resulted in surprisingly favorable storage properties which approach the sought-after material targets for on-board storage (Figure 1).

The laboratory has continued to evaluate important new classes of materials whose validation of hydrogen storage properties is regarded as a high-priority within the solid-state storage community and the DOE. The most recent priorities for the laboratory have concentrated on evaluating hydrogen sorption in PEEK-derived nanoporous carbon and more conventional microporous carbon. A significant amount of experimental and modeling effort was dedicated to the analysis of a PPN based on tetrakis(4-bromophenyl) silane building units [PPN-4(Si)] developed by H-C Zhou's

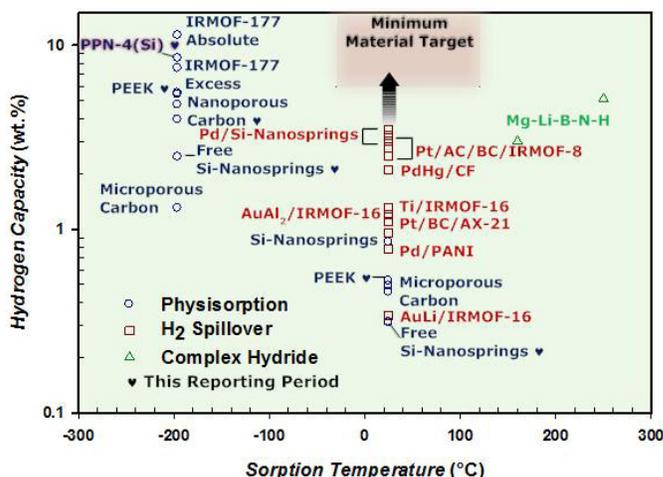

FIGURE 1. Status of material technologies for reversible hydrogen storage via physisorption, spillover, and chemisorption in proximity to DOE material target. New benchmark for excess adsorption is highlighted.

group at TAMU [5]. This material has been shown to exhibit exceptionally-high Brunauer-Emmett-Teller specific surface areas (6,470 m²/g) with a correspondingly-high gravimetric excess capacity (8.5 wt% at 60 bar) at 77 K: the highest surface area and hydrogen uptake reported to date for a physisorption material.

Approach

Validating the sorption behavior of storage materials and uncovering the mechanisms involved are approached through close collaboration with researchers among the materials centers of excellence (e.g., the Physisorption Center of Excellence), the international community, and SwRI's Internal Research & Development (IR&D) program. The laboratory employs a "best practices" approach based on standard operating procedures-documented analytical methods to critically evaluate novel storage materials of potential impact to the sought-after storage goals. By leveraging SwRI's IR&D program, fundamental aspects of materials research are addressed where critical knowledge or physical matter is presently lacking. This element of the program provides a venue for the discovery of new materials and the elucidation of unknown mechanisms.

Results

PEEK-Derived Carbon

The results of our studies over the past year are highlighted in Table 1. In the case of PEEK-derived carbon (as well as other carbon materials), high-pressure volumetric analysis was encumbered by this material's propensity to absorb helium, thus invalidating the use of a helium calibration for determining the skeletal density of the sample (or free volume of the system). To overcome this

TABLE 1. Overall Summary of Results for Various Classes of Storage Materials under Investigation

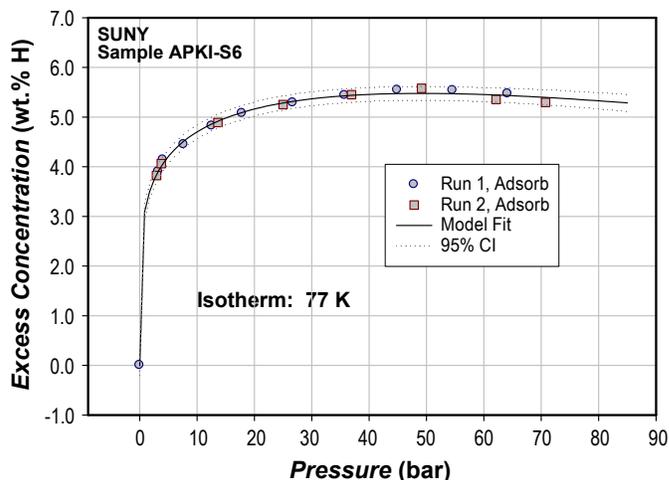

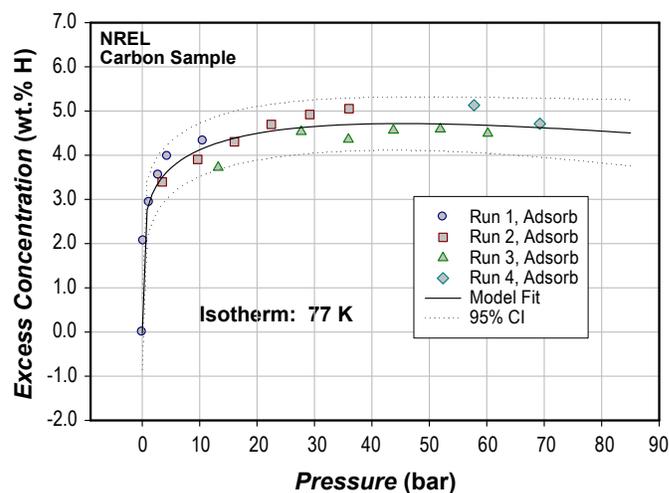

Material	Source	Surface Excess Amount (wt% H)		Absolute Volumetric Capacity (g/L) 77 K	MOF-177 Benchmark 77 K	
		298 K	77 K		(wt% H)	(g/L)
CO ₂ -Activated PEEK-Derived Carbon	Duke University	0.52 @ 80 bar	5.39 @ 55 bar	30 @ 70 bar	7.5 @ 70 bar	47 @ 70 bar
PEEK-Derived Carbon	SUNY	0.31 @ 81 bar	5.50 @ 49 bar	38 @ 71 bar		
Microporous Carbon	NREL	0.49 @ 80 bar	4.75 @ 45 bar	28 @ 70 bar		
Porous Polymer Network [PPN-4(Si)]	TAMU	0.97 @ 92 bar	8.48 @ 60 bar	28 @ 86 bar		

analytical challenge, the high-pressure gravimetric technique was employed to measure the hydrogen isotherm at room temperature. We then assume in the formal definition of the Gibbs excess that the free energy of the adsorbed fluid is equal to the bulk-gas free energy plus a surface potential term, which we equate to the measured Gibbs excess for the gravimetric mass balance, and thus arrive at a simplified local density (SLD) model. When combined with the Bender equation state to accurately calculate hydrogen gas densities and the gas fugacity, the combined expressions for the SLD model were used in a fitting algorithm to derive the hydrogen skeletal density and the pore volume of the sample by treating these characteristic properties as fitting parameters [6].

The corrected hydrogen isotherms at 77 K measured by the volumetric technique are shown in Figure 2. Here the maximum excess concentration for hydrogen uptake was 5.50 wt% at 49 bar. Using the pore volume derived from the SLD model and fitting algorithm, the profile for absolute volumetric capacity was computed. The absolute volumetric capacity for this material approached 38.2 g/L at 71 bar and, while this is a remarkable result, it falls slightly short of the current benchmark of 40 g/L at 70 bar for MOF-177.

Microporous Carbon

Low-temperature (77 K) hydrogen isotherms were determined using the volumetric technique, again employing the gravimetric technique at room temperature and the SLD model to determine the skeletal density and pore volume of this material. The corrected hydrogen sorption profile, shown in Figure 3, was constructed from four separate analyses due to the long equilibration times associated with each pressure point in the profile. The combined data was fitted to a dose response model in order that the statistical variance of the measurements and the peak excess could be derived. Based on the model fit, a peak uptake for surface excess of 4.75 wt% at 45.3 bar was calculated. The absolute volumetric capacity at 77 K was also determined using the semi-empirically derived pore volume (gravimetric analysis). On this basis, an absolute volumetric capacity of 28 g/L was computed at 69 bar.

**FIGURE 2.** Low-temperature (77 K) hydrogen isotherms measured for PEEK-derived nanoporous carbon.**FIGURE 3.** Low-temperature (77 K) hydrogen isotherms measured for microporous carbon.

PPN

As in the previous cases for highly active, high surface-area physisorption materials, the analysis of PPN-4(Si) required special attention due to this material's tendency to adsorb helium, thus preventing accurate measurement of the true Gibbs excess concentration and subsequent determination of absolute volumetric capacity. This behavior required that the actual skeletal density be determined using the gravimetric technique. We determined the skeletal density using hydrogen gas and adopted the SLD model as described previously. Additionally, the extremely high specific surface area (6,470 m²/g) and low bulk density of this material required careful handling methods to prevent fluidization during weighing and sample transfers. These properties further required that the material be mechanically compacted in the sample vessel prior to analysis.

The room temperature gravimetric hydrogen isotherms for the Gibbs excess are compared in Figure 4 with analyses using the volumetric technique at room temperature. The two results are shown to correlate very well after correcting the volumetric measurements for the SLD-derived skeletal density.

The same SLD-derived skeletal density was used to correct low-temperature hydrogen isotherms. After taking into consideration thermal gradient effects, the corrected hydrogen isotherm curves derived from the analyses are represented in Figure 5. In this case, two adsorption and desorption runs (Runs 1 and 2), with thermal-vacuum conditioning between them, were required to construct the composite full-pressure isotherm curves. In order to derive characteristic parameters for the composite data points, a parametric dose-response model was used. The fitted values for the maximum Gibbs-excess concentration at 77 K was 8.4 wt%, which occurred at 60 bar and is higher than our benchmark material, MOF-177 (Table 1).

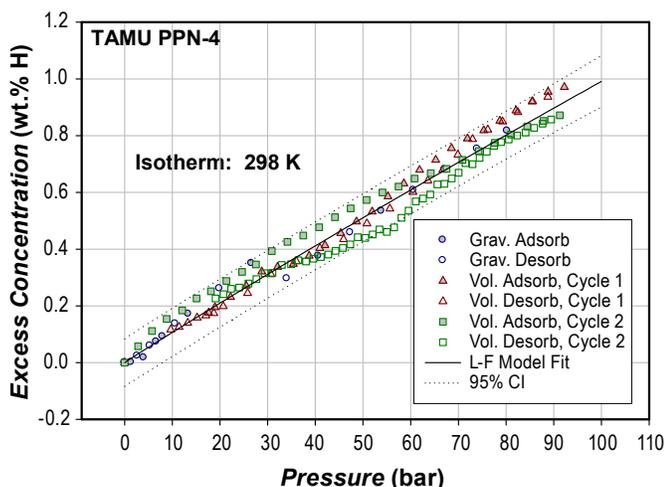

FIGURE 4. Room temperature (298 K) hydrogen isotherms measured for PPN [PPN-4(Si)] using both the volumetric and gravimetric techniques.

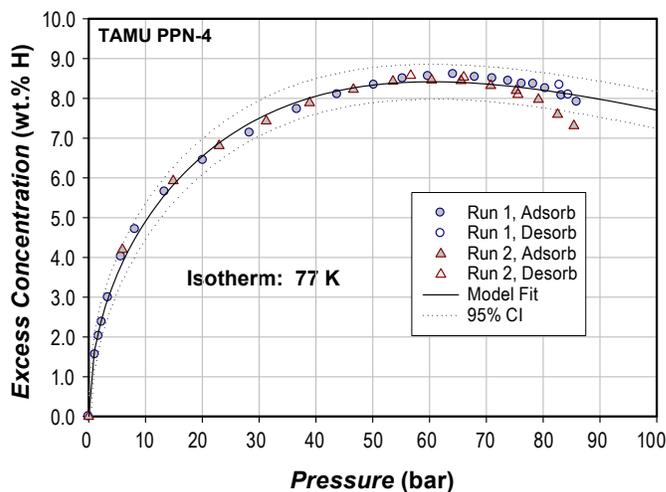

FIGURE 5. Low-temperature (77 K) hydrogen isotherms measured for PPN [PPN-4(Si)] using the volumetric technique.

Additionally, the absolute volumetric capacity was estimated using the SLD-derived skeletal density and adsorbed volume (i.e., pore volume). A value of ~28 g/L absolute volumetric capacity was calculated at 85 bar (77 K). Presently, we have not verified the absolute data theoretically using void-space routines and the kinetic diameter of hydrogen (or helium) since the material is completely amorphous.

Conclusions and Future Directions

In the search for novel forms of active materials for physisorption storage, robust materials have emerged with remarkably high surface areas. Nanoporous carbon derived from PEEK exhibits promising characteristics for hydrogen storage in terms of specific surface area and chemical stability. We found from previous analyses that two forms of such PEEK-derived materials, Duke vs. SUNY, prepared by independent process methods yielded remarkably similar results (Table 1). Additional gains in performance may, however, still be possible as processing methods for the PEEK polymer are further refined.
